LINE POLARIZATION OF MOLECULAR LINES AT RADIO FREQUENCIES: THE CASE OF DR 21(OH)

P. C. Cortes, R. M. Crutcher, and W. D. Watson

ABSTRACT

We present polarization observations in DR 21(OH) from thermal dust emission at 3 mm and from CO $J = 1 \rightarrow 0$ line emission. The observations were obtained using the Berkeley-Illinois-Maryland Association (BIMA) array. Lai et al. observed this region at 1.3 mm for the polarized continuum emission and also measured the CO $J = 2 \rightarrow 1$ polarization. Our continuum polarization results are consistent with those of Lai et al. However, the direction of the linear polarization for the $J = 1 \rightarrow 0$ is perpendicular to that of the CO $J = 2 \rightarrow 1$ polarization. This unexpected result was explored by obtaining numerical solutions to the multilevel radiative transfer equations for a gas with anisotropic optical depths. We find that in addition to the anisotropic optical depths, anisotropic excitation due to a source of radiation that is external to the CO is needed to understand the orthogonality in the directions of polarization. The continuum emission by dust grains at the core of DR 21(OH) is sufficient to provide this external radiation. The CO polarization must arise in relatively low density ($n_{H_2} \sim 100 \text{ cm}^{-3}$) envelope gas. We infer $B \sim 10 \mu G$ in this gas, which implies that the envelope is subcritical.

1. INTRODUCTION

The star formation process is one of the most complicated problems in current astrophysical research. Its study includes several physical parameters, of which the magnetic field is the least observed. Magnetic field observations are divided into measurements of the Zeeman effect (in order to obtain the magnetic field strength in the line of sight) and linear polarization observations of the Zeeman effect. Combining this effect with observation of the polarized line radiation from the molecular radiation. The CO polarization must arise in low density ($n_{H_2} \sim 100 \text{ cm}^{-3}$) envelope gas. We infer $B \sim 10 \mu G$ in this gas, which implies that the envelope is subcritical.

CO $J = 1 \rightarrow 0$ line polarization. These observations were compared with the Lai et al. (2003) polarization observations at 1 mm and CO $J = 2 \rightarrow 1$, particularly the line polarization, which has more extended emission than the dust. We found a 90° difference in the position angle when comparing the line polarization data for the two transitions. This difference motivated a numerical study to explore polarized line emission orientation in different transitions.

The paper is divided into three major sections. In § 2 we discuss the source and observation procedure, the line and dust polarization observations, and the comparison with the Lai et al. (2003) results. The numerical calculational procedure and results are described § 3. Section 4 contains the discussion and summary.

2. OBSERVATIONS AND DATA REDUCTION

2.1. Source Description

DR 21(OH) is a young massive star-forming region located in the $-3 \text{ km s}^{-1}$ DR 21/W75S molecular cloud complex, centered at R.A. 20°38′30″ and decl. 42°22′46″ (J2000 coordinates). This region is also at the northeastern part of the giant Cygnus X HI complex. The distance to DR 21(OH) is assumed to be 3 kpc; however, the value is uncertain. Dickel et al. (1978) used a value of 2 kpc. From thermal emission of dust, Woody et al. (1989) resolved two compact cores in DR 21(OH), MM1 and MM2, with a total mass of $\sim 125 M_{\odot}$. The MM1 component is the brighter one, with an integrated flux of 0.27 Jy at 2.72 mm (Mangum et al. 1991). DR 21(OH) has been extensively mapped in CO by Dickel et al. (1978), Woody et al. (1989), Mangum et al. (1991), and Chandler et al. (1993a) and in CS by Plambeck & Menten (1990) and Chandler et al. (1993b). DR 21(OH) is also known for its association with maser emission from OH (Norris et al. 1982), H$_2$O (Genzel & Downes 1977), and CH$_3$OH (Batrla & Menten 1988; Plambeck & Menten 1990). DR 21(OH) has also been observed in the far-infrared (Harvey et al. 1986) and submillimeter (Gear et al. 1988; Richardson et al. 1994). No centimeter-wavelength continuum sources have been observed in DR 21(OH) (Johnston et al. 1984); therefore, HI regions have not yet developed, so it appears to be in an early stage of formation.

evolution. This makes DR 21(OH) a good candidate for early star formation and magnetic field studies.

