(Dated: July 27, 2010)

We outline the expected constraints on non-Gaussianity from the cosmic microwave background (CMB) with current and future experiments, focusing on both the third ($f_{NL}$) and fourth-order ($g_{NL}$ and $\tau_{NL}$) amplitudes of the local configuration or non-Gaussianity. The experimental focus is the skewness (two-to-one) and kurtosis (two-to-two and three-to-one) power spectra from weighted maps. In addition to a measurement of $\tau_{NL}$ and $g_{NL}$ with WMAP 5-year data, our study provides the first forecasts for future constraints on $g_{NL}$. We describe how these statistics can be corrected for the mask and cut-sky through a window function, bypassing the need to compute linear terms that were introduced for the previous-generation non-Gaussianity statistics, such as the skewness estimator. We discuss the ratio $A_{NL} = \tau_{NL}/(6f_{NL}/5)^2$ as an additional test of single-field inflationary models and discuss the physical significance of each statistic. Using these estimators with WMAP 5-Year V+W-band data out to $l_{\text{max}} = 600$ we constrain the cubic order non-Gaussianity parameters $\tau_{NL}$ and $g_{NL}$ and find $-7.4 < g_{NL}/10^5 < 8.2$ and $-0.6 < \tau_{NL}/10^7 < 3.3$ improving the previous COBE-based limit on $\tau_{NL} < 10^6$ nearly four orders of magnitude with WMAP.

I. INTRODUCTION

We have now entered an exciting time in cosmological studies where we are now beginning to constrain simple slow-roll inflationary models with high precision observations of the cosmic microwave background (CMB) and large-scale structure. In addition to constraining inflationary model parameter space with traditional parameters such as the spectral index $n_s$ and the tensor-to-scalar ratio $r$, we may soon be able to use parameters associated with primordial non-Gaussianity to improve model selection.

In the simplest realistic inflationary models, the field(s) responsible for inflation have minimal interactions. Such an interaction-less situation should have led to Gaussian primordial curvature perturbations, assuming that perturbations in the inflaton field generates the curvature perturbation. In this case, the two point correlation function contains all the information on these perturbations. If the early inflation field(s) have non-trivial interactions, higher-order correlation functions of the curvature perturbations will contain connected pieces encoding information about the primordial inflationary interactions. This is analogous to the situation encountered in particle physics where correlation functions can be separated into unconnected and connected Feynman diagrams, the later containing information about the underlying interactions (see Eq. 1 for an example involving the four-point function). A detection of non-Gaussianity therefore gives an important window into the nature of the inflation field(s) and their interactions.

To parameterize the non-Gaussianity of a nearly Gaussian field, such as the primordial curvature perturbations $\zeta(x)$, we can expand them perturbatively [29] to second order as:

$$\zeta(x) = \zeta_g(x) + \frac{3}{5} f_{NL} \left[ \zeta^2_g(x) - \frac{1}{3} \zeta^2_g(x) \right] + \frac{9}{25} g_{NL} \zeta^3_g(x).$$

where $\zeta_g(x)$ is the purely Gaussian part with $f_{NL}$ and $g_{NL}$ parametrizing the first and second order deviations from Gaussianity. This parameterization of the curvature perturbations is known as the local model as this definition is local in space.

Much effort has already gone into measuring non-Gaussianity at first-order in curvature perturbations using the bispectrum of the CMB anisotropies or large-scale structure galaxy distribution parameterized by $f_{NL}$ (see Eq. 1). These studies have found $f_{NL}$ to be consistent with zero [14]. However, there is hope that a significant detection may be possible by future surveys that will lead to improved errors [5].

In the trispectrum, two parameters of second-order non-Gaussianity at fourth-order in curvature perturbations, $\tau_{NL}$ and $g_{NL}$, can be measured. In this paper we also introduce a third parameter, $A_{NL}$, which is an additional parameter that compares $\tau_{NL}$ of the trispectrum...
to \((6f_{NL}/5)^2\) from the bispectrum as a ratio:
\[
A_{NL} = \frac{\tau_{NL}}{(6f_{NL}/5)^2}. \tag{2}
\]
This ratio can be quite different for many inflationary models \([6, 7]\) and, as will be shown below, \(A_{NL} \neq 1\) rules out single-field inflationary models altogether, including the standard curvaton scenario (which neglects perturbations from the inflaton field).

In this paper we discuss the skewness and kurtosis power spectra method for probing primordial non-Gaussianity and give constraints for the first \((f_{NL})\) and second-order \((g_{NL} and \tau_{NL})\) amplitudes of the local model in addition to their ratio \(A_{NL}\). Using the bispectrum of CMB anisotropies as seen by WMAP 5-year data, Smidt et al. (2009) found \(-36.4 < f_{NL} < 58.4\) at 95\% confidence \([8]\). This is to be compared with the most recent WMAP 7 measurement of \(-10 < f_{NL} < 74\) \([8]\), where part of the discrepancy is due to a difference in optimization \([8]\). As outlined in Section VI, the bispectrum of the same data we find that \(-0.6 < \tau_{NL}/10^4 < 3.3\) and \(-7.4 < g_{NL}/10^5 < 8.2\) at 95\% confidence level showing second order non-Gaussianity is consistent with zero in WMAP. This paper serves as a guide to the analysis process behind our derived limits on \(\tau_{NL}, g_{NL}\) and \(A_{NL}\).

Furthermore, in this paper we analyze what to realistically expect when measuring non-Gaussianity from CMB temperature data. We believe establishing what constraints can be placed upon \(f_{NL}, \tau_{NL}, g_{NL}\) and \(A_{NL}\) by future experiments is important in determining what models may and may not be tested by future data. We also highlight several advantages of our work, including ways to correct the cut-sky and mask through a window function without using linear terms which are computationally prohibitive \([9, 10]\).

This paper is organized as follows: In Section \(\text{III}\) we review how non-Gaussianity may be used to distinguish between common inflationary models and stress the physical significance of each statistic. In Section \(\text{III}\) we describe the skewness and kurtosis power spectra and explain how they may be used to extract information about primordial non-Gaussianity from the CMB. In Section \(\text{V}\) we describe the signal-to-noise of each estimator, how to add the experimental beam and noise to these calculations and discuss why these power spectra have the advantage for dealing with a cut sky. In Section \(\text{V}\) we calculate the fisher bounds for upcoming experiments for each statistic. In Section \(\text{VII}\) we discuss the technical details for measuring non-Gaussianity in the trispectrum and in Section \(\text{VII}\) we conclude with a discussion.

\section{Non-Gaussianity from Common Inflationary Models}

Non-Gaussianity is a powerful tool that may be used to distinguish between inflationary models. The simplest models do not produce a detectable amount of non-Gaussianity. Maldacena \([11]\) has shown that a single-field, experiencing slow roll with canonical kinetic energy and an initial Bunch-Davies vacuum state produces
\[
f_{NL} = \frac{5}{12}(n_s + f(k)n_t). \tag{3}
\]
Here \(n_s\) and \(n_t\) are the scalar and tensor spectral indices respectively. The function \(f(k)\) has a range \(0 \leq f(k) < \frac{5}{6}\) based on the triangle shapes (see below) of the \(k_i\) such that \(f = 0\) in the squeezed limit and \(f = \frac{5}{6}\) for an equilateral triangle. For this reason, \(f_{NL} < 1\) will remain undetectable in the simple slow roll scenario with CMB data alone. If any of the above assumptions are violated, very specific types of non-Gaussianity are produced \([5, 12, 13]\). In the bispectrum \(B_k(k_1, k_2, k_3)\) defined by
\[
\langle \zeta_{k_1} \zeta_{k_2} \zeta_{k_3} \rangle = (2\pi)^3 \delta(k_1 + k_2 + k_3) B_k(k_1, k_2, k_3), \tag{4}
\]
where \(\zeta\) is the primordial curvature perturbation, non-Gaussianities show up as triangles in Fourier space. Different triangle shapes are be produced by different underlying physics, for example:

- **squeezed triangle** \((k_1 \sim k_2 \gg k_3)\) This is the dominating shape from multi-field, curvaton, inhomogeneous reheating and Ekpyrotic models.
- **equilateral triangle** \((k_1 = k_2 = k_3)\) This shape is produced by non-canonical kinetic energy with higher derivative interactions and non-trivial speeds of sound.
- **folded triangle** \((k_1 = 2k_2 = 2k_3)\) These triangles are produced by non-adiabatic-vacuum models.

