IS PGD-ADVERSARIAL TRAINING NECESSARY? ALTERNATIVE TRAINING VIA A SOFT-QUANTIZATION NETWORK WITH NOISY-NATURAL SAMPLES ONLY

Tianhang Zheng, Changyou Chen, Kui Ren
State University of New York at Buffalo

ABSTRACT

Recent work on adversarial attack and defense suggests that projected gradient descent (PGD) is a universal $l_\infty$ first-order attack, and PGD adversarial training can significantly improve network robustness against a wide range of first-order $l_\infty$-bounded attacks, represented as the state-of-the-art defense method. However, an obvious weakness of PGD adversarial training is its highly-computational cost in generating adversarial samples, making it computationally infeasible for large and high-resolution real datasets such as the ImageNet dataset. In addition, recent work has suggested a simple “close-form” solution to a robust model on MNIST. Therefore, a natural question raised is that is PGD adversarial training really necessary for robust defense? In this paper, surprisingly, we give a negative answer by proposing a training paradigm that is comparable to PGD adversarial training on several standard datasets, while only using noisy-natural samples. Specifically, we reformulate the min-max objective in PGD adversarial training by a minimization problem of the original network loss plus $l_1$ norms of its gradients evaluated on the inputs (including adversarial samples). The original loss can be solved by natural training; for the $l_1$-norm loss, we propose a computationally-feasible solution by embedding a differentiable soft-quantization layer after the input layer of a network. We show formally that this soft-quantization layer trained with noisy-natural samples is an alternative approach to minimizing the $l_1$-gradient norms as in PGD adversarial training. Extensive empirical evaluations on three standard datasets including MNIST, CIFAR-10 and ImageNet show that our proposed models are comparable to PGD-adversarially-trained models under PGD and BPDA attacks using both cross-entropy and CW$_\infty$ losses. Remarkably, our method achieves a 24X speed-up on MNIST while maintaining a comparable defensive ability, and for the first time fine-tunes a robust Imagenet model within only two days. Code for the experiments is provided on [https://github.com/tianzheng4/Noisy-Training-Soft-Quantization](https://github.com/tianzheng4/Noisy-Training-Soft-Quantization).

1 INTRODUCTION

Although deep neural networks (DNNs) have achieved remarkable performance on various machine-learning tasks such as object detection and recognition (Krizhevsky et al., 2012), natural language processing (Cho et al., 2014) and game playing (Silver et al., 2016), they also have been shown to be vulnerable to adversarial perturbations (Szegedy et al., 2013; Biggio et al., 2013). This issue has led to broad research on adversarial attack and defense. As representative work, Madry et al. (2017) suggest that Project Gradient Descent (PGD) is a universal first-order attack algorithm, and PGD adversarial training is an effective method to defend $l_\infty$ first-order attacks. This conclusion is strengthened by Carlini et al. (2017), who experimentally demonstrated that PGD-adversarial training provably succeeds at increasing the distortion required to construct adversarial examples by a factor of 4.2. Furthermore, PGD adversarial training is the only method that significantly increases network robustness among all the defenses appearing in ICLR2018 and CVPR2018 (Athalye et al., 2018, 2018; Athalye & Carlini, 2018), thus representing as the state-of-the-art defense method.
Despite the success of PGD adversarial training, one obvious limitation is that it is too computationally expensive to generate PGD adversarial examples, and thus PGD adversarial training is impractical/infeasible on large datasets such as the ImageNet. We observe that even on the much smaller CIFAR-10 dataset, PGD adversarial training takes a few days, while natural training only requires several hours on a TITAN V GPU. Moreover, recent work suggests that there exists a simple “close-form” solution to achieve robustness against $l_{\infty}$ attacks (Tramèr et al., 2017). The authors observed that on average for a MNIST image, over 80% of the pixels are in $\{0, 1\}$ and only 6% are in the range $[0.5 – 0.3, 0.5 + 0.3]$. Thus, adversarial perturbations are $0.3/1.0$ $l_{\infty}$-bounded, and the binarized versions of natural and adversarial samples can only differ in at most 6% of the input dimensions. By simply binarizing the inputs of a naturally trained model, a robust model with only 11.4% error under a white-box iterative FSGM attack could be achieved. All the above observations raise an important question: Is PGD adversarial training really necessary in order to learn a robust model against $l_{\infty}$ attacks? In this paper, we suggest the answer is “Probably No”. To support our conclusion, we propose an alternative training approach that only requires training with noisy-natural samples, with an objective approximately equivalent to the min-max objective in PGD adversarial training. Specifically, we reformulate the min-max objective of PGD adversarial training to an alternative form, which minimizes the original network loss plus the $l_{1}$ norms of its gradients in the whole data space. The original network loss can be minimized by natural training; and we also propose noisy natural-sample training on a soft-quantization network to achieve the $l_{1}$-norm minimization. We show that our proposed soft-quantization layer enforces nearly zero-gradients in most areas of the data space, and noisy natural-sample training can smooth out the remaining sharp areas to further enhance network robustness.