Magnetic field observations have been carried out measuring Zeeman splittings. The CN line Zeeman splitting has been detected in both cores (the CN line traces $n_H \sim 10^5$–$10^6$ cm$^{-3}$) giving a line-of-sight magnetic field strength, $B_{\text{los}}$, of $0.4$ mG for MM1 and $0.7$ mG for MM2 (Crutcher 1999). Lai et al. (2003) observed the CO $J = 2 \rightarrow 1$ molecular line and the 1.3 mm dust continuum simultaneously using the BIMA array. They obtained a detailed polarization map for the whole region. Their results show a remarkably uniform polarization pattern for the line over the main two continuum sources, while the dust polarization appears to be mostly perpendicular to the line. These results seem to be consistent with theoretical predictions.

2.2. Observation Procedure

We observed DR 21(OH) from 2001 October to November, mapping the continuum emission at 3 mm and the CO $J = 1 \rightarrow 0$ molecular line (at 115.2712 GHz), using the BIMA array in C configuration. We set the digital correlator in mode 8 to observe both the continuum and the CO $J = 1 \rightarrow 0$ line simultaneously. The 750 MHz lower side band was combined with 700 MHz from the upper side band to map the continuum emission, leaving a 50 MHz window for the CO line observation (at a resolution of 2.06 km s$^{-1}$). Each BIMA telescope has a single receiver, and thus the two polarizations must be observed sequentially. A quarter wave plate to select either right (R) or left (L) circular polarization is alternately switched in to the signal path ahead of the receiver. Switching between polarizations was sufficiently rapid (every 11.5 s) to give essentially identical UV coverage. Cross-correlating the R and L circularly polarized signals from the sky gave RR, LL, LR, and RL for each interferometer baseline, from which maps in the four Stokes parameters were produced. The instrumental polarization was calibrated by observing 3C 279, and the “leakages” solutions were calculated from these observations. The phase calibrator used was BL Lac. We used the same calibration procedure described by Lai et al. (2001).

The Stokes images $I, U, Q$, and $V$ were obtained by Fourier transforming the visibility data using natural weighting. The 3 mm continuum-synthesized beam had a major axis of 8$''$4 and a minor axis of 6$''$9, with a position angle (P.A.) of 35$^\circ$. The MIRIAD (Sault & Killeen 1995) package was used for data reduction.

2.3. 3 mm Continuum Results

Our 3 mm continuum results did not resolve the two continuum sources (MM1 and MM2) resolved by Lai et al. (2003). The larger beam at 3 mm gives poorer resolution than the 1.3 mm observations (with BIMA at the same configuration). Our 3 mm continuum observations have a peak emission of 0.22 Jy beam$^{-1}$, centered at R.A. 20$^h$39$^m$00$''$ and decl. 42$^\circ$22$'$35$''$–42$^\circ$23$'$29$''$ (J2000). This center coincides roughly with the center of the MM1 continuum source. Johnston et al. (1984) found no continuum emission at 14.5 GHz from DR 21(OH). Therefore, we assume that free-free emission is negligible and all the continuum radiation comes from dust emission. The peak emission is consistent with Mangum et al. (1991), who obtained 0.192 Jy beam$^{-1}$ at 2.7 mm with a comparable beam size.

Polarization detection is very sensitive to the signal-to-noise ratio. Because of bad weather conditions during part of our observations, we did not achieve the same level of polarization sensitivity as Lai et al. (2003) did. We have 3 $\sigma$ polarization detections (Fig. 1) scattered over three positions in the map. The dust polarization detected is consistent with the result of Lai et al. (2003).

