Geographic Differences in Endovascular Treatment and Retreatment of Cerebral Aneurysms

ABSTRACT

BACKGROUND AND PURPOSE: Comparing outcomes between endovascular aneurysm coiling trials can be difficult because of heterogeneity in patients and end points. We sought to understand the impact of geography on aneurysm retreatment in patients enrolled in the Matrix and Platinum Science Trial.

MATERIALS AND METHODS: Post hoc analysis was performed on data from the Matrix and Platinum Science trial. Patients were stratified as either North American or international. Baseline patient demographics, comorbidities, aneurysm characteristics, procedural complications, and clinical and angiographic outcomes were compared.

RESULTS: We evaluated 407 patients from 28 North American sites and 219 patients from 15 international sites. Patient demographics differed significantly between North American and international sites. Aneurysms were well occluded postprocedure more often at international than North American sites (P < .001). Stents were used significantly more often at North American sites (32.7% [133 of 407]) compared with international sites (10.0% [22 of 219]; P < .001). At 455 days, there was no difference in the proportion of patients alive and free of disability (P = .56) or with residual aneurysm filling (P = .10). Ruptured aneurysms were significantly more likely to have been retreated at North American sites within the first year (P < .001) and at 2 years (P < .001). Among all patients for whom the treating physician believed there to be Raymond 3 aneurysm filling at follow-up, absolute rates of retreatment at international and North American sites were similar by 2-year follow-up.

CONCLUSIONS: Data from the Matrix and Platinum Science Trial demonstrate that aneurysm retreatment occurs with different frequency and at different times in different regions of the world. This trend has critical value when interpreting trials reporting short-term outcomes, especially when judgment-based metrics such as retreatment are primary end points that may or may not take place within the defined study follow-up period. Though these variations can be controlled for and balanced within a given randomized trial, such differences in practice patterns must be accounted for in any attempt to compare outcomes between different trials. Despite these differences, endovascular-treated intracranial aneurysms around the world have similar clinical outcomes.

The International Subarachnoid Aneurysm Trial1,2 was the landmark prospective randomized trial demonstrating the safety and effectiveness of endovascular treatment of ruptured aneurysms compared with surgical clipping. More recently, results from the Barrow Ruptured Aneurysm Trial3 further support coiling as a treatment technique associated with good patient outcomes comparable with clipping in the setting of SAH. Moreover, the results of several recently published multinational randomized controlled trials4-6 demonstrated ruptured and unruptured aneurysms can be safely and effectively treated by using various coil types. Many comparisons generalizing results of these various trials have been made. However, comparing outcomes between trials can be difficult and misleading because of different trial
different trials cannot overcome these problems.

The very low bleeding or rebleeding rates of treated aneurysms has led most trial investigators to use angiographic outcomes to compare device performance. However, there are no agreed-upon standards for acceptable angiographic outcomes. Recently, the value of target aneurysm recurrence was explored as a new clinically relevant composite end point in a large-scale multicenter randomized trial comparing outcomes of patients with intracranial saccular aneurysms treated with 2 different embolic coil types.4,8,9 In this study, target aneurysm recurrence was defined as clinically relevant aneurysm recurrence resulting in target aneurysm re-intervention, rupture/rupture, and/or death from an unknown cause. The advantage of this end point is that it is definitive that the event has happened and that these events are of clear relevance to the patient. The disadvantage of these end points is the variability of the decision to retreat because physician judgment often varies with the training, economic incentives, and regulatory structure of the local health system.

Both angiographic assessments and the decision to retreat aneurysms are subjective, leaving tremendous opportunity for individual or regional factors to influence trial results. We sought to understand the impact of geography on aneurysm retreatment in patients randomized in the Matrix and Platinum Science Trial.

MATERIALS AND METHODS

The Matrix and Platinum Science Trial was a randomized controlled trial of 626 intent-to-treat patients. The methodology and primary outcomes of this trial have been previously published.4 Anticipating variability in retreatment rates across enrolling sites, the trial stratified randomization by both aneurysm rupture status and enrolling site. For this analysis, the Matrix and Platinum Science Trial data base was interrogated and all aneurysms divided into groups based on geographic location of the medical center where they were treated. All baseline patient demographics, including cardiovascular risk factors, were documented. Aneurysm location, rupture status, and characteristics were also evaluated. Angiographic and clinical outcomes were compared. An independent core radiology laboratory performed all angiographic analyses.

All patients in the Matrix and Platinum Science Trial were used for this analysis. For data dependent upon core laboratory angiographic analysis, patients with unreadable images were excluded. Patients were categorized into 2 groups: North American and international sites (including sites in Europe, Australia, and China). Few patients were enrolled in Asia and Australia; therefore, they were combined with Europe to create the complete international cohort. Patients were further explored based on their baseline rupture status, comorbidities, and angiographic core laboratory evaluations. Retreatment rates within each subgroup were calculated and compared.