Though obtaining good performance, our framework seems to cause the problem of gradient masking (Papernot et al. (2017)). In order to show our framework is still effective, we evaluate the framework together with natural and PGD adversarial training under both white-box PGD and BPDA + PGI (Athalye et al., 2018) on three standard datasets, i.e., MNIST, CIFAR-10, and ImageNet. It is worth noting that the other two attacks proposed in (Athalye et al., 2018), i.e., EOT and Reparameterization, are not applicable to our defense since no randomization or optimization loop is incorporated in our testing stage. Surprisingly, our proposed method is comparable to PGD adversarial training in terms of defense accuracy, while achieving significant speed-ups in training as no adversarial samples are required. Specifically, the accuracy of our model is 98.49% under 100-step PGD and 87.32% under BPDA on MNIST ($l_{\infty}$ perturbations of $\epsilon = 0.3/1.0$); when $l_{\infty}$ perturbations are less than 0.1/1.0, our model even surpasses PGD adversarial training under the BPDA attack. On CIFAR-10, 20-step PGD and BPDA + PGD attacks reduce the accuracy of our model to 78.01% and 34.43% respectively, compared to 46.62% for PGD adversarial training ($l_{\infty}$ perturbations of $\epsilon = 8.0/255.0$). To the best of our knowledge, our white-box result on CIFAR10 is currently the second-best only behind PGD adversarial training and its variants, when considering the attacks proposed in (Athalye et al., 2018) [Athalye & Carlini, 2018]. For ImageNet, 20-step PGD attack reduces the Top 1 and Top 5 accuracies of the TensorFlow-Slim library’s public Inception_v3 model to 5.974% and 10.460% ($l_{\infty}$ perturbations of $\epsilon = 4.0/255.0$). When applying our proposed defense (computationally infeasible with PGD adversarial training), we are able to obtain 32.578% Top 1 and 69.718% Top 5 accuracies under PGD attack, and 22.582% Top 1 and 65.576% Top 5 accuracies under BPDA attack. To our knowledge, this is currently the best white-box result on ImageNet (50000 testing samples) under PGD and BPDA + PGD.

2 Preliminaries

2.1 Adversarial samples

We focus on adversarial samples on DNNs for classification, with final layers as softmax layers. Given an input $x$, the network output is represented as a vector function $\{F_i(x)\}_i$ with the predicted label $y = \arg\max_i F_i(x)$. A sample $x'$ is defined as an adversarial sample if $\arg\max_i F_i(x') \neq y$, where $y$ is the ground-truth label and $x'$ is close to the original $x$ under a certain distance metric.

*Backward Pass Differentiable Approximation, an effective attack that breaks 5 gradient-masking-based defenses in ICLR2018 and CVPR2018 (Athalye et al., 2018).*
Fast Gradient Sign Method (FGSM)  Fast Gradient Sign Method (FGSM) is a single-step adversarial attack proposed by Szegedy et al. (2013). FGSM performs a single step update on the original sample $x$ along the direction of the gradient of the loss function $L(x, y; \theta)$ w.r.t. $x$. The update rule can be formally expressed as

$$x' = \text{clip}_{[v_{min}, v_{max}]} \{ x + \epsilon \cdot \text{sign}(\nabla_x L(x, y; \theta)) \},$$

where $\epsilon$ controls the maximum $l_\infty$ perturbation of the adversarial samples; $[v_{min}, v_{max}]$ is the image value range and $\text{clip}_{[a, b]}(\cdot)$ function forces its input to reside in the range of $[a, b]$.

Project Gradient Descent (PGD)  Projected Gradient Descent (PGD) is the strongest iterative variant of FGSM. In each iteration, PGD follows the update rule: $x'_{l+1} = \text{clip}_{[a, b]} \{ \text{FGSM}(x'_{l}) \}$, where $\text{FGSM}(x'_{l})$ represents an FGSM update of $x'_{l}$ as in (1). The outer clip function $\text{clip}$ keeps $x'_{l+1}$ within a predefined perturbation range. PGD can also be interpreted as an iterative algorithm to solve the optimization problem: $\max_{x': ||x' - x||_\infty < \alpha} L(x', y; \theta)$.

Madry et al. (2017) observe that the local maxima of the cross-entropy loss found by PGD with $10^5$ random starts are distinctive, but all have similar loss values, for both naturally- and adversarially-trained networks. Inspired by this concentration phenomena, they suggest that PGD is a universal adversary among all the first-order adversaries, i.e., attacks only relying on first-order information. It is worth noting that PGD is a stronger attack than Basic Iterative FSGM because the clip function enables PGD to iterate for more steps with an appropriate step size.