Additionally, linear combinations of the above shapes or intermediate cases such as elongated triangles \((k_1 = k_2 + k_3)\) and isosceles triangles \((k_1 > k_2 = k_3)\) are possible \([8]\).
common configurations as:

\[ S_{\text{local}}(k_1, k_2, k_3) \propto \frac{K_3}{K_{111}}, \]
\[ S_{\text{equil}}(k_1, k_2, k_3) \propto \frac{k_1 k_2 k_3}{K_{111}}, \]
\[ S_{\text{folded}}(k_1, k_2, k_3) \propto \frac{1}{K_{111}} (K_{12} - K_3) + 4 \frac{K_2}{k_1 k_2 k_3} \]

where

\[ K_p = \sum_i (k_i)^p \quad \text{with} \quad K = K_1, \]
\[ K_{pq} = \frac{1}{\Delta_{pq}} \sum_{i \neq j} (k_i)^p (k_j)^q, \]
\[ K_{pqr} = \frac{1}{\Delta_{pqr}} \sum_{i \neq j \neq l} (k_i)^p (k_j)^q (k_l)^r, \]
\[ \tilde{k}_{ip} = K_p - 2(k_i)^p \quad \text{with} \quad \tilde{k}_i = \tilde{k}_{i1}, \]

with \( \Delta_{pq} = 1 + \delta_{pq} \) and \( \Delta_{pqr} = \Delta_{pq} (\delta_{qr} + \delta_{pr}) \) (no summation). Plots for the local and equilateral shapes are given in Figure 2.

In addition to \( f_{\text{NL}} \) being generated by different shapes, it also may vary with scale. Recently, a new parameter has been introduced to measure this scale dependence defined as:

\[ n_{f_{\text{NL}}}(k) = \frac{d \ln |f_{\text{NL}}(k)|}{d \ln k}. \]

This scale dependence has the ability to test the ansatz \[1\] to test whether the local model should allow for \( f_{\text{NL}} \) to vary with scale \[15\]. Using the results of Smidt et al. (2009) (Fig. 16 of Ref \[4\]) and assuming

\[ f_{\text{NL}}(l) = f_{\text{NL}200} \left( \frac{l}{200} \right)^{n_{f_{\text{NL}}}(l)}, \]

we can constrain \( n_{f_{\text{NL}}}(l) \) to roughly \(-2.5 < n_{f_{\text{NL}}}(l) < 2.3 \) at 95\% confidence. We therefore find \( f_{\text{NL}} \) is consistent with having no scale dependance.

In this paper we focus on the local model that probes non-Gaussianity of a squeezed shape. As mentioned above, simple inflationary models can not produce a detectable amount of non-Gaussianity for local models. We now review the prediction for local non-Gaussianity for the most common models.

A. Review Of The \( \delta N \) formalism.

The curvature perturbation can be conveniently described using the \( \delta N \) formalism \[16\] \[20\]. During inflation, spacetime expands by a certain number of e-folds \( N \). By Heisenberg's uncertainty principle, expansion for each point in space ends at slightly different times pro-
ducing a spatially dependent total e-fold:

\[ N(x) = \int_{t_i}^{t_f} H(x,t) \, dt, \tag{15} \]

where \( H(x,t) \) is the Hubble parameter allowing us to define \( N(x) = N + \delta N(x) \). The fluctuations in e-fold about the mean value \( N \), which correspond to perturbations in local expansion, are the curvature perturbations \( \zeta = \delta N \).

In addition to a spatial parameterization, we may parameterize the number of e-folds by the underlying fields \( \zeta = N(\phi^A) - N \) where \( \phi^A \) represents the initial values for the scalar fields. If we write out the fields as \( \phi^A = \bar{\phi}^A + \delta \phi^A \) we can expand the curvature perturbations as

\[ \zeta = \delta N = \sum_n \frac{1}{n!} N_{A_1 A_2 \ldots A_n} \delta \varphi^{A_1} \delta \varphi^{A_2} \ldots \delta \varphi^{A_n}. \tag{16} \]

The \( N_x \) means the derivative of \( N \) with respect to the fields \( x \). For example, \( N_{A_1 A_2} \equiv \frac{\partial_N N_{A_1 A_2}}{\partial \varphi^A \partial \varphi^B} \). In this equation there is an implicit sum over the \( A_i \). Einstein summation is implicit in all equations relating to the \( \delta N \) formalism.

Using this formalism we may compute to first order from \( \zeta = N_A \delta \varphi^A \):

\[ \langle \kappa \kappa' \rangle = N_A N_B C^{AB}(k) (2\pi)^3 \delta^3(\mathbf{k} + \mathbf{k}'), \tag{17} \]

where \( C^{AB}(k) \) in the slow roll limit becomes to leading order \( \delta^{AB} P(k) \).

Likewise, we can calculate the bispectrum and trispectrum in this formalism:

\[ B_\zeta(k_1, k_2, k_3) = N_A N_B C^{AB}(k_1) C^{BD}(k_2) + C^{AB}(k_1) C^{BD}(k_2) + C^{AB}(k_1) C^{BD}(k_2), \tag{18} \]

\[ T_\zeta(k_1, k_2, k_3, k_4) = N_{A_1 A_2} N_{B_1 B_2} N_{C} N_{D} \]

\[ \times [C^{A_1 B_2}(k_1) C^{A_2 C}(k_2) C^{B_1 D}(k_2) + (11 \text{ perms})] + N_{A_1 A_2 A_3} N_{B_1 B_2} N_{C} N_{D} \]

\[ \times [C^{A_1 B}(k_1) C^{A_2 C}(k_2) C^{B_2 D}(k_2) + (3 \text{ perms})], \tag{19} \]

where \( k_{ij} = |k_i + k_j| \). In the slow roll limit to leading order these expressions may be rewritten as:

\[ B_\zeta(k_1, k_2, k_3) = \frac{6}{5} f_{NL} P_\zeta(k_1) P_\zeta(k_2) + P_\zeta(k_2) P_\zeta(k_3) + P_\zeta(k_3) P_\zeta(k_1), \tag{20} \]

\[ T(k_1, k_2, k_3, k_4) = \tau_{NL} [P_\zeta(k_{13}) P_\zeta(k_{34}) P_\zeta(k_4) + (11 \text{ perms})] + \frac{54}{25} g_{NL} [P_\zeta(k_2) P_\zeta(k_3) P_\zeta(k_4) + (3 \text{ perms})], \tag{21} \]

where \( P_\zeta(k) = N_A N_B C^{AB}(k) \) and therefore in the slow roll limit \( P_\zeta(k) = N_A N^A P(k) \).

From the above two expressions we can read off the values for each statistic:

\[ f_{NL} = \frac{5}{6} \frac{N''}{(N')^2}; \tag{22} \]

\[ \tau_{NL} = \frac{N'' N^A N^B N^C}{(N')^3}; \tag{23} \]

\[ g_{NL} = \frac{25}{54} \frac{N'' N^A N^B N^C}{(N')^3}; \tag{24} \]

\[ A_{NL} = \frac{\tau_{NL}^2}{(6 f_{NL}/5)^2}. \tag{25} \]

B. General Single-Field Models

For a single scalar field \( \varphi \) perturbing \( N(\varphi) \) we may expand \( \zeta \), using the above formalism [18], as:

\[ \zeta = N' \delta \varphi + \frac{1}{2} N'' \delta \varphi^2 + \frac{1}{6} N''' \delta \varphi^3 + \ldots, \tag{26} \]

where \( N' = dN/d\varphi \). Note that we do not require that \( \varphi \) is the inflaton field, it could be the curvaton or a field which modulates the efficiency of reheating. From equations [22] [24] we may immediately read off

\[ f_{NL} = \frac{5}{6} \frac{N''}{(N')^2}; \tag{27} \]

\[ \tau_{NL} = \frac{(N'')^2}{(N')^3}; \tag{28} \]

\[ g_{NL} = \frac{25}{54} \frac{N''}{(N')^3}; \tag{29} \]

\[ A_{NL} = 1. \tag{30} \]

Equations [27] and [28] yield a very important consequence of single-field models namely \( \tau_{NL} = (6 f_{NL}/5)^2 \). This is a general result and therefore \( A_{NL} \neq 1 \) may be used to rule out single-field models all together.