2.4. CO $J = 1 \rightarrow 0$ Observational Results

Figure 2 shows the Stokes $I$ spectra integrated over a region that contains the MM1 and MM2 sources (Lai et al. 2003). This region covers the box from R.A. $20^h39m20^s$–$20^h38m59^s$ to decl. $42^\circ22'35''$–$42^\circ23'29''$. Potted over the Stokes $I$ spectra are the P.A. and the fractional polarization at each velocity channel. The Stokes $I$ spectra generally agree with the CO $J = 2 \rightarrow 1$ spectra from Lai et al. (2003). In our case the spectrum has a peak at $v_{\text{lsr}} = -8$ km s$^{-1}$, a minimum at $v_{\text{lsr}} = -2$ km s$^{-1}$, and a second peak at $v_{\text{lsr}} = 2$ km s$^{-1}$. The velocity of these peaks are different from previous CS and CN observations, which are at $-5$ km s$^{-1}$ (Chandler et al. 1993b; Richardson et al. 1994), and $-5$, and $-1$ km s$^{-1}$ (Crutcher 1999). The CO line is optically thick (Fig. 2), and the dip, or zero emission range, observed in both CO $J = 2 \rightarrow 1$ and $J = 1 \rightarrow 0$ lines, is probably due to self-absorption. In CO $J = 1 \rightarrow 0$, the dip covers a velocity range from $-6$ to 2 km s$^{-1}$, which coincides with the C$^{34}$S $J = 2 \rightarrow 1$ emission peak range from Chandler et al. (1993b), which extends from $-6$ to 1.5 km s$^{-1}$. In the same velocity range $^{13}$CO emission was detected (Dickel et al. 1978) from $-3$ to 0.5 km s$^{-1}$. C$^{34}$S traces higher densities than CO, and $^{13}$CO is more optically thin than CO. The presence of peak emission from these lines in the same velocity range of our dip suggests that our CO observations may come from a different region from the higher density gas (which probably comes from the core). Additionally, it is expected that CO polarized line emission will arise from optically thin regions ($\tau \sim 1$) (Goldreich & Kylafis 1981; Deguchi & Watson 1984). Therefore, it is likely that the CO polarized emission that we detected comes from an envelope around DR 21(OH).

Figure 3 shows our CO polarization map at $v_{\text{lsr}} = -8$ km s$^{-1}$. This map represents the highest significance polarization distribution in our observations. It also coincides with the peak emission of the CO. Figure 4 shows our polarization map at

FIG. 1.—Polarization map of DR 21(OH) at 3 mm. The contours represent Stokes $I$ at $-0.02, 0.02, 0.04, 0.07, 0.09, 0.11, 0.14, 0.16,$ and 0.18 Jy beam$^{-1}$. The pixel gray scale shows 3 $\sigma$ polarization intensity ($[Q^2 + U^2]^{1/2}$) for the dust continuum emission, also in Jy beam$^{-1}$. The dust emission. The peak emission is consistent with Mangum et al. (2003) observed the CO $J = 2 \rightarrow 1$ molecular line and the 1.3 mm dust continuum simultaneously using the BIMA array. They obtained a detailed polarization map for the whole region. Their results show a remarkably uniform polarization pattern for the line over the main two continuum sources, while the dust polarization appears to be mostly perpendicular to the line. These results seem to be consistent with theoretical predictions.
In our case the $v_{lsr} = 10$ km s$^{-1}$ map does not present the same spatial distribution of polarization as the $v_{lsr} = 8$ km s$^{-1}$ map, almost certainly due to the limited sensitivity of the polarization data. Table 1 gives a comparison between P.A. for both CO transitions. We can see that there is a consistent 90$^\circ$ difference between the transitions.

2.5. Comparison between CO $J = 1 \rightarrow 0$ and CO $J = 2 \rightarrow 1$ Polarization

Lai et al. (2003) presented a single velocity channel map of their line polarization observations (at $v_{lsr} = 10$ km s$^{-1}$); this is the velocity of the peak value in the Stokes $I$ emission. Our CO $J = 1 \rightarrow 0$ observations have a peak Stokes $I$ at $v_{lsr} = 8$ km s$^{-1}$ (Fig. 3), which also coincides with our most complete polarization spatial distribution.