Obfuscated gradients  Athalye et al. (2018) proposed that many recent defense methods that yield obfuscated gradients are seemingly but not actually robust against iterative optimization-based white-box attacks. Obfuscated gradients refer to gradients that are nonexistent, non-deterministic, vanishing or exploding, thus using the above gradient-based algorithms to directly evaluate those defense methods is inappropriate. Three strategies, namely Backward Pass Differentiable Approximation (BPDA), Expectation over Transformation (EOT), and Reparameterization, are proposed in (Athalye et al., 2018) to generate approximate gradients for obfuscated gradients-based defenses appearing in ICLR-2018 (Buckman et al., 2018; Ma et al., 2018; Guo et al., 2017; Dhillon et al., 2018; Xie et al., 2017; Song et al., 2017; Samangouei et al., 2018; Na et al., 2017), which are able to further attack all those defenses. The only survived defense is PGD adversarial training.

2.2 Adversarial Training

Min-max objective  Adversarial training is a defense against adversarial samples first proposed by Goodfellow et al. (2014), which aims to improve the robustness of a network by training with adversarial samples. The objective of adversarial training can be formulated as a min-max problem:

$$\min_{\theta} \max_{x': D(x, x') < \epsilon} L(x', y; \theta).$$

The inner maximization problem aims to find an adversarial sample $x'$ that yields a high loss. The outer minimization is to find model parameters to minimize a loss given on adversarial samples.

PGD adversarial training  The proposition that PGD adversary is a first-order universal adversary indicates that PGD-adversarially-trained models should yield robustness against all first-order $l_\infty$ adversaries [Madry et al., 2017] Therefore, Madry et al. (2017) propose to implement the above min-max objective with a PGD adversary to solve the inner adversarial problem, called PGD adversarial training. Notably, a lot of recent work shows that PGD adversarial training is currently the most successful defense method, which maintains an 88.79% accuracy on MNIST ($l_\infty$ perturbation of $\epsilon = 0.3/1.0$) and a 44.71% accuracy on CIFAR-10 ($l_\infty$ perturbation of $\epsilon = 8.0/255.0$) until now (Carlini et al., 2017; Athalye et al., 2018; Zheng et al., 2018).

3 Defense via Differentiable Soft Quantization

We first introduce the concept of hard quantization, then extend it to soft quantization—a differential version used in our proposed framework.
Hard quantization  Hard quantization is a technique to discretize the input space. Specifically, given any test input, hard quantization converts each pixel value into a $b$-bit integer before feeding the input into a network. Hard quantization was first proposed by Xu et al. (2017) as a feature squeezing method to detect adversarial samples. Cai et al. (2018); Rakin et al. (2018) tried to employ hard quantization in adversarial training to improve its defensive effectiveness against PGD. However, since hard quantization is non-differential, the defense incorporating hard quantization will generate infinite gradients, and thus can not be directly evaluated by gradient-based attack algorithms. Recent work also shows that on the one hand, binarization (i.e., 1-bit hard quantization) can provide a simple robust model against $l_\infty$ attacks on MNIST; on the other hand, a naturally-trained network incorporating hard quantization is vulnerable to an adaptive CW-L2 attack (He et al., 2017). A similar discretization method proposed in (Buckman et al., 2018) is also shown vulnerable to BPDAttack (Athalye et al., 2018). Therefore, the impact of hard quantization on network robustness is still full of uncertainty.

Soft-quantization network  We propose a differentiable soft-quantization layer, whose behavior approaches hard quantization when $\alpha$ is large enough but always yields finite gradients that can be flattened by noisy training (detailed in Section 4), leading to more robust defensive ability. Specifically, a K-level soft-quantization function (layer) is defined as

$$S(x) = \frac{1}{K} \sigma \left( \alpha \left( x - \frac{2k + 1}{2K} \right) \right) + \frac{k}{K}, \quad \text{where} \quad k = \min_{i \in \{0, \ldots, K-1\}} \{ i : \frac{i}{K} < x < \frac{i+1}{K} \},$$

(3)

where $\alpha$ is a hyper-parameter, $\sigma(\cdot)$ is the sigmoid function. This soft-quantization function is applied element-wise when the input $x$ is a vector, and is defined with input value ranging between $[0, 1]$. For other arbitrary image-value ranges $[v_{min}, v_{max}]$, the soft-quantization function can be equally transformed into $v_{min} + (v_{max} - v_{min})S(x)$. Note larger $\alpha$ makes the soft-quantization function closer to a hard quantization function. An example of soft quantization is plotted in Figure 2 (left).