C. Multi-Field Inflationary Models

Suyama and Yamaguchi showed in general \( \tau_{NL} \geq (6 f_{NL}/5)^2 \) by the Cauchy-Schwartz inequality and equality only holds if \( N_A \) is an eigenmode of \( N_{AB} \) [20]. Models where equality does not hold can not be those of a single-field. We now examine such models.

Unlike the single-field case, using the \( \delta N \) formalism to make general statements about multi-field models is nearly impossible. Instead, one is forced to work with specific models that utilize simplifying assumptions. We now present a class of multi-field models that we believe is sufficiently general to uncover many details that are characteristic of multi-field models in general.

Recently, Byrnes and Choi reviewed two field models with scalar fields \( \varphi \) and \( \chi \) that have a separable potential
\[ W(\varphi, \chi) = U(\varphi)V(\chi) \text{[6 21–24].} \] The slow roll parameters for these models are:
\[ \epsilon_\varphi = \frac{M_p^2}{2} \left( \frac{U_{\varphi\varphi}}{U} \right)^2, \quad \epsilon_\chi = \frac{M_p^2}{2} \left( \frac{V_{\chi\chi}}{V} \right)^2, \] (31)
\[ \eta_{\varphi\varphi} = M_p^2 \frac{U_{\varphi\varphi\varphi}}{U}, \quad \eta_{\varphi\chi} = M_p^2 \frac{U_{\varphi\chi\chi}}{W}, \quad \eta_{\chi\chi} = M_p^2 \frac{V_{\chi\chi\chi}}{V}, \] (32)
from which we can define
\[ \tilde{r} = \frac{\epsilon_\chi}{\epsilon_\varphi} e^{2(\eta_{\varphi\varphi} - \eta_{\chi\chi})N}. \] (33)

For this class of models, in the regions where \(|f_{NL}| > 1\) we have
\[ f_{NL} = \frac{5}{6} \eta_{\chi\chi} \frac{\tilde{r}}{(1 + \tilde{r})} e^{2(\eta_{\varphi\varphi} - \eta_{\chi\chi})N}; \] (34)
\[ g_{NL} = \frac{10}{3} \frac{\tilde{r} (\eta_{\varphi\varphi} - 2\eta_{\chi\chi}) - \eta_{\chi\chi} f_{NL}}{1 + \tilde{r}}; \] (35)
\[ \tau_{NL} = \frac{1 + \tilde{r}}{\tilde{r}} \left( \frac{6 f_{NL}}{5} \right)^2; \] (36)
\[ A_{NL} = \frac{1 + \tilde{r}}{\tilde{r}}. \] (37)

It is worth noting that both \(\tau_{NL}\) and \(g_{NL}\) are related to \(f_{NL}\) for this class of models. Here we have \(|g_{NL}| < |f_{NL}|\) which will therefore be much harder to detect. On the contrary, \(\tau_{NL} > (6f_{NL}/5)^2\) so that non-Gaussianity may in fact be easier to detect in the bispectrum than the bispectrum for some multi-field models. Here we find \(A_{NL} = (1 + \tilde{r})/\tilde{r} > 1\). The scale dependence of \(f_{NL}\) has also been worked out for this class of models and was found to be \(n_{f_{NL}} = -4(\eta_{\varphi\varphi} - \eta_{\chi\chi})/(1 + \tilde{r}) < 0\).

### D. Curvaton Models

In the curvaton scenario, a weakly interacting scalar field \(\chi\) exists in conjunction to the inflaton \(\varphi\) \([15–25–28]\). During inflation, the curvaton field is subdominant, but after inflation \(\chi\) can dominate the energy density. The decay of the inhomogeneous curvaton field in this scenario produces the curvature perturbations and not the inflaton.

If such a curvaton field is the soul contributor to curvature perturbations, we can write out the perturbations using the \(\delta N\) formalism as we did in the single field case:
\[ \zeta = N' \delta \chi + \frac{1}{2} N'' \delta \chi^2 + \frac{1}{6} N''' \delta \chi^3 + \ldots, \] (38)
where now \(N' = dN/d\chi\). Immediately we recover the relations \([27–29]\) and find for such curvaton models \(A_{NL} = 1\) as should be expected from curvature perturbations generated by a single-field.

Recently, curvaton models with generic potentials of the form
\[ V = \frac{1}{2} m^2 \chi^2 + \lambda \chi^{n+4}, \] (39)
have been analyzed [27–28]. Here \(m\) is the curvaton’s mass and \(\lambda\) is a coupling constant. For such models \(N\) in Equation 38 has been worked out giving:
\[ f_{NL} = \frac{5}{4r_{\chi}} (1 + h) - \frac{5}{3} - \frac{5r_{\chi}}{6}, \] (40)
\[ g_{NL} = \frac{25}{54} \left[ \frac{5}{4r_{\chi}^3} (\tilde{h} + 3h) - \frac{9}{r_{\chi}} (1 + h) \right. \] (41)
\[ \left. + \frac{1}{2} (1 - 9h) + 10r_{\chi} + 3r_{\chi}^2 \right], \]
where
\[ r_{\chi} = \frac{3\Omega_{\chi,D}}{4 - \Omega_{\chi,D}}, \quad h = \frac{\chi_0' \chi''}{\chi_0^2}, \quad \tilde{h} = \frac{\chi_0'' \chi'''}{\chi_0'^2}. \] (42)

Here \(\Omega_{\chi,D}\) is the energy density at time of curvaton decay, \(\chi_0\) is the curvaton field during oscillations just before decay and the primes here denote derivatives with respect to time.

Unlike single scalar field inflation, curvaton models can have large self interactions. Enqvist et al. pointed out that even if \(f_{NL}\) is small, \(g_{NL}\) can be large for significant levels of self-interactions [28]. This places a physical significance on \(g_{NL}\) that can be thought of as parameterizing large self-interactions.

### E. Brief Summary

In this section we have discussed the physical significance of each statistic \(f_{NL}\), \(g_{NL}\), \(\tau_{NL}\) and \(A_{NL}\). In the bispectrum, \(f_{NL}\) receives contributions from different shaped triangles in Fourier space related to different underlying physics. By analyzing the amount of non-Gaussianity from these different shapes we can distinguish between models with multiple fields, non-canonical kinetic energy and non-adiabatic vacuums.

In addition we stressed the physical significance of local non-Gaussianity in the trispectrum. The relation \(A_{NL} = \tau_{NL}/(6f_{NL}/5)^2\) is an important constraint of multi-field models. A general result for single-field models is \(A_{NL} = 1\). Lastly, \(g_{NL}\) will place important constraints on the level of self-interactions.

### III. POWER SPECTRA ESTIMATORS FOR FIRST AND SECOND-ORDER NON-GAUSSIANITY

We would like to find a way to measure the non-Gaussianity of these fields from something directly observable. Fortunately, information about the curvature
perturbations are contained within the CMB through the spherical harmonic coefficients of the temperature anisotropies:

$$a_{lm} = 4\pi (-i)^l \int \frac{d^3k}{(2\pi)^3} \Phi(k) g_{Tl}(k) Y^m_l(k),$$ (43)

$$\theta(\hat{n}) = \frac{\delta T}{T}(\hat{n}) = \sum_{lm} a_{lm} Y^m_l(\hat{n}),$$ (44)

where $\Phi(k)$ are the primordial curvature perturbations, $g_{Tl}$ is the radiation transfer function that gives the angular power spectrum $C_l = (2/\pi) \int k^2 dk P_\theta(k) g_{Tl}^2(k)$, $\theta$ is the field of temperature fluctuations in the CMB and $Y^m_l$'s are the spherical harmonics. (In this equation, the curvature perturbation $\Phi$ is related to $\zeta$ through the relation $\Phi = (3/5)\zeta$.)