The Lai et al. (2003) map shows distributed CO emission that is more extensive than the region of the 1.3 mm continuum sources. We see a similar situation in our observations (Fig. 3). We also see that our line polarization has better coverage over the CO emission than the Lai et al. (2003) observations (Fig. 4). Our observations seem to indicate that with a better signal-to-noise ratio, it might be possible to achieve complete polarization coverage over the region of CO emission. The maximum polarized intensity coincides with the position of the continuum source, a fact which suggests the importance of a continuum radiation field in polarizing the line emission. This was studied in our numerical calculation.

Comparing polarization vectors from Figures 3 and 4 with the map presented by Lai et al. (2003), we found that the P.A. differ; in the central region in both maps most of the P.A. are 90$^\circ$ different.
strong inequality is easily satisfied here. The quantization z-axis is along the magnetic field direction, and the quantum states are specified in the usual way by the total angular momentum \( J \) (there is no fine or hyperfine structure here) and by its projection \( M \) on the z-axis. Under these conditions the radiative transfer equations for radiation associated with transitions between upper state \( J \) and lower state \( J' \) can be written as

\[
\frac{dI_{J'}}{ds} = -\kappa_{J'}^\perp (I_{J'}^\perp - S_{J'}^\perp) \tag{1}
\]

\[
\frac{dI_{J'}^\parallel}{ds} = -\kappa_{J'}^\parallel (I_{J'} - S_{J'}^\parallel), \tag{2}
\]

where \( \parallel \) and \( \perp \) indicate the intensity of the radiation with a linear polarization parallel and perpendicular to the magnetic field, respectively.

The difference with Goldreich & Kylafis (1981) comes in expressing the opacity and source terms in a way to allow for arbitrary angular momenta. The opacity and source terms are thus written as \( \kappa_{JM'J'M'} \) and \( S_{JM'J'M'} \), such that \( \kappa_{J'M'}^\parallel \) and \( S_{J'M'}^\parallel \), (where \( q \) stands for \( \parallel \) or \( \perp \)),

\[
\kappa_{J'M'} = \frac{1}{2} \phi(\nu - \nu_{J'}) \sum_{\Delta M=1} \kappa_{JM'J'M'}, \tag{3}
\]

\[
S_{J'M'}^\parallel = \sum_{\Delta M=1} \frac{\kappa_{JM'J'M'} S_{JM'J'M'}}{\sum_{\Delta M=1} \kappa_{JM'J'M'}} , \tag{4}
\]

\[
\kappa_{J'M'}^\parallel = \phi(\nu - \nu_{J'}) \left( \sum_{\Delta M=0} \kappa_{JM'J'M'} \right) + \frac{1}{2} \cos^2 \theta \sum_{\Delta M=1} \kappa_{JM'J'M'}, \tag{5}
\]

\[
S_{J'M'} = \left( \sum_{\Delta M=0} \kappa_{JM'J'M'} S_{JM'J'M'} \right) + \frac{1}{2} \cos^2 \theta \sum_{\Delta M=1} \kappa_{JM'J'M'} \right)^{-1}, \tag{6}
\]

where the symbol \( \theta \) represents the angle between the magnetic field and the direction of propagation, and \( \kappa_{JM'J'M'} \) and \( S_{JM'J'M'} \) are defined in terms of Einstein \( A \) coefficients, and the populations \( n_{JM} \) per magnetic substate are

\[
\kappa_{JM'J'M'} = \frac{3}{8\pi} \left( \frac{c}{\nu_{J'}} \right)^2 A_{JM'J'M'} (n_{JM'} - n_{JM}), \tag{7}
\]

\[
S_{JM'J'M'} = \frac{\hbar v_{J'}}{c^2} n_J n_{JM'} - n_{JM}. \tag{8}
\]

Some equations here differ slightly from those in Deguchi & Watson (1984), because we are treating all magnetic substates explicitly. All statistical weight factors are 1 and are thus omitted for simplicity.