The soft-quantization layer can be normally embedded as an extra layer after the input layer of a network. The network robustness can also be normally evaluated by gradient-based attack algorithms due to the differentiability. We call such an extended network soft-quantization network. Empirically we found that the performance of a naturally-trained network with our proposed soft-quantization layer is comparable to the performance of a PGD adversarially trained network on several standard datasets. Although this observation sounds inconceivable, we show formally in the next section that by injecting appropriate noise in the training stage, a naturally-trained soft-quantization network achieves a similar objective as PGD adversarial training.

4  WHY DOES SOFT-QUANTIZATION & NOISY-TRAINING WORK?

In this section, we show the combination of soft-quantization & noisy-training is an approximation to the min-max objective in Eq. 3 which explains underlying intuitions why our strategy works.

4.1  PGD-BASED APPROXIMATION OF THE MIN-MAX OBJECTIVE

According to the PGD update rule, when ignoring the clip function, a first-order approximation of the increment of the loss under PGD can be derived as

$$\mathcal{L}(x^{t+1}, y; \theta) - \mathcal{L}(x^t, y; \theta) = \nabla_{x^t} \mathcal{L}(x^t, y; \theta) \cdot \epsilon \cdot \text{sign}(\nabla_{x^t} \mathcal{L}(x^t, y; \theta)) = \epsilon \cdot ||\nabla_{x^t} \mathcal{L}(x^t, y; \theta)||_1,$$

where the last equation follows by the definition of the 1-norm. Thus, the approximate maximum $\mathcal{L}(x^t, y; \theta)$ found by a $N$-step PGD can be expressed as:

no random start:  $\mathcal{L}(x^t, y; \theta) \approx \mathcal{L}(x, y; \theta) + \sum_{t=0}^{N-1} \epsilon \cdot ||\nabla_{x^t} \mathcal{L}(x^t, y; \theta)||_1 \triangleq \tilde{\mathcal{L}}(x^t, y; \theta).$  \hfill (4)

In order to enrich adversarial samples, a variant called “PGD with random starts” adds random noise to the input before applying PGD. Because of the clip function, in most cases, $\mathcal{L}(x^t, y; \theta)$ is upper bounded by $\tilde{\mathcal{L}}(x^t, y; \theta)$. Since the inner maximization of PGD adversarial training is approximately
Consequently, according to Hölder’s inequality, the $\|\nabla x L(x, y; \theta)\|_1$ can be approximately rewritten as (no random start)
\[
\min_\theta L(x, y; \theta) + \sum_{t=0}^{N-1} \epsilon \cdot \|\nabla x L(x^t, y; \theta)\|_1. \tag{5}
\]

As shown in Figure 1 with random starts, $\{x^t\}$ can be considered as arbitrary samples in the data space. As a result, the approximate objective (5) can be interpreted as simultaneously minimizing $L(x, y; \theta)$ w.r.t. the model parameter $\theta$ and $\|\nabla x L(x, y; \theta)\|_1$ throughout the whole data space. The first half of this approximate objective, $L(x, y; \theta)$, can be achieved by natural/noisy training; For the term related to 1-norm minimization, we show in the following that it can be achieved by soft-quantization & noisy training, leading to similar defense behavior as PGD adversarial training.

**Remark 1** [Goodfellow et al. (2017)] found that adversarial training accidentally performs gradient masking, which can be explained by our derived gradient-masking objective (5). Actually, this objective is intuitively correct for PGD adversarial training, in the sense that for a defense model, it is expected not only to perform well on natural samples (the $L(x, y; \theta)$ term), but also to be robust to adversarial samples. The later is achieved by the 1-norm term as nearly-zero $\|\nabla x L(x, y; \theta)\|_1$ prevents generations of adversarial samples via gradient-based attack algorithms.

### 4.2 An approximate solution with a soft-quantization network

We represent a soft-quantization network as
\[
y_{\text{pred}} = F(S(x)), \tag{6}
\]
where $S(\cdot)$ is the soft-quantization function and $F(\cdot)$ is a standard base network. With a cross-entropy loss, written as $L(F(S(x)); y)$, the gradient w.r.t. the input $x$ is calculated by the chain rule as
\[
\nabla x L(x, y; \theta) = \frac{\partial L(F; y)}{\partial F} \frac{\partial F(S)}{\partial S} \frac{\partial S(x)}{\partial x}. \tag{7}
\]
Consequently, according to Hölder’s inequality, the $l_1$ norms are upper bounded as:
\[
\|\nabla x L(x, y; \theta)\|_1 \leq \|\frac{\partial L(F; y)}{\partial F}\|_{\infty} \|\frac{\partial F(S)}{\partial S}\|_1 \|\frac{\partial S(x)}{\partial x}\|_1. \]
Thus, to control the 1-norm $\|\nabla x L(x, y; \theta)\|_1$, it suffices to control either $\|\frac{\partial S(x)}{\partial x}\|_1$ or $\|\frac{\partial L(F; y)}{\partial F}\|_{\infty} \|\frac{\partial F(S)}{\partial S}\|_1$, which is discussed in the following.