If the curvature perturbations are purely Gaussian, all the statistical information we can say about them is contained in the two point correlation function $\langle \Phi(x_1) \Phi(x_2) \rangle$. The information contained in the two point function is usually extracted in spherical harmonic space, leading to the power spectrum $C_l$, defined by:

$$C_l = \langle a_{lm} a_{lm}^* \rangle = \frac{1}{(2l+1)} \sum_m a_{lm} a_{lm}^*, $$ (45)

However, if the curvature perturbations are slightly non-Gaussian, this two point function is no longer sufficient to articulate all the information contained in the field. With non-Gaussianity, extra information can be extracted from the three, four and higher $n$-point correlation functions.

We now discuss estimators that can be used to measure non-Gaussianity at first and second order corresponding to the third and fourth-order in curvature perturbations respectively.

### A. Skewness Power Spectrum Estimator for the Bispectrum.

In order to detect Gaussianity at first order, we must turn to the three point correlation function of the primordial curvature perturbations $\langle \Phi(x_1) \Phi(x_2) \Phi(x_3) \rangle$. As mentioned above, we can extract information from the curvature perturbations by analyzing the $a_{lm}$s of the CMB. The three point correlation function of the $a_{lm}$s is called the bispectrum can be decomposed as follows:

$$\langle a_{lm} a_{lm'} a_{lm''} \rangle = B_{l l' l''} \langle \frac{l}{m} \frac{l'}{m'} \frac{l''}{m''} \rangle,$$ (46)

where

$$B_{l l' l''} = \sqrt{\frac{(2l+1)(2l'+1)(2l''+1)}{4\pi}} \left( \frac{l}{m} \frac{l'}{m'} \frac{l''}{m''} \right) b_{l l' l''},$$ (47)

Here the symbols in parenthesis are called the Wigner-3j symbols and enforce rotational invariance of the CMB, as well as ensuring the proper triangle equality holds between $l, l'$ and $l''$ namely: $|l_i - l_j| \leq l_k \leq |l_i + l_j|$ for any combination of $i, j$ and $k$. For more information on the wigner 3j symbols, the reader is directed to the appendix of Ref. [30].

The quantity $b_{l l' l''}$, known as the reduced bispectrum, encases all the other information in the bispectrum and for the local model can be computed analytically as:

$$b_{l_1 l_2 l_3} = 2f_{NL} \int r^2 dr \left[ \alpha_l(r) \beta_{l_2}(r) \beta_{l_3}(r) + \text{cyc.perm} \right]$$ (48)

where

$$\alpha_l(r) = \frac{2}{\pi} \int_0^\infty k^2 dk g_{Tl}(k) j_l(kr),$$

$$\beta_l(r) = \frac{2}{\pi} \int_0^\infty k^2 dk P_\Phi(k) g_{Tl}(k) j_l(kr).$$ (49)

Here, $P_\Phi(k) \propto k^{n_s-4}$ is the primordial power spectrum of curvature perturbations, $g_{Tl}(k)$ is defined above, $j_l(kr)$ are the spherical Bessel functions and $r$ parameterizes the line of sight.

Traditionally, the non-Gaussianity parameter $f_{NL}$ is given as a single number where the information from all the triangles configurations are collapsed into a single number called skewness ($S_3$) defined as

$$S_3 \equiv \int r^2 dr \int d\hat{n} A(r, \hat{n}) B^2(r, \hat{n}).$$ (50)

where $A(r, \hat{n})$ and $B(r, \hat{n})$, are defined below in equations [31] and [32]. Recently, new techniques have been developed to measure $f_{NL}$ from a power spectrum called the skewness power spectrum [31][32]. These new estimators based on the analysis of power spectra are equivalent to $S_3$ in the limit of homogeneous noise [3] but have certain
advantages discussed at the bottom of this subsection. These advantages include the ability to separate backgrounds and other secondary non-Gaussian signals and the ability to correct for the cut-sky without having to compute so-called linear terms.

To extract the skewness power spectrum from data we must begin with temperature maps optimally weighted for the detection of non-Gaussianity following [33]:

\[ A(r, \hat{n}) \equiv \sum_{lm} Y_{lm}(\hat{n}) A_{lm}(r); \quad A_{lm}(r) \equiv \frac{\alpha_l(r)}{C_l} b_l a_{lm}, \quad (51) \]

\[ B(r, \hat{n}) \equiv \sum_{lm} Y_{lm}(\hat{n}) B_{lm}(r); \quad B_{lm}(r) \equiv \frac{\beta_l(r)}{C_l} b_l a_{lm}, \quad (52) \]

Here \( C_l \equiv C_l b_l^2 + N_l \) where \( b_l \) and \( N_l \) are the beam transfer functions and noise power spectrum respectively as described below in Section IV B and \( C_l \) is the usual two point correlation function defined above in equation (45).

From the two above weighted maps we can create two unique two-one power spectra, each of which contribute to the full \( C_l^{(2,1)} \) estimator defined as:

\[ C_l^{A,B^2} \equiv \int r^2 dr \ C_l^{A,B^2}(r), \quad (53) \]

\[ C_l^{AB,B} \equiv \int r^2 dr \ C_l^{AB,B}(r), \quad (54) \]

where

\[ C_l^{A,B^2}(r) = \frac{1}{2l+1} \sum_{m} \text{Real} \left\{ A_{lm}(r) B_{lm}^{(2)}(r) \right\}; \quad (55) \]

\[ C_l^{AB,B}(r) = \frac{1}{2l+1} \sum_{m} \text{Real} \left\{ (AB)_{lm}(r) B_{lm}(r) \right\}; \quad (56) \]

It should make sense that the integrals with respect to the line of sight are needed since the final power spectra must only be an \( l \) dependent quantity.

In the above equations, the squared multipole moments are defined in relation to the squared optimized temperature maps as:

\[ B(r, \hat{n})^2 = \sum_{lm} B_{lm}(r) Y_{lm}^m(\hat{n}); \quad (57) \]

\[ A(r, \hat{n}) B(r, \hat{n}) = \sum_{lm} (AB)_{lm}(r) Y_{lm}^m(\hat{n}). \quad (58) \]

Combining the two unique contributions from equations (53) and (54) gives us our full skewness power spectrum estimator:

\[ C_l^{(2,1)} \equiv (C_l^{A,B^2} + 2C_l^{AB,B}). \quad (59) \]

Once \( C_l^{(2,1)} \) has been extracted from data, we can compute the amount of non-Gaussianity found therein by relating this estimator to its analytical expression for a model with \( f_{NL} = 1 \) that turns out to be:

\[ C_l^{(2,1)} = \frac{f_{NL}}{(2l+1)} \sum_{\ell'} \sum_{\ell''} \left\{ B_{\ell\ell'} B_{\ell''}\ell'' \right\} C_l C_{\ell'} C_{\ell''}. \quad (60) \]

Here, \( C_l \) is the weighted two point power spectrum defined below equation (52) \( B_{\ell\ell'} \) is the full bispectrum and \( B_{\ell''}\ell'' \) is the local model with \( f_{NL} = 1 \) calculated from equations (47) and (48).

Measuring non-Gaussianity using a power spectrum has a few advantages related to the fact that all information is not squeezed into a single number. First, different physics that contribute to the bispectrum, such as point sources and secondaries, can be directly accounted for and measured using curve fitting techniques utilizing each quantities two-one spectrum and fitting all parameters simultaneously as was done recently in Smidt et. al 2009 [4]. Second, each statistic can be tested for scale dependance with ease. This was also done in [4] where it was found that \( f_{NL} \) is consistant with zero for all \( l \). Third, effects due to the cut sky can be removed easily without needing to calculate linear terms needed with \( S_3 \). We discuss this later issue in Section [IV C]. Lastly, for the trispectrum analysis discussed below, both second order statistics \( T_{NL} \) and \( g_{NL} \) can be calculated simultaneously using the two kurtosis spectra.