Since the radiative transfer equations are functions of the populations, rate equations must be solved for these populations. We
assume steady state \( \partial n_i / \partial t = 0 \). The rate equations for the populations per magnetic substate are

\[
\frac{\partial n_i}{\partial t} = - \sum_j P_{ij} + \sum_j P_{ji} + \sum_j (C_{ij} n_j - C_{ji} n_i) = 0, \quad (9)
\]

where the \( P_{ij} \) (which involve the radiation) are given in terms of the Einstein \( A_{J'M'J} \) coefficients and the stimulated emission coefficients \( R_{ij} \). The indices \( i \) and \( j \) correspond to \((J, M)\) and \((J', M')\). The \( C_{ij} \) are the collisional excitation rates from state \( i \) to state \( j \). Deguchi & Watson (1984) used the \( C_{ij} \) given by Green & Chapman (1978). In our calculation we have updated the values of \( C_{ij} \) with the values provided by Flower (2001), which are given for a wide range of gas temperatures. We used a weighted average for the contribution of ortho and para hydrogen cross sections, specifically, \( C_{ij} = 0.7 \times C^\text{para}_{ij} + 0.3 \times C^\text{ortho}_{ij} \). We considered temperatures up to \( T_\text{gas} = 200 \text{ K} \) and angular momenta up to \( J = 9 \). The expressions for the \( P_{ij} \) are

\[
P_{ij} = A_{ij} [n_i + R_{ij} (-n_j + n_i)]. \quad (10)
\]

The population equations constitute a nonlinear system, which we solve by numerical iteration.

In the limit in which the macroscopic velocity differences of the gas in the cloud are greater than the thermal velocities of the molecules, the LVG approximation can be used to simplify the solution for the radiative transfer equations. The LVG approximation expresses the intensity as a function of local variables.

The intensity that emerges from the gas cloud and is detected by the solution for the radiative transfer equations. The LVG approximation can be used to simplify the calculation and the escape probability function is \( \beta_{JJ'}^\text{g} = 1 - \exp(-\tau_{JJ'}^\text{g}) \), and \( S(\Omega) \) represents the radiation that is incident from a compact, external source. We express \( S(\Omega) \) as

\[
S(\Omega) = (1 - e^{-\tau_K}) B_\nu(T_{\text{source}}) \quad (17)
\]

for directions \( \Omega \) that are subtended by the external source as viewed from the location of the CO. In other directions, \( S(\Omega) = 0 \). In equation (17), \( B_\nu(T_{\text{source}}) \) is the Planck function, \( T_{\text{source}} \) is the source temperature, and \( \tau_K \) is the continuum optical depth of the source at the relevant frequency. We adopted the parameterization of Mangum et al. (1991) for the combined emission from the dust core of DR 21(OH), specifically, \( T_{\text{source}} = 42 \text{ K}, \tau_K = 1.5(0.25/\lambda[\text{mm}])^2 \), and an effective source angular size (radius) of \( 10'' \) as seen from the earth. At the location of the CO, the angular size (radius) for the source is then approximately \( \frac{1}{2} \) radian (assuming 0.3 pc for the separation between the CO and the source). Finally, the fractional polarization is expressed as

\[
P = \frac{I_\perp - I_\parallel}{I_\perp + I_\parallel}. \quad (18)
\]

\section*{3.3. Calculation Results}

The objective of this calculation is to understand why the directions of the polarizations for the CO \( J = 1 \rightarrow 0 \) and the CO \( J = 2 \rightarrow 1 \) radiation are perpendicular to one another in the DR 21(OH) observations described in §2, with the \( J = 1 \rightarrow 0 \) polarization parallel to that of the emission by the dust grains. We want to calculate the linearly polarized radiation emitted by CO for physical conditions that are representative for the DR 21(OH) star-forming region and determine whether the observed directions and magnitudes of the polarization can be reproduced. The orthogonality of the polarizations is reflected by a sign difference in \( P \) in equation (18). If \( P > 0 \), \( I_\perp \) dominates the emission, and the polarization is perpendicular to the magnetic field. In the other case it is parallel.

The physical conditions for our multilevel calculation are described below. These conditions are consistent with the assumption that the polarized emission comes from a cold envelope around the DR 21(OH) continuum sources. We assumed that the physical conditions are the same in the gas for both CO transitions.