**Controlling $\|\frac{\partial S(x)}{\partial x}\|_1$ with bounded $\|\frac{\partial L(F; y)}{\partial F}\|_{\infty} \|\frac{\partial F(S)}{\partial S}\|_1$** We first consider the case that if $\|\frac{\partial S(x)}{\partial x}\|_1$ can be controlled small, $\|\nabla x L(x, y; \theta)\|_1$ from our soft-quantization network defined in Eq. (5) would also be small. According to Eq. (6)
\[
\frac{\partial S(x)}{\partial x} = \frac{\alpha}{K} \sigma(\alpha(x - \frac{2k + 1}{2K})) (1 - \sigma(\alpha(x - \frac{2k + 1}{2K}))) \tag{8}
\]
where $k = \min_{i \in \{0, \ldots, K-1\}} i : \frac{i}{K} < x < \frac{i+1}{K}$

Note (8) is typically small due to the saturation property of the sigmoid function. As an illustration, we plot the soft-quantization function and its gradient in Figure 2 for $K = 8$ and $\alpha = 1000$, which shows that $\frac{\partial S(x)}{\partial x}$ is nearly zero in most areas of the whole space. As a result, $\|\frac{\partial L(F; y)}{\partial F}\|_{\infty} \|\frac{\partial F(S)}{\partial S}\|_1$ close to zero for most $x$ since $\|\frac{\partial L(F; y)}{\partial F}\|_{\infty} \|\frac{\partial F(S)}{\partial S}\|_1$ is bounded. Note there are some techniques to control $\|\frac{\partial L(F; y)}{\partial F}\|_{\infty} \|\frac{\partial F(S)}{\partial S}\|_1$, e.g., via a weight-decay scheme which reduces model complexity to prevent abrupt changes in objective functions.

**Controlling $\|\frac{\partial L(F; y)}{\partial F}\|_{\infty}$ in the sharp area of $\frac{\partial S(x)}{\partial x}$** As shown in Figure 2 (right), there exists area where the gradient $\frac{\partial S(x)}{\partial x}$ is sharp. In order to make $\|\nabla x L(x, y; \theta)\|_1$ small, one also

\[
\min_\theta L(x, y; \theta) + \sum_{t=0}^{N-1} \epsilon \cdot \|\nabla x L(x^t, y; \theta)\|_1. \tag{5}
\]
There are two cases: I) After training for a certain number of steps, the samples far from the sharp areas would not contribute too much for the training. This is because their randomly-uniformly-perturbed samples are most likely in the zero-gradient area, and thus they tend to be very close to the original samples after soft-quantization. Consequently, according to the gradient (7), the network would not adjust for those noisy samples as long as the original samples are correctly classified. II) For the natural samples near/in the sharp areas, it is very likely that their randomly-uniformly-perturbed samples are still uniformly distributed around the sharp areas. In the following we show by noisy training, gradients of the objective on these samples will also be small. For any perturbed samples are most likely in the zero-gradient area, and thus they tend to be very close to the original samples after soft-quantization. Consequently, according to the gradient (7), the network would not contribute too much for the training. This is because their randomly-uniformly-perturbed samples are still uniformly distributed around the sharp areas. In the following we show by noisy training, gradients of the objective on these samples will also be small. For any perturbed samples \( x' \) generated from the same natural sample near/in the sharp areas, we assume there is an \( x_0 \) such that \( F(S(x_0)) \approx y \), then the cross-entropy between \( y \) and \( F(S(x')) \) can be expressed as

\[
\mathcal{L}(F(S(x')), y) = \mathcal{L}(y, y) + \{\mathcal{L}(F(S(x')), y) - \mathcal{L}(y, y)\} 
\approx 0 + \{\mathcal{L}(F(S(x')), y) - \mathcal{L}(F(S(x_0)), y)\} = \int_{x_0}^{x'} \nabla_x S(x, y; \theta) \cdot dx
\]

The training minimizes \( \mathcal{L}(F(S(x')), y) \), leading to small \( \nabla_x \mathcal{L}(x, y; \theta) \). A detailed proof is given in Appendix A.

**Remark 2** Using noisy samples is similar to stability training (Zheng et al. 2016), except that we do not include the additional KL-divergence between the network outputs of natural samples and their noisy samples in the objective. We adopt this simply because of its lower computational cost.