### B. Kurtosis Power Spectrum Estimators for the Trispectrum

In order to extract non-Gaussianity at second order we must consider the trispectrum or four point function of temperature anisotropies which conveniently breaks into a Gaussian and non-Gaussian or connected piece [34]:
Here, \( P_{l}(l) \) in the spectral relations for the Gaussian parameters using the reduced trispectrum, we are additional cross terms in our analysis that we then to measure a single term of the full trispectrum. There are additional cross terms in our analysis that we then. The approximation we implement here is already costly computationally and the lack of including cross terms associated with permutation, at most, causes our error bars on the non-Gaussian parameters to be overestimated. Furthermore, as we measure non-Gaussian parameters using the reduced trispectrum, we can directly compare our results with the previous predictions that also utilized the same approximation.  

In above, the quantity \( h_{l_{1}l_{2}l_{3}} \) is defined such that
\[
h_{l_{1}l_{2}l_{3}} = \left(\begin{array}{ccc} (2l_{1} + 1)(2l_{2} + 1)(2l_{3} + 1) \\ 4\pi \end{array} \right) \left( \begin{array}{c} l_{1} \ l_{2} \ l_{3} \end{array} \right),
\]
\[(66)\]

Here, \( P_{l}(k) \propto k^{n_{s} - 4} \) is the primordial power spectrum of curvature perturbations, the \( \alpha(r) \), \( \beta(r) \) and \( g_{l} (k) \) are defined above and \( j_{l}(kr) \) are the spherical bessel functions and \( r \) parameterizes the line of sight.

As with the bispectrum, we would like to figure out how to calculate power spectra that can be related to analytical expressions proportional to \( \tau_{NL} \) and \( g_{NL} \). To do this we begin with the same weighted maps defined in equations \( 51 \) and \( 52 \) which leads to the spectra:
\[
K^{(3,1)}_i = (5/3)^2 \tau_{NL} J^{ABAB}_i + 2 g_{NL} L^{AB^2}_i, \quad (68)
\]
\[
K^{(2,2)}_i = (5/3)^2 \tau_{NL} J^{ABA}_i + 2 g_{NL} L^{ABA^2}_i, \quad (69)
\]
where the unique two-two and three-one power spectra are:
\[
\begin{align*}
J^{ABA}_i &= \int d^3 k j_{i}(kr) j_{i}(kr_2), \\
L^{ABA^2}_i &= \int d^3 k j_{i}(kr) j_{i}(kr_2), \\
J^{ABA}_i &= \int d^3 k j_{i}(kr) j_{i}(kr_2), \\
L^{ABA^2}_i &= \int d^3 k j_{i}(kr) j_{i}(kr_2).
\end{align*}
\]

Here \( J^{ABA}_i(r_1, r_2), L^{ABA^2}_i(r), J^{ABA}_i(r_1, r_2), \) and \( L^{ABA^2}_i(r) \) are the angular power spectra of their respective maps. For example \( L^{ABA^2}_i(r) \) is defined as:
\[
L^{ABA^2}_i(r) = \frac{1}{2l+1} \sum_{l} (AB^2)_{lm} B^*_{lm}, \quad (74)
\]
where \( (AB^2)_{lm} \) and \( B^*_{lm} \) are defined analogously with equations \( 57 \) and \( 58 \).

Once the kurtosis estimators have been extracted from temperature data, we can fit the two unknowns \( \tau_{NL} \) and \( g_{NL} \) from the two estimators simultaneously by comparing them to their analytical expressions with \( \tau_{NL} = g_{NL} = 1 \) that turn out to be [30]:
\[
\begin{align*}
K^{(2,2)}_i &= \frac{1}{2l+1} \sum_{l} \frac{1}{\tau_{NL}} \frac{1}{g_{NL}} T^{ABAB}_i(L) \tilde{T}^{ABAB}_i(L), \\
K^{(3,1)}_i &= \frac{1}{2l+1} \sum_{l} \frac{1}{\tau_{NL}} \frac{1}{g_{NL}} T^{ABA}_i(L) \tilde{T}^{ABA}_i(L).
\end{align*}
\]

where \( \tilde{T}^{l_{1}l_{2}l_{3}}_i \) is the full bispectrum and \( \tilde{T}^{ABAB}_i(L) \) is the local model with \( \tau_{NL} = g_{NL} = 1 \) calculated from equation [63]

**IV. FISHER BOUNDS**

**A. The Ideal Experiment**

In order to determine the optimal error bars for these estimators we must properly calculate their signal-to-noise ratios. For the bispectrum, the signal-to-noise ratio takes on the simple form
\[
\left( \frac{S}{N} \right)^2_{(2,1)} = \sum_{l} (2l+1) C^2_{(2,1)}(l), \quad (77)
\]
where \( C^2_{(2,1)} \) is defined above in eq [60].

For the trispectrum we must calculate the signal-to-noise for both \( K^{(2,2)}_i \) and \( K^{(3,1)}_i \). In a best case scenario, the two estimators above are not correlated. In this case
the signal-to-noise for each estimator is:

\[
\left( \frac{S}{N} \right)^2_{(2,2)} = \sum_l (2l+1)K_l^{(2,2)}; \tag{78}
\]
\[
\left( \frac{S}{N} \right)^2_{(3,1)} = \sum_l (2l+1)K_l^{(3,1)}. \tag{79}
\]

Given the positive definite nature of \((S/N)^2\), the signal-to-noise increases as one computes to higher \(l\) values. In fact, for the trispectrum it has been shown that \((S/N)^2 \sim l_{\text{max}}^4\) where \(l_{\text{max}}\) represents the maximum \(l\) used in the analysis \[29\].

In addition to the estimators themselves being correlated, contributions to the terms proportional to \(\tau_{\text{NL}}\) and \(g_{\text{NL}}\) come from different quadratic contributions in Fourier space. This further allows us to calculate the signal-to-noise for each of these terms in each estimator by setting the other to zero. For example, we can determine the optimal signal-to-noise for the \(\tau_{\text{NL}}\) term from the \(K_l^{(2,2)}\) estimator by setting \(g_{\text{NL}} = 0\) embedded in equation \[78\].

Once the signal-to-noise is known, we immediately have a bound on the optimal error bars for our estimators through the inverse square root. For example, if we wanted to know the optimal 1\(\sigma\) error bar that can be placed on \(\tau_{\text{NL}}\) from the \(K_l^{(2,2)}\) estimator, we can compute the Fisher bound as

\[
\sigma(\tau_{\text{NL}}) = \frac{1}{\sqrt{(S/N)^2_{(2,2)} | \tau_{\text{NL}}}}, \tag{80}
\]

with the restriction on \((S/N)^2_{(2,2)}\) to \(\tau_{\text{NL}}\) by setting \(g_{\text{NL}} = 0\) in this calculation.

### B. The Realistic Experiment.

In the above equations we assumed a “perfect” experiment with no noise or beam with a full sky. We now must take in to account that real world experiments have an inherent noise associated with the detector and a beam to characterize its angular resolution. Both the noise and the beam reduce the signal-to-noise. Furthermore, the mask yields a cut sky that must be dealt with properly.

The noise is often reasonably approximated assuming a homogeneous spectrum calculating \(N_l\) from the following relation:

\[
N_l = \sigma_{\text{pix}}^2 \Omega_{\text{pix}}, \tag{81}
\]

where \(\sigma_{\text{pix}}\) is the rms noise per pixel and \(\Omega_{\text{pix}}\) is the solid angle per pixel.

For the noise calculation taking into the inhomogeneous coverage of real world experiments and a cut sky, the beam reduce the signal-to-noise. Furthermore, the inherent noise associated with the detector and a beam to characterize its angular resolution. Both the noise and the beam reduce the signal-to-noise. Furthermore, the mask yields a cut sky that must be dealt with properly.

The noise is often reasonably approximated assuming a homogeneous spectrum calculating \(N_l\) from the following relation:

\[
N_l = \sigma_{\text{pix}}^2 \Omega_{\text{pix}}, \tag{81}
\]

where \(\sigma_{\text{pix}}\) is the rms noise per pixel and \(\Omega_{\text{pix}}\) is the solid angle per pixel.

For the noise calculation taking into the inhomogeneous coverage of real world experiments and a cut sky, the beam reduce the signal-to-noise. Furthermore, the inherent noise associated with the detector and a beam to characterize its angular resolution. Both the noise and the beam reduce the signal-to-noise. Furthermore, the mask yields a cut sky that must be dealt with properly.