Table 1: Patient demographics

| Variable                     | Location, (n [%]) | P Value |
|------------------------------|-------------------|---------|
| Total patients               | 407               | 219     |         |
| No. of sites                 | 28                | 15      |         |
| Female sex                   | 309 (75.9%)       | 131 (59.8%) | <.001  |
| Age ≥ 55 yr                  | 218 (53.6%)       | 88 (40.2%) | <.001  |
| White                        | 350 (86.0%)       | 158 (72.1%) | <.001  |
| Current/previous smoker      | 261 (64.3%)       | 130 (59.4%) | 24      |
| Hypertension                 | 124 (30.5%)       | 33 (15.1%) | <.001  |
| Hyperlipidemia/hypercholesterolemia | 217 (53.3%) | 83 (37.9%) | <.001  |
| Diabetes                     | 122 (30.0%)       | 34 (15.5%) | <.001  |
| Coronary disease             | 43 (10.6%)        | 11 (5.0%) | .02      |
| Prior cerebrovascular accident | 63 (15.5%)  | 10 (4.6%) | <.001  |
| Hunt and Hess grade 3 or 4 in ruptured patients | 54 (13.3%) | 15 (6.8%) | .02      |

| Value North America | International | P Value |
|---------------------|---------------|---------|
| 38/115 (33.0%)      | 24/113 (21.2%) | .045    |

We used logistic regression modeling to answer our research questions: 1) “What are the predictive characteristics of retreatment in ruptured and unruptured aneurysms?” and 2) “Are there differences in retreatment rates between geographical regional groups?” All baseline aneurysm characteristics and immediate postprocedure angiography readings by the core laboratory were first tested in univariate models to determine the association with the retreatment outcome. All potential covariates with a P value ≤ .10 in a univariate model were included in the covariate pool drawn upon during the stepwise multivariate model selection process. In the final model, only those covariates with a P value < .05 were retained. Finally, to control for potential site effect, we used a generalized linear mixed-effect model within the 2 subsets of baseline ruptured or unruptured cohorts. In this model, we specified “site” as the random effect so that retreatment rates were not assumed to be equal among sites and, therefore, we could estimate common odds ratios across sites. Geography and stent usage (for unruptured aneurysms) were forced as fixed effects.

Kaplan-Meier survival curves were constructed to evaluate the difference in days to first retreatment between North American and international patient subgroups. Separate curves were constructed for baseline ruptured and baseline unruptured patients. The log-rank test was used for the P value calculations of the difference between the 2 curves from 2 regions.

RESULTS

Between March 2007 and October 2009, 626 patients were randomized into the Matrix and Platinum Science Trial at 43 sites in 11 countries. Among 407 North American patients enrolled at 28 sites, 115 had ruptured aneurysms and 292 had unruptured aneurysms. The 15 international sites treated 219 patients, of whom 113 had ruptured aneurysms and 106 had unruptured aneurysms. (Table 1). Approximately 95% of patients in both the North American and international subgroups had follow-up data available after 1 year (>275 days); follow-up data were available after 2 years (>640 days) for 81.0% and 84.5% of North American and international patients, respectively.

Baseline Demographics

Patient demographics differed between North American and international groups, with the most significant differences being the...
proportions of female patients with ruptured aneurysms, white patients, and patients with more than 1 cardiovascular risk factor (Table 1 and Table 2).

**Angiographic and Clinical Outcomes**

Core laboratory occlusion assessment was performed by using the modified 3-point Raymond scale. Immediately postprocedure, angiographic and clinical outcomes (Table 1 and Table 2) were recorded. Patients with more than 1 cardiovascular risk factor had a Raymond score of 3 (residual aneurysm) compared with patients at international sites (43.5% [140 of 322] versus 26.5% [44 of 166]; P < .001). This higher proportion of postprocedure residual aneurysms among North American patients was observed in both ruptured (29.8% [28 of 94] versus 16.7% [13 of 78]) and unruptured (49.1% [112 of 228] versus 35.2% [31 of 88]) subgroups. However, the proportion of patients with a packing attenuation >25% was similar in North American (42.5% [173 of 407]) and international (38.4% [84 of 219]) groups. Stents were used more frequently in unruptured aneurysms treated in North American than international sites (44% versus 19%, respectively; P < .001).