### 4.3 Discussion on the choice of soft-quantization parameter

A soft-quantization layer has two hyper-parameters as shown in Eq. (3), i.e., \( \alpha \) and level \( K \). Parameter \( \alpha \) controls the sharpness of quantization and the width of each sharp area. In the extreme case of \( \alpha = +\infty \), the soft-quantization function reduces to hard quantization, yielding infinite gradients in a subspace of measure 0. In this case, sharp areas are small, but the infinite gradients would cause training instability. Therefore, in practice, an appropriate \( \alpha \) should be selected. In addition, a \( K \)-level quantization would induce \( K^n \) sharp areas in the whole space, where \( n \) is the dimension of \( x \). Thus, a small but appropriate \( K \) should be chosen, as a large \( K \) would increase the sharpness intensity while a too small \( K \) would deteriorate the input too much. For MNIST, a good setting is to set \( K = 1 \), equivalent to binarization if \( \alpha = +\infty \). For CIFAR-10, a good setting we found is to set \( K = 2 \), and for ImageNet, our setting is \( K = 8 \). More details are provided in the Appendix.

### 5 Experiments

We conduct extensive experiments to compare our defense framework with the state-of-the-art defense, i.e., PGD adversarial training, on three standard datasets: MNIST, CIFAR-10 and ImageNet. For the first time, we successfully train a defense model on the largest ImageNet dataset, which is computationally too expensive for PGD adversarial training. We detail our experiments mainly under two white-box settings.

**Adversarial setting** We consider two white-box settings where the adversaries have full access to networks including their parameters. In the first setting, the noisily-trained soft-quantization network is directly evaluated by PGD, i.e., adversarial samples are directly crafted from the soft-quantization network by the PGD algorithm. In the second setting, due to the gradient masking (vanishing) effect caused by our soft-quantization layer, we evaluate our model against the BPDA adversary proposed in (Athalye et al. 2018), which breaks many recent gradient-masking-based defenses including 5...
white-box defenses in ICLR2018 and CVPR2018 (Athalye et al. [2018] Athalye & Carlini [2018]. Since in our proposed network $F(S(x))$, $S(x)$ is the major cause of gradient masking, according to (Athalye et al. [2018]), we substitute $S(x)$ with $x$ and craft adversarial samples from $F(x)$ using PGD on cross-entropy and $CW_\infty$ losses. It is worth noting that the Expectation over Transformation (EOT) and Reparameterization methods proposed in (Athalye et al. [2018]) are not applicable to our model, since we do not incorporate any randomization or optimization loop in the testing stage of our model. Besides, for Natural and PGD adversarial training, the BPDA adversary is equivalent to PGD attack, since there is no transformation $g(\cdot)$ that mainly causes gradient masking in Natural or PGD adversarial training (Athalye et al. [2018]). In the following, we denote a naturally-trained network as Natural, a PGD adversarially-trained model as PGD-Defense, a Naturally-trained Soft-Quantization network as SQ, and a Noisily-trained Soft-Quantization network as NSQ.

**MNIST** In this experiment, we adopt a basic network as a convolutional neural network (CNN) with two convolutional layers and a fully connected layer. A soft-quantization layer with $K = 1$ and $\alpha = 1000$ is embedded as a soft-quantization network, which is trained with natural samples injected with random uniform noise in the range of $[-0.3/1.0, 0.3/1.0]$. The naturally-trained model and PGD adversarially-trained model for comparisons are adopted from MIT MadryLab. The classification accuracies of the three methods under 100-step PGD and BPDA + PGD are shown in Figure 3. With only PGD attacks, SQ and NSQ even slightly outperform PGD-Defense. Specifically, the accuracy of our NSQ remains $98.49\%$, nearly $6\%$ higher than the accuracy of PGD-Defense (with $l_\infty$ perturbations of $\epsilon = 0.3/1.0$). When considering gradient masking, the classification accuracy of NSQ remains $87.32\%$, only $5\%$ lower than the accuracy of PGD-Defense. Interestingly, when the $l_\infty$ perturbations are smaller than $0.1/1.0$, NSQ even outperforms PGD-Defense under the BPDA attack. Notably, to achieve such robustness against PGD and BPDA adversaries, our NSQ only takes about $5\text{ mins}$ with a TITAN V GPU for a 50000-iteration training procedure with minibatch size 100, while PGD-adversarial training takes about $2\text{ hours}$, achieving a 24X speed-up.

**CIFAR-10** We use a residual CNN consisting of five residual units and a fully connected layer as the basic network. A soft-quantization network with $K = 2$ and $\alpha = 100 \times 255$ soft-quantization layer is adopted, which is trained by natural samples injected with $[-16.0/255.0, 16.0/255.0]$ random uniform noise. Again, the naturally-trained model and PGD adversarially-trained model are adopted from MadryLab. The accuracies of all the models under 20-step PGD and BPDA are shown in Figure 4. Specifically, 20-step PGD and BPDA attacks reduce the accuracy of NSQ to $78.01\%$ and $34.43\%$ respectively (with $l_\infty$ perturbations of $\epsilon = 8.0/255.0$). To the best of our knowledge, this is the second-best white-box result on CIFAR-10 (only worse than PGD adversarial training), considering all defenses proposed in ICLR2018 and CVPR2018. In terms of the running time, our NSQ only takes $9\text{ hours}$ training for 80000 iterations with minibatch size set to 128, while PGD-adversarial training takes more than $3\text{ days}$ on a TITAN V GPU.