The noise is often reasonably approximated assuming a homogeneous spectrum calculating \(N_l\) from the following relation:

\[
N_l = \sigma_{\text{pix}}^2 \Omega_{\text{pix}}, \tag{81}
\]

where \(\sigma_{\text{pix}}\) is the rms noise per pixel and \(\Omega_{\text{pix}}\) is the solid angle per pixel.

For the noise calculation taking into the inhomogeneous coverage of real world experiments and a cut sky, the beam reduce the signal-to-noise. Furthermore, the inherent noise associated with the detector and a beam to characterize its angular resolution. Both the noise and the beam reduce the signal-to-noise. Furthermore, the mask yields a cut sky that must be dealt with properly.

Working in spherical harmonic space, it is easy to correct our estimators \(k_l^{(2,2)}\) and \(k_l^{(3,1)}\) for the effects due to noise and the beam. All that must be done is to preform

\[
N_l = \Omega_{\text{pix}} \int \frac{d^2 \hat{n}}{4\pi f_{\text{sky}}} \frac{\sigma_{\text{pix}}^2 M(\hat{n})}{N_{\text{obs}}(\hat{n})}, \tag{82}
\]

where \(f_{\text{sky}}\) is the fraction of sky observed and \(N_{\text{obs}}\) is the number of observations per pixel \[3\].

In addition to noise, realistic detectors have limits to their resolving power. The resolution limits of the instrument, encoded in the parameter \(\theta_{\text{FWHM}}\) which represents the full-width-half-max of the resolving power. We can map this information into harmonic space in the beam transfer function \(b_l\)

\[
b_l = \exp \left(-l^2 \sigma_{\text{beam}}^2 \right) \tag{83}
\]

\[
\sigma_{\text{beam}}^2 = \frac{\theta_{\text{FWHM}}^2}{(8 \ln(2))} \tag{84}
\]

Beam transfer functions for the WMAP, Planck and EPIC experiments are plotted in Figure 4. As one would expect, a larger \(\theta_{\text{FWHM}}\) results in the suppression of information on larger scales.

| Mission | \(\theta_{\text{FWHM}}\) | \(\sigma_{\text{pix}}\) | \(\Omega_{\text{pix}}\) | Frequency |
|---------|----------------|----------------|----------------|-----------|
| Planck  | 7.1' | \(2.2 \times 10^{-6}\) | 0.0349 | 143 (GHz) |
| EPIC    | 5.0' | \(8 \times 10^{-9}\) | 0.002 | 150 (GHz) |

**TABLE I:** Parameters used to calculate the simulated noise and beam transfer functions for the Planck and EPIC experiment \[38,39\]. We obtained WMAP noise and beam functions from publicly available data.
the transformation:
\[ C_L \rightarrow C_l + \frac{N_l}{b_l^2}. \] (85)
in the denominator of Eq. 75 and 75. As should be intuitively expected, a large amount of noise, or poor resolution will result in a smaller signal-to-noise. Therefore, how much the signal-to-noise is effected is related to the relationship between \( C_l \) and \( N_l/b_l^2 \). For \( N_l/b_l^2 \gg C_l \), the signal is greatly diminished. The relation between \( C_l \) and \( N_l/b_l^2 \) for the WMAP, Planck and EPIC experiments is plotted in Figure 5.

C. Mask And Cut Sky

To remove cut sky effects using the traditional \( S_3 \) estimator, many linear must be computed that must be subtracted off [9, 10, 37]. Furthermore, the number of terms that must be computed grows for higher n-correlation functions. The difficulty arises because the cut sky effects are compressed into a single number, making it difficult to subtract out.

One advantage of probing primordial non-Gaussianity with skewness power spectra is that we can use techniques pioneered by Hivon et al. to remove mask effects from the spectra [40]. This technique is relatively simple and works identically for correlation functions of arbitrary order.

When one uses realistic data, a mask \( W(n) \) must be applied to an all sky map \( M(n) \) to get rid of unwanted sources such as the galactic plane. This mask therefore affects the \( \hat{a}_{lm} \)'s derived from the all sky \( A(r, \hat{n}) \) and \( B(r, \hat{n}) \) defined in equations 51 and 52 used in the bispectrum and trispectrum analysis producing cut sky \( \hat{a}_{lm} \):
we use the V frequency band and for Planck and EPIC we use the 143 and 150 GHz frequency bands respectively. The noise and beam for the WMAP 7-Year band was taken from the WMAP team and those for Planck and EPIC were computed using the values in Table I as described in Section IV.

It should be noted that combining different frequency bands and adding polarization can further reduce the expected error. For example, with the recent WMAP 7-year findings error bars on $f_{\text{NL}}$ from one frequency band, V or W, is $\pm 24$ but the full temperature analysis combining V+W bands gives a reduced error bar of $\pm 21$. (About a 12.5% improvement over one temperature frequency band alone.)

For each of these calculations $C_l$, $\alpha(r)$, $\beta(r)$ and $F_L(r_1, r_2)$ were calculated from Eq. 49 and 67 using a modified version of CAMB based on the WMAP 7-Year best fit cosmological parameter values. The quantities $C_l$, $\alpha(r)$ and $\beta(r)$ are plotted in Figure 3.

For the bispectrum we can form one skewness power spectrum estimator $C_i^{(2,1)}$ which places bounds on the first order non-Gaussian parameter $f_{\text{NL}}$. To calculate the signal-to-noise we use the V frequency band and for Planck and EPIC we use the 143 and 150 GHz frequency bands respectively. The noise and beam for the WMAP 7-Year V band was taken from the WMAP team and those for Planck and EPIC were computed using the values in Table I as described in Section IV.

It should be noted that combining different frequency bands and adding polarization can further reduce the expected error. For example, with the recent WMAP 7-year findings error bars on $f_{\text{NL}}$ from one frequency band, V or W, is $\pm 24$ but the full temperature analysis combining V+W bands gives a reduced error bar of $\pm 21$. (About a 12.5% improvement over one temperature frequency band alone.)

For each of these calculations $C_l$, $\alpha(r)$, $\beta(r)$ and $F_L(r_1, r_2)$ were calculated from Eq. 49 and 67 using a modified version of CAMB based on the WMAP 7-Year best fit cosmological parameter values. The quantities $C_l$, $\alpha(r)$ and $\beta(r)$ are plotted in Figure 3.

For the bispectrum we can form one skewness power spectrum estimator $C_i^{(2,1)}$ which places bounds on the first order non-Gaussian parameter $f_{\text{NL}}$. To calculate the signal-to-noise we use the V frequency band and for Planck and EPIC we use the 143 and 150 GHz frequency bands respectively. The noise and beam for the WMAP 7-Year V band was taken from the WMAP team and those for Planck and EPIC were computed using the values in Table I as described in Section IV.

It should be noted that combining different frequency bands and adding polarization can further reduce the expected error. For the bispectrum we can form one skewness power spectrum estimator $C_i^{(2,1)}$ which places bounds on the first order non-Gaussian parameter $f_{\text{NL}}$. To calculate the signal-to-noise we use the V frequency band and for Planck and EPIC we use the 143 and 150 GHz frequency bands respectively. The noise and beam for the WMAP 7-Year V band was taken from the WMAP team and those for Planck and EPIC were computed using the values in Table I as described in Section IV.
non-Gaussianity detection that together place bounds on the second order non-Gaussian parameters $\tau_NL$ and $g_NL$. The first of these, $K^{(2,2)}_l$, is computed from eq. [79] after this calculation, the signal-to-noise is computed from eq. [78] summing all $l$ up to some $l_{max}$ between 2 < $l$ < 1000 for all $l$ except the diagonal one. (The diagonal being the $l$ in parenthesis of $T^{\ell_1\ell_2\ell_3}(l).$) It was confirmed, as was previously reported [29], that nearly all the signal-to-noise can be calculated only summing up the $l$ in the diagonal of the trispectrum up to $l = 10$, saving a tremendous amount of computational time. In this analysis, however, we summed up the diagonal in both trispectrum estimators to $l = 20$ so as to be more conservative. The error bars on $\tau_NL$ and $g_NL$ from this estimator are then computed from equation eq. [80]. Results from this estimator for $\tau_NL$ are seen in Fig. 10. As with the $C^{(2,1)}_l$ estimator above, we show the 1σ bound for the case without noise and beam as well as for the WMAP 7-Year, Planck and EPIC experiments. For the case of no noise or beam, the error bars for this estimator fall off as $\sim 1/\sqrt{\tau_NL}$. Also plotted in the figure is the amplitude $A_NL$ assuming $f_NL = 32$, the WMAP 7-year best fit value. Therefore, if $f_NL = 32$ then we must have $A_NL > 1$ for Planck to be able to have a detection of $\tau_NL$. However, even if $A_NL \sim 1$, EPIC should be able to detect $\tau_NL$, especially since EPIC will be able to use data much past $l_{max} = 1000$. We also compute error bars for $\tau_NL$ from our second skewness power spectrum estimator for the trispectrum $K^{(3,1)}_l$ by first calculating the signal-to-noise from eq. [79] and [79] then solving for $\sigma(\tau_NL)$ from the fisher matrix [80]. Results for this calculation are plotted in Fig. 11. Along with the 1σ error bars for each experiment, is the amplitude $A_NL$ assuming $f_NL = 50$. The purpose of setting the amplitude to this value is to demonstrate that if $f_NL$ is large enough, models with $A_NL < 1$ may be able to be
tested by upcoming experiments, especially EPIC.