To obtain a qualitative understanding of how the polarizations can be orthogonal for the two transitions, consider the \( J = 1 \rightarrow 0 \) transition by itself, and first without any external radiation. If the velocity gradients are smaller in directions parallel to the magnetic field than in directions perpendicular to the magnetic field, the optical depths for spectral lines will be the largest parallel to the field lines. The escape of radiation involved in deexciting the upper \( J = 1 \) state will then be reduced more in directions along the field lines than in directions perpendicular to the field lines. This in turn leads to populations of the \( M = \pm 1 \) substates that are larger than the populations of the \( M = 0 \) substate because of the difference in the angular distributions of the deexciting radiation. The angular distribution of the
\( \sigma \) radiation \((M - M' = 1 \) transitions\) peaks in directions along the field lines, whereas that of the \( \pi \) radiation \((M - M' = 0 \) transitions\) peaks in directions perpendicular to the magnetic field. Hence, when the velocity gradients are smallest along the magnetic field, the rate for deexcitation of the \( M = \pm 1 \) substates is decreased more by trapping of the radiation than is the deexcitation rate of the \( M = 0 \) substate. The excitation rate for all magnetic substates by collisions is the same. Under isotropic conditions, the populations of the magnetic substates are equal. For any direction, the \( \sigma \) and \( \pi \) radiation that emerges from the radiative decays of these states will combine to give zero net polarization. However, when the \( M = \pm 1 \) states have larger populations, the \( \sigma \) radiation will be relatively stronger in comparison with the \( \pi \) radiation. Their contributions to the polarization will not then cancel, and the combined radiation will be linearly polarized in the direction of the polarization of the \( \sigma \) radiation, which is perpendicular to the magnetic field.

Now consider by itself a compact, external source of radiation (i.e., no anisotropy in the optical depths as in the above paragraph) that is located in a direction perpendicular to the magnetic field. Because the angular distribution associated with \( \pi \) transitions is larger for this direction than is the angular distribution of the \( \sigma \) transitions, the \( J = 1, M = 0 \) substate will be excited more rapidly by absorption of this radiation than will be the \( J = 1, M = \pm 1 \) substates. The \( J = 1, M = 0 \) substate would then become overpopulated in comparison with the other two magnetic substates, and radiation that emerges from the gas would be polarized in the direction of \( \sigma \) radiation, parallel to the magnetic field.

Although the reasoning is more complicated because of the additional substates and transitions, analogous conclusions apply for the polarization of the radiation associated with the \( J = 2 \rightarrow 1 \) and higher transitions of the CO molecule.

When the above anisotropic velocity gradients and external source of radiation are both present, the direction of the polarization of the radiation that is emitted by the gas is determined by the relative importance of these two causes of anisotropy. Their relative importance is not, however, the same for the \( J = 2 \rightarrow 1 \) as for the \( J = 1 \rightarrow 0 \) transition. The dust radiation from the core of DR 21(OH) is much higher at the \( J = 2 \rightarrow 1 \) transition frequency than the \( CO \ J = 1 \rightarrow 0 \) frequency, and thus the external radiation will play a greater role for the polarization of the \( J = 2 \rightarrow 1 \) transition than it does for the \( J = 1 \rightarrow 0 \) transition. The effect of the anisotropic velocity gradients is about the same for the two transitions, since the collisional excitation rates are about the same for both transitions (the excitation energies for these states of CO are less than \( kT_{gas} \)). The \( J = 2 \rightarrow 1 \) radiation can then reflect the influence of the radiation and be polarized parallel to the magnetic field under conditions for which the \( J = 1 \rightarrow 0 \) radiation reflects the influence of the velocity gradient and is polarized perpendicular to the magnetic field. The results presented below from the numerical calculations demonstrate that this orthogonality in the polarizations occurs for physical conditions that are likely for the gas that is emitting the polarized CO radiation from DR 21(OH). Velocity gradients that are anisotropic and systematically larger in the direction perpendicular to the magnetic field occur in magnetohydrodynamic turbulence (see Watson et al. 2004).

Calculations were performed for gas temperatures between 15 and 50 K and for a range of densities. Dickel et al. (1978) obtained \( T_{gas} = 28 \) K; this temperature is used as a reference for our calculations. The velocity gradient must be largest in the direction perpendicular to the magnetic field, according to the above reasoning. We thus focus on \( \alpha = 0.1 \) in the expression for \( L(\theta) \), although we also present results for \( \alpha = 0.3 \) for comparison.