At 30 days, patients with ruptured aneurysms were more likely to have been discharged from North American sites than patients treated at international sites (85.2% [98 of 115] versus 66.4% [75 of 113]; P < .001). At 455 days, there was no difference in the proportion of patients alive and free of disability among those with ruptured aneurysms (North American: 90.4% [94 of 104] versus international: 94.0% [94 of 100]) and unruptured aneurysms (North American: 95.4% [250 of 262] versus international: 97.0% [97 of 100]) and no significant difference in the proportion of patients with core laboratory adjudicated residual aneurysms (36.4% versus 28.7%; P = .10). Ruptured aneurysms were more likely to have been retreated at North American sites compared with international sites (21.7% versus 4.4%; P < .001), whereas there were no significant regional differences in retreatment rates among patients with unruptured aneurysms. Kaplan-Meier curves demonstrate no difference in freedom from retreatment in patients in the unruptured group and a sustained difference in patients in the ruptured group (Figure).

Multivariate analysis of ruptured aneurysms at 455 days demonstrated that geography (adjusted common odds ratio 6.2; 95% CI, 2.0–18.8; P < .001), neck size ≥4 mm (adjusted common odds ratio 4.3; 95% CI, 1.6–11.5; P = .004), and residual aneurysm on postprocedure angiogram (adjusted common odds ratio 7.2; 95% CI, 2.6–19.7; P < .001) were the most significant predictors of retreatment (Table 3). For unruptured aneurysms at 455 days, dome size ≥10 mm (adjusted common odds ratio 4.1; 95% CI, 1.2–14.2; P = .025) and residual aneurysm on postprocedure angiogram (adjusted common odds ratio 3.6; 95% CI, 1.1–12.4; P = .040) were significant predictors of retreatment. Geography was not an independent predictor of retreatment in unruptured aneurysms.

Multivariate analysis of ruptured aneurysms at 820 days demonstrated that predictors of retreatment did not change from 455 days (Table 4). In the unruptured cohort, the only significant predictor of retreatment at 820 days was dome size ≥10 mm (adjusted common odds ratio 3.3; 95% CI, 1.0–10.4; P = .047). Postprocedure angiographic results were no longer significant at 820 days.

**DISCUSSION**

One of the most striking findings in this study is the significantly higher retreatment rate of aneurysms in North American...
ica, especially among ruptured aneurysms and in the first 455 days postprocedure. Though the difference in retreatment rates between North America and international sites was persistent out to 820 days (Figure), there appears to be eventual consistency in global retreatment rates among patients judged to have residual aneurysms at follow-up. At 820 days, 55.7% of North American residual aneurysms had been retreated compared with 47.6% in international sites. Earlier in follow-up, at 455 days, 49.2% of North American residual aneurysms had already been retreated compared with just 19.0% of international residual aneurysms.

The geographic differences in frequency of retreatment were only significant in the ruptured aneurysm cohort. This could indicate a North American preference to treat the rupture minimally, with a willingness to do a follow-up retreatment if necessary. It also may be tied to an increased use of stents in patients with unruptured aneurysms in North America, though multivariate analysis did not show the impact of stents on retreatment rates to be significant at 455 or 820 days (Table 3).

Differences between geographies were present, beginning with patient baseline characteristics and extending through aneurysm treatment and subsequent follow-up. North American operators treated significantly more patients who were older in age with multiple cardiovascular risk factors and more likely to have a higher Hunt and Hess grade. When North American operators identified residual aneurysm filling at follow-up, they were more likely to immediately retreat these remnants than operators in other regions of the world.

A significantly higher proportion of aneurysms treated at North American sites had residual filling immediately postprocedure than aneurysms treated at international sites (43.5% versus 26.5%, respectively). These initial occlusion rates indicate a more aggressive treatment approach at international sites. However, similar packing densities across regions imply that physicians are implanting similar volumes of coils. This discrepancy could be attributed to complex aneurysm morphologies and the imperfect nature of packing attenuation calculations that assume an elliptical aneurysm shape.

Stent-assisted coiling was used significantly more frequently in North America and was associated with better angiographic outcomes at 455 days than aneurysms treated by coiling alone. Though there were more ischemic events associated with stented aneurysms, multivariate analysis demonstrated that this was because of the width of the aneurysm neck and a history of stroke.\textsuperscript{11}

Despite these differences, there was no significant difference in mRS between North American and international cohorts at 455 days.

Though these data of 626 patients are strengthened through the prospective randomized trial design, retrospective identification of subgroups for analysis remains a limitation. The utilization of an angiographic core laboratory also further strengthens the data, though

CONCLUSIONS

Data from the Matrix and Platinum Science Trial demonstrate that aneurysm retreatment occurs with different frequency and at different times in different regions of the world. This trend has critical value when interpreting trials reporting short-term outcomes, especially when judgment-based metrics such as retreatment are primary end points that may or may not take place within the defined study follow-up period. Though these variations can be controlled for and balanced within a given randomized trial, such differences in practice patterns must be accounted for in any attempt to compare outcomes among different trials. Despite these differences, endovascular-treated intracranial aneurysms around the world have similar clinical outcomes.