**ImageNet** For the large ImageNet dataset, we adopt the widely-used Inception_v3 model as the basic network (Szegedy et al. [2016]). A soft-quantization network with $K = 8$ and $\alpha = 10000$ for our model, $g(\cdot)$ is the soft-quantization layer $S(\cdot)$.

1. [https://github.com/MadryLab/mnist_challenge](https://github.com/MadryLab/mnist_challenge)
2. In the implementation with a pixel-value range of $[0, 255]$, $\alpha$ is set to 100. This corresponds to $\alpha = 100 \times 255$ in (3) if the pixel values are normalized to $[0, 1]$
3. [https://github.com/MadryLab/cifar10_challenge](https://github.com/MadryLab/cifar10_challenge)
is used, which is fine-tuned from a pre-trained Inception_v3 model with noisy natural samples of $[-8.0/255.0 \times 2.0, 8.0/255.0 \times 2.0]$ random uniform noise (All the images are normalized to $[-1.0, 1.0]$ in the preprocessing stage). Fine-tuning such a model takes less than 2 days on a TITAN GPU. Code for implementing PGD attack is adopted from (Kannan et al., 2018). To our knowledge, there are no public PGD adversarial-trained models except only a few one-step adversarial trained models for this large and high-resolution dataset (Kurakin et al., 2016; Tramer et al., 2017) due to computational infeasibility. Specifically, we observe that a single run of 10-step PGD on the ImageNet testing dataset needs about 2 hours on a TITAN GPU. Since MadryLab’s secret CIFAR-10 model uses 128 \times 70000 adversarial samples for training, and PGD adversarial training on ImageNet should need at least 100 times more due to its high resolution and large data size, thus an initial estimation of the time for PGD adversarial training on ImageNet is over 1500 days on one TITAN GPU. As a result, we were not able to run the PGD adversarial trained model for comparison. Our defense results are shown in Table 1, which suggest that with little sacrifice of the accuracy compared to natural training on the clean images (no perturbation), our model obtains significant defense accuracies under 4-pixel perturbation white-box PGD and BPDA attacks (enhance the Inception_v3 model by 17% top-1 and 55% top-5 accuracies).

6 Discussion and Conclusion

Discussion Similar to PGD adversarial training, our defense method only focuses on first-order $l_{\infty}$ attacks. Both PGD adversarial training and our method seem to be vulnerable to adversarial samples with large $l_{\infty}$ perturbations such as CW-L2 (Carlini & Wagner, 2017) and EAD (Sharma & Chen, 2018). It seems that our method is still not very optimal in terms of defense accuracy, leaving rooms for improvements in two directions: I) The current defense layer is a simple soft-quantization layer. Smarter design of similar defense layers based on the pixel-value statistics might lead to more robust defensive networks. II) Only noisy-natural samples are used to train the soft-quantization networks. A straightforward yet efficient way to improve the network robustness is to incorporate FSGM adversarial samples in the training stage, whose generation cost is much cheaper than that of PGD adversarial samples.

Conclusion We avoid the adversarial-sample generation in PGD adversarial training by proposing an alternative training scheme with only noisy-natural samples. We achieve the goal by reformulating the min-max objective of adversarial training as approximately minimizing the original network loss plus additional $l_1$ norms of gradients in the whole data space. To alternatively achieve this objective, we embed a soft-quantization layer into a basic network such that it yields zero-gradients in most areas of the data space, and train the soft-quantization network with noisy natural-samples to flatten the remaining sharp-gradient areas. Due to the gradient masking effect caused by our approach, we evaluate our model against white-box PGD and BPDA + PGD. Extensive evaluations demonstrate that our training paradigm is comparable to PGD adversarial training in most cases.
while obtaining significant speed-ups, indicating the possibility of learning a robust model with much less effort using only noisy-natural samples.