In addition to $\tau_{NL}$, bounds can be put on $g_{NL}$ from the two before mentioned four point estimators. To do this, we calculate the estimators from eq. 75 and 76 setting $\tau_{NL} = 0$ and $g_{NL} = 1$. From here, we calculate the signal-to-noise from eq. 78 and 79 whereupon we compute Fisher bounds from equation 80. The results are seen in Fig. 11.

Combining the two estimators $\mathcal{K}^{(2,2)}_l$ and $\mathcal{K}^{(3,1)}_l$ gives the minimum error bars for $\tau_{NL}$ and $g_{NL}$ seen in Table II as well as Figure 12. These are comparable to those of Okamoto and Hu [35] and Komatsu [29] who calculated Fisher bounds assuming only cosmic variance limited sky. They did not use the power skewness estimator, however, their estimator is equivalent in the limit of homogeneous noise [3]. Kogo and Komatsu [29] found a higher signal-to-noise than did Okamoto and Hu [35]. This paper finds a signal-to-noise in between these values.

| $l_{max}$ | 500  | 1000 | 1500 | 2000 |
|-----------|------|------|------|------|
| $f_{NL}$  |      |      |      |      |
| Planck    | 16   | 10   | 8    | 8    |
| EPIC      | 15   | 7.5  | 5    | 3    |
| $\tau_{NL}$ | 4350 | 1640 | 1550 | 1550 |
| Planck    | 3700 | 920  | 400  | 225  |
| EPIC      |      |      |      |      |
| $g_{NL}$  |      |      |      |      |
| Planck    | $1.6 \times 10^5$ | $1.4 \times 10^5$ | $1.3 \times 10^5$ | $1.3 \times 10^5$ |
| EPIC      | $1.5 \times 10^5$ | $1.1 \times 10^5$ | $8.4 \times 10^4$ | $6.0 \times 10^4$ |
| $A_{NL}$  |      |      |      |      |
| Planck    | 3.0  | 1.1  | 1.0  | 1.0  |
| EPIC      | 2.5  | 0.6  | 0.3  | 0.15 |

TABLE II: The minimum error bars at 1σ for $f_{NL}$, $\tau_{NL}$ and $g_{NL}$, using both $\mathcal{K}^{(2,2)}_l$ and $\mathcal{K}^{(3,1)}_l$ estimators, for the Planck and EPIC experiments up to $l_{max} = 2000$. As stated in text, this assumes only one temperature frequency band is used in the analysis.

From this table we see that $\tau_{NL}$ can be detected at 95% confidence level by Planck if $\tau_{NL} > 3000$ and EPIC for $\tau_{NL} > 600$. If $f_{NL} = 32$ in the bispectrum, this equivalently means $\tau_{NL}$ can be detected if $A_{NL} > 2$ and $A_{NL} > 0.4$ respectively, again alluding to the fact that EPIC will be able to test some inflationary models with $A_{NL} < 1$.

Furthermore, as can be seen in Fig. 13 for large enough $A_{NL}$, the trispectrum is more sensitive to non-Gaussianity, even for Planck. This may turn out to be very important as some models predict $A_{NL} > 1$. It is therefore imperative that Planck examines the trispectrum for non-Gaussianity as it may turn out to be more likely to get a detection there than in the bispectrum.

Some models predict an undetectable amount of non-Gaussianity in the bispectrum (For example, $f_{NL} \sim 1$) with a large amount of non-Gaussianity in the trispectrum. These plots let us know just how big $A_{NL}$ must be in order for a detection of non-Gaussianity to be made in the trispectrum for such scenarios.

From these plots we see, for $f_{NL} = 1$, the trispectrum becomes more sensitive to non-Gaussianity than the bispectrum at $l = 1450, 830,$ and $500$ for $A_{NL} = 50, 90$ and $120$ respectively. For $f_{NL} = 32$, the trispectrum has more sensitivity at $l = 2350, 1150,$ and $450$ for $A_{NL} = 1, 3$ and $10$ respectively and for $f_{NL} = 50$ we have more sensitivity at $l = 1500, 750,$ and $300$ for $A_{NL} = 1, 3$ and $10$ respectively.

Figure 14 shows $(A_{NL} - 1)/\Delta A_{NL}$ for both Planck and EPIC. In this plot it is clear that both Planck and EPIC are in a position to rule out single field inflation by determining $A_{NL} \neq 1$. Large sections of the parameter space, consistent with current measurements, will rule out $A_{NL}$ equal to unity by $>5\sigma$.

Note from Table II that the expected bound on $g_{NL}$ is about two orders of magnitude weaker than that on $\tau_{NL}$, even though both parameters are suppressed by a power spectrum cubed in (21). One reason is that the $k$ dependent shape factor multiplying $\tau_{NL}$ in (21) diverges whenever $k_{ij} \rightarrow 0$, while the factor multiplying $g_{NL}$ only...
FIG. 13: Comparison of the sensitivity of both the bispectrum and the trispectrum to non-Gaussianity assuming different values of $f_{NL}$ and $A_{NL}$.

diverges when one of the $k_i \to 0$ (and in this case the same applies for $\tau_{NL}$ as well).

VI. PRIOR ANALYSIS USING THESE ESTIMATORS

These skewness and kurtosis power spectrum estimators have recently been employed to constrain non-Gaussianity in the WMAP 5-year data. Using the bispectrum, Smidt et al. (2009) found that $-36.4 < f_{NL} < 58.4$ at 95% confidence [4]. This bound puts the 1σ error bars at $\pm 23.5$, within about 12% of the optimal Fisher bound.

The analysis for the trispectrum is more difficult and we therefore elaborate about it here. Our recipe for analysis is

1. We calculate $K_{l}^{(3,1)}$ and $K_{l}^{(2,2)}$ in Eq. 75-76 for $\tau_{NL}$ and $g_{NL} = 1$.

2. We extract $K_{l}^{(3,1)}$ and $K_{l}^{(2,2)}$ directly from WMAP 5-year data.

3. We perform the extraction of $K_{l}^{(3,1)}$ and $K_{l}^{(2,2)}$ from 250 Gaussian maps, allowing us to determine error bars and the Gaussian piece of each estimator.

4. We subtract off the Gaussian contribution to these estimators to ensure we are fitting to the non-Gaussian contribution.

5. We fit the two unknowns $\tau_{NL}$ and $g_{NL}$ from data using the two equations simultaneously. The amplitudes the theoretical curves must be scaled by gives the values for $\tau_{NL}$ and $g_{NL}$.

6. We constrain $A_{NL}$ by comparing $\tau_{NL}$ from the trispectrum with $(6f_{NL}/5)^2$ coming from the bispectrum.

This recipe is described in greater detail below:

First we calculate $K_{l}^{(3,1)}$ and $K_{l}^{(2,2)}$ theoretically using equations Eq. 54 67 and Eq. 75 76 for a model with
\( \tau_{NL} \) and \( g_{NL} = 1 \). To obtain \( C_l \) we use CAMB \(^1\) with the WMAP 5-year best fit parameters and use the beam transfer functions from the WMAP team. We then obtain the connected piece using a modified version of the CMBFAST code \(^2\). \(^3\) Plots of many of the quantities used for these calculations can be found in Ref. \(^4\).