Three curves for polarization versus LVG optical depth that correspond to calculations with densities \( n_{H_2} = 25, 75, \) and 225 cm\(^{-3}\) are shown in Figure 5 for \( T_{gas} = 28 \) K. These densities are in agreement with what we might expect in a lower density envelope. Padin et al. (1989) obtained a \( n_{H_2} \) density of \( n_{H_2} = 5 \times 10^6 \) cm\(^{-3}\), but this corresponds to the MM1 continuum source and not to the DR 21(OH) envelope. At the lowest optical depths, the external continuum source dominates in determining the direction of the polarization for both transitions, whereas at the highest optical depths this radiation is largely excluded, and the velocity gradient determines the direction of the polarization for both transitions. However, because the continuum emission from the core of DR 21(OH) is much higher at the frequency of the \( J = 2 \rightarrow 1 \) transition than at the frequency of the \( J = 1 \rightarrow 0 \), the external radiation remains more important to higher optical depths for the \( J = 2 \rightarrow 1 \) transition than for the \( J = 1 \rightarrow 0 \). Hence, a range of optical depths occurs over which the polarizations are orthogonal. This range of optical depths is mostly from \( \log \tau \simeq 0 \) to \(-1 \) in Figure 5. In this range of optical depths, the fractional polarizations typically are a few percent
transitions are never orthogonal (i.e., they always have the same sign).

In our calculations, we also varied the gas temperature in order to explore the influence of uncertainty about the gas temperature in the envelope around DR 21(OH). We found no significant variation in the polarizations for $T_{\text{gas}}$ between 15 and 50 K. What we found is that the range in $\tau$ for which the polarizations are orthogonal shifts slightly in $\tau$; there is a displacement to lower $\tau$ for higher temperatures. A molecular envelope might be heated by external UV photons or cosmic rays. This insensitivity to gas temperature shows a degree of robustness for the results of our calculations. We have also verified that the results are insensitive to the temperature of the dust by performing computations with $T_{\text{source}}$ up to 60 K.

The polarizations presented in Figures 5–7 are for the radiation that is emitted by the gas at an angle of 90° with respect to the magnetic field. We have verified that the polarization characteristics are similar for emission at angles from 90° to about 40°. At smaller angles, the polarized fraction decreases significantly, approaching zero at 0°, as expected.

3.4. Magnetic Field Strength and Cloud Support

Our work has shown that the line polarization will trace magnetic field geometry at lower densities than the dust polarization. However, comparing with the results of Lai et al. (2003), we believe that there is a correlation between the field traced by the dust (core) and the field traced by the line (envelope). Our dust polarization result at 3 mm shows similar P.A. to the 1.3 mm dust polarization of Lai et al. (2003). Also, we now know why the line polarizations are perpendicular to the dust polarization. The agreement in the geometries of the dust and line polarization suggests that the field in the core and the envelope are connected and not independent.

Lai et al. (2003) estimated the magnetic field strength to be about 0.9 mG for MM1 ($n_{\text{H}_2} \sim 1 \times 10^6$ cm$^{-3}$) and 1.3 mG for MM2 ($n_{\text{H}_2} \sim 2 \times 10^6$ cm$^{-3}$). Crutcher (1999) measured a magnetic field in the line of sight $B_{\text{los}} \sim -0.4$ mG for MM1,
and $B_{\text{los}} \sim -0.7$ mG for MM2. Chandrasekhar & Fermi (1953) predicted a magnetic field dependence proportional to $\rho^{1/2}$.

$$B_{\text{chf}} = Q \sqrt{4\pi\rho^2} \frac{\Delta v_{\text{los}}}{\Delta \rho}.$$  \hfill (19)