A Proof for Equation [9]

We divide the cross-entropy between $F(S(x'))$ and $y$ into two terms by adding and subtracting $\mathcal{L}(y, y)$ as

$$
\mathcal{L}(F(S(x')), y) = \mathcal{L}(y, y) + \{\mathcal{L}(F(S(x')), y) - \mathcal{L}(y, y)\}. 
$$

(10)

The first term is 0 since

$$
\mathcal{L}(y, y) = -\sum_{i=1}^{n} y_i \log y_i \geq 0. \text{ because } y_i = 0 \text{ or } 1.
$$

Since $F(S(x))$ is the output of our soft-quantization network given input as $x$, $\mathcal{L}(F(S(x')), y)$ is exactly $\mathcal{L}(x', y; \theta)$. Therefore, the second term can be rewritten as

$$
\mathcal{L}(F(S(x')), y) - \mathcal{L}(y, y) \approx \mathcal{L}(F(S(x')), y) - \mathcal{L}(F(S(x_0)), y)
$$

(11)

$$
= \mathcal{L}(x', y; \theta) - \mathcal{L}(x_0, y; \theta) = \int_{x_0}^{x'} \nabla_x \mathcal{L}(x, y; \theta) \cdot dx
$$

B Parameter Study on CIFAR-10

In this section, we study the impacts of two major hyperparameters in our framework, i.e., $K$ and $\alpha$, on the robustness of NSQ against the BPDA adversary. Because I) MNIST dataset is too peculiar in terms of its simple binarization (i.e., $K = 1$ and $\alpha = +\infty$) solution for defense as discussed in section 2.2 [Tramèr et al., 2017]; II) it is computationally infeasible for extensive evaluations on ImageNet, we therefore only conduct experiments on CIFAR-10 for parameter study. We plot the classification accuracies of NSQs with different $K$ and $\alpha$ in Fig. 6 and 7. As we can see, $K$ mainly affects the robustness of NSQ against white-box adversaries. Specifically, increasing $K$ will enhance the clarity of the soft-quantized images as shown in Appendix C and thus increase the classification accuracy on clean images, but simultaneously induce more sharp areas, and therefore deteriorate network robustness. We also observe that increasing $\alpha$ from $100 \times 255$ to $10000 \times 255$ will also slightly degrade the robustness of NSQ, which can serve as weak evidence for the proposition that the infinite gradients caused by hard quantization might lead to training instability. Considering all of the above, $K = 4$ and $\alpha = 100 \times 255$ is a good choice for NSQ.

Figure 5: CIFAR-10: classification accuracy of different K-level soft-quantization networks under 20-step BPDA + PGD on cross-entropy and $CW_{\infty}$ loss ($\alpha = 1 \times 255$).
Figure 6: CIFAR-10: classification accuracy of different K-level soft-quantization networks under 20-step BPDA + PGD on cross-entropy and $CW_{\infty}$ loss ($\alpha = 100 \times 255$).

Figure 7: CIFAR-10: classification accuracy of different K-level soft-quantization networks under 20-step BPDA + PGD on cross-entropy and $CW_{\infty}$ loss ($\alpha = 10000 \times 255$).

C VISUALIZATION OF SOFT-QUANTIZED IMAGES

The images soft-quantized by our proposed soft-quantization layer with different $K$ and $\alpha$ are visualized in Fig. 8, 9, 10, 11, 12 and 13. As we can see, soft-quantization with appropriate $K$ and $\alpha$ rectifies redundant information that leaves more space for an adversary to search, but retains the sketch information that is useful for classification. As $K$ increases, the soft-quantized images look more like the original images, then the soft-quantization network will be more similar to the basic network and thus more vulnerable to white-box adversaries. Hence, a small $K$ is preferred. However, if $K$ is too small, especially for datasets of large diversity like ImageNet, the remaining information after soft-quantization will be too limited for the classification task, thus the accuracy of NSQ on both clean and adversarial samples will decrease. Therefore, in practice, selecting a small but appropriate $K$ is crucial to establishing and training a successful NSQ.
Figure 8: MNIST: soft-quantization level $K = 1$. From left to right, up to down: original images, $\alpha = 10$, $\alpha = 1000$, $\alpha = 100000$
Figure 9: CIFAR-10: soft-quantization level $K = 2$. From left to right, up to down: original images, $\alpha = 1 \times 255$, $\alpha = 100 \times 255$, $\alpha = 10000 \times 255$
Figure 10: CIFAR-10: soft-quantization level $K = 4$. From left to right, up to down: original images, $\alpha = 1 \times 255$, $\alpha = 100 \times 255$, $\alpha = 10000 \times 255$
Figure 11: ImageNet: from left to right, from up to down: original images, $K = 4$ $\alpha = 1$, $K = 4$ $\alpha = 10000$, $K = 4$ $\alpha = 1000000$. 
Figure 12: ImageNet: from left to right, from up to down: original images, $K = 8 \alpha = 1$, $K = 8 \alpha = 10000$, $K = 8 \alpha = 100000$
Figure 13: ImageNet: from left to right, from up to down: original images, $K = 16 \alpha = 1$, $K = 16 \alpha = 10000$, $K = 16 \alpha = 1000000$