Plots of \( K^{(2,1)}_{l} \) and \( K^{(3,1)}_{l} \) are shown in Figure 15. These curves will be compared with estimators derived from data to determine the magnitude of each statistic. Since we have two estimators, we can solve for the two unknowns \( \tau_{NL} \) and \( g_{NL} \) by fitting both estimators simultaneously.

To calculate\(^3\) the estimators from data, used in the lefthand side of equations (75) and (76), we use both the raw and foreground-cleaned WMAP 5-Year Stokes I maps for V- and W-bands masked with the KQ75 mask \(^4\). We use the Healpix library to analyze the maps. For this analysis we only considered data out to \( l_{\text{max}} = 600 \). We correct for the KQ75 mask using a matrix \( M_{\text{sk}} \), based on the power spectrum of the mask, as described above.

Figure 15 shows the results for \( K^{(3,1)}_{l} \) and \( K^{(2,2)}_{l} \) for the V and W frequency bands extracted from the raw WMAP 5-Year maps. In order to do proper statistics for our data fitting we create 250 simulated Gaussian maps of each frequency band with \( n_{\text{side}} = 512 \). To obtain Gaussian maps we run the \texttt{synfast} routine of Healpix with an in-file representing the WMAP 5-year best-fit CMB anisotropy power spectrum and generate maps with information out to \( l = 600 \). We then use \texttt{anafast}, without employing an iteration scheme, masking with the KQ75 mask, to produce \( a_{th} \)’s for the Gaussian maps out to \( l = 600 \). Obtaining estimators from these Gaussian maps allows us to uncover the Gaussian contribution to each estimator in addition to providing us information needed to calculate the error bars on our results.

This whole process is computationally intensive. To calculate all theoretical estimators took nearly 8,000 CPU hours. Furthermore, all the estimators from Gaussian and data maps combined took an additional 1600 CPU hours.

As previously discussed, the full trispectrum can be decomposed into both a Gaussian and non-Gaussian or connected piece. To make a measurement of non-Gaussianity we to subtract off the Gaussian piece from the full trispectrum. Figure 16 shows the the relationship between the full trispectrum and the Gaussian piece. In this plot the Gaussian piece was calculated in two different ways as a sanity check. First, the Gaussian maps were averaged over. Second, the Gaussian piece of each estimator is calculated theoretically using Eq. 65.

TABLE III: Results for each frequency band to 1σ. Values for $g_{NL}$, $\tau_{NL}$ and $A_{NL}$ on the top are for raw maps. The values on the bottom are for foreground clean maps. $A_{NL}$ is estimated assuming $f_{NL} = 32 \pm 21$ from the WMAP-7 analysis and the tabulated 1σ uncertainty is based on an analytical error propagation.

| Band | W     | V     | V+W   |
|------|-------|-------|-------|
| Raw  | $4.7 \times 10^4 \pm 5.3 \times 10^5$ | $4.6 \times 10^4 \pm 5.9 \times 10^5$ | $4.7 \times 10^4 \pm 3.9 \times 10^5$ |
| $g_{NL}$ | $(1.63 \pm 1.27) \times 10^4$ | $(1.68 \pm 1.31) \times 10^4$ | $(1.64 \pm 0.98) \times 10^4$ |
| $\tau_{NL}$ | $7.4 \pm 7.3$ | $6.3 \pm 6.0$ | $11.1 \pm 7.3$ |
| $A_{NL}$ | $6.0 \pm 6.7$ | $5.2 \pm 5.7$ | $9.2 \pm 6.1$ |
| FC   | $4.2 \times 10^4 \pm 5.3 \times 10^5$ | $4.1 \times 10^4 \pm 5.9 \times 10^5$ | $4.2 \times 10^4 \pm 3.9 \times 10^5$ |
| $g_{NL}$ | $(1.32 \pm 1.27) \times 10^4$ | $(1.39 \pm 1.31) \times 10^4$ | $(1.35 \pm 0.98) \times 10^4$ |
| $\tau_{NL}$ | $6.0 \pm 6.7$ | $5.2 \pm 5.7$ | $9.2 \pm 6.1$ |

FIG. 17: The 95% confidence levels for $g_{NL}$ versus $\tau_{NL}$. The red and orange represent the 68% and 95% intervals respectively for the combined V+W analysis. The light blue regions represent the 95% confidence intervals for the V band analysis, and the light green regions are for the W band.

V+W-band in foreground-cleaned maps. The 95% confidence intervals of $g_{NL}$ versus $\tau_{NL}$ are plotted in Figure 16 for each band. For a V band analysis alone, the 68% confidence intervals are $\tau_{NL} = (1.39 \pm 1.31) \times 10^4$ and $g_{NL} = 4.6 \times 10^4 \pm 5.9 \times 10^5$. These error bars are within ~40% and ~20% of the optimal Fisher values discussed above comparing with WMAP 7-year level noise for $\tau_{NL}$ and $g_{NL}$ respectively.

Combining $f_{NL} = 11 \pm 24$ from Ref. 14 and $\tau_{NL} = (1.35 \pm 0.98) \times 10^4$ from our skewness analysis we get $-649 < A_{NL} < 805$ at 95% confidence. If instead we had assumed $f_{NL} = 32 \pm 21$ from WMAP-7 analysis 2 and same $\tau_{NL}$ reported here we find $-3 < A_{NL} < 21.4$ at 95% confidence. The difference of the two estimates is a reflection on the central value of $f_{NL}$ since $A_{NL} = \tau_{NL}/(6f_{NL}/5)^2$ and therefore a smaller $f_{NL}$ results in a larger uncertainty in $A_{NL}$. This behavior is also seen in Fig. 16.

No measurements involving WMAP 7-year data have been preformed using these estimators. It is our opinion that the results for WMAP 7-year data will not be much different than for the WMAP 5-year data, just as the optimal results using the traditional skewness statistic $S_3$ do not differ significantly between these two data sets. 2

Planck, on the other hand, is in a position to make significant improvements in the measurement of non-Gaussianity using these estimators. Since Planck is taking data, we encourage any plans to measure $f_{NL}$, $g_{NL}$ and $\tau_{NL}$ using the skewness and kurtosis statistics that we have proposed. In addition to ruling out the standard single-field slow-roll inflation model with a detection of non-Gaussianity in general, Planck is in a position to possibly rule out all single-field models with a measurement of $A_{NL} \neq 1$.

VII. CONCLUSIONS

In this paper we discussed the skewness and kurtosis power spectrum approach to probing primordial non-Gaussianity. We outlined the expected constraints these techniques will place using future experimental data. These constraints were calculated by computing the signal-to-noise for each estimator, properly taking into account the noise and beam of each experiment. Optimal error bars for $f_{NL}$, $g_{NL}$ and $\tau_{NL}$ are listed as a function of $l_{max}$.

It was argued that the skewness and kurtosis power spectrum approach to measure non-Gaussianity has several advantages. These advantages include the ability to separate foregrounds and other secondary non-Gaussian signals, the ability to measure the scale dependence of each statistic and an advantage that the cut sky can be corrected from a matrix $M_{ll'}$ without needing to compute extra linear terms.

The physical significance of each non-Gaussian statistic is discussed. In the bispectrum, different non-Gaussian triangle configurations in Fourier space contributing to $f_{NL}$ are related to different underlying physics. By adding a local measurement of the trispectrum, a new statistic $A_{NL} = \tau_{NL}/(6f_{NL}/5)^2$ will be a powerful probe...
to distinguish between multi-field models. Single-field models can be ruled out in general if \( A_{NL} \neq 1 \) and we discussed how this may be a real possibility with Planck or EPIC. Furthermore, for \( A_{NL} \) large enough, the trispectrum becomes a better probe for non-Gaussinity than the bispectrum for analysis utilizing information on very small scales. The parameter \( g_{NL} \) will be the hardest to constrain. A constraint on this parameter will uncover information on self-interactions.