The dispersions in the measured velocities and P.A. are similar for the $J = 1 \rightarrow 0$ and $J = 2 \rightarrow 1$ lines. Therefore, we can extrapolate the values of the magnetic field measured in the core to the envelope following a $\rho^{1/2}$ law. The molecular hydrogen number density for the cores is in the order of $n_{\text{H}_2} = 10^6$ cm$^{-3}$, and taking a density of $n_{\text{H}_2} = 100$ cm$^{-3}$ for the envelope, we get a magnetic field in the envelope 100 times smaller than the core value of $\sim 1$ mG (at $n_{\text{H}_2} \sim 1 \times 10^6$ cm$^{-3}$), or about 10 $\mu$G. We can use this value to estimate the mass to magnetic flux ratio; its critical value is given by (Mouschovias & Spitzer 1976) as

$$\frac{M}{\Psi_{\text{B, crit}}} = \frac{1}{\sqrt{63 \, \text{G}}}.$$  \hfill (20)

This equation can be expressed as a function of volume density in a spherical model, using the molecular hydrogen mass, equation (20), and expressing the magnetic field in G units and the distance in cm. We arrived at

$$\frac{M/\Phi}{M/\Phi_{\text{crit}}} = 9.1 \times 10^{-27} \frac{R[\text{cm}]n[\text{cm}^{-3}]}{B[\text{G}]},$$  \hfill (21)

in which $R$ is the radius of the cloud, $n$ is the number density of hydrogen molecules, and $B$ is the magnetic field. Using a density $n = 100$ cm$^{-3}$, $B = 10 \mu$G, and a radius of $R = 0.3$ pc, we obtain a mass-to-flux ratio of 0.13 times the critical value, and thus highly subcritical. Hence, the envelope is supported against gravitational contraction by the magnetic field. The value of $R$ represents an angular distance of 0.3 pc for DR 21(OH). This radius may be underestimated due to resolution of more extended structure by the interferometer. However, single dish maps (Wilson & Mauersberger 1990) suggest that $R < 1$ pc.

4. SUMMARY AND CONCLUSIONS

DR 21(OH) was observed in 3 mm dust continuum and CO $J = 1 \rightarrow 0$ line emission. Comparing our line observations with Lai et al. (2003), we observed a consistent difference in polarization direction between the CO $J = 2 \rightarrow 1$ and CO $J = 1 \rightarrow 0$ lines; they are perpendicular to each other over the central region (which coincides with the position of the MM1 and MM2 continuum sources). We developed a code based on the Deguchi & Watson (1984) calculation in order to solve the radiative transfer equations and calculate the fractional linear polarization for different transitions of the CO molecule. We found that the presence of a small continuum source will likely produce an increase in the anisotropy of the radiation field over the CO gas. An anisotropic radiation field will unevenly populate the magnetic sublevels of the CO molecule, which will produce linearly polarized emission. We showed that the presence of a compact continuum source will produce a gradual change in the fractional polarization, with a sign change, as a function of optical depth. This would explain the orthogonal orientations of the CO polarization in different transitions. In the particular case of DR 21(OH), the physical conditions that are consistent with the polarization data correspond to a hot continuum source ($T_{\text{dust}} \sim 42 \, \text{K}$) and a CO gas temperature of $T_{\text{gas}} \sim 28 \, \text{K}$, for a $n_{\text{H}_2} \sim 100$ cm$^{-3}$.

Line polarization observations can become a powerful tool to constrain the magnetic field geometry. We have seen that a clear understanding of the physical conditions in a molecular cloud will give more accurate information about the fractional polarization sign. A good knowledge of the sources of anisotropy in a cloud will help to understand and constrain the geometry in line polarization observations at multiple frequencies.

We also found that line polarization traces low-density material; this is important in order to connect the magnetic field geometries at different densities. In the particular case of DR 21(OH), we believe that there may be a correlation between the field traced by the dust at densities of $10^6$ cm$^{-3}$ and the field traced by line polarization at $10^2$–$10^3$ cm$^{-3}$. However, we were only able to compare our calculation with polarization observations of CO molecular transitions. We believe that polarization information from additional molecules may probe the magnetic field geometry at intermediate densities giving a more accurate picture of the field morphology in star-forming regions.

Having information about the magnetic field at different densities is useful to test the gravitational state of equilibrium for the cloud. Polarization mapping can allow the Chandrasekhar-Fermi method to be used to obtain an estimate of the magnetic field strength and test whether the envelope is magnetically supported or not. The envelope of DR 21(OH) appears to be magnetically supported.
