Brief segments of neurophysiological activity enable individual differentiation

Jason da Silva Castanheira1,3, Hector Domingo Orozco Perez2,3, Bratislav Misic1✉ & Sylvain Baillet1✉

Large, openly available datasets and current analytic tools promise the emergence of population neuroscience. The considerable diversity in personality traits and behaviour between individuals is reflected in the statistical variability of neural data collected in such repositories. Recent studies with functional magnetic resonance imaging (fMRI) have concluded that patterns of resting-state functional connectivity can both successfully distinguish individual participants within a cohort and predict some individual traits, yielding the notion of an individual’s neural fingerprint. Here, we aim to clarify the neurophysiological foundations of individual differentiation from features of the rich and complex dynamics of resting-state brain activity using magnetoencephalography (MEG) in 158 participants. We show that akin to fMRI approaches, neurophysiological functional connectomes enable the differentiation of individuals, with rates similar to those seen with fMRI. We also show that individual differentiation is equally successful from simpler measures of the spatial distribution of neurophysiological spectral signal power. Our data further indicate that differentiation can be achieved from brain recordings as short as 30 seconds, and that it is robust over time: the neural fingerprint is present in recordings performed weeks after their baseline reference data was collected. This work, thus, extends the notion of a neural or brain fingerprint to fast and large-scale resting-state electrophysiological dynamics.
Understanding the biological nature of individual traits and behavior is an overarching objective of neuroscience research\(^4\). The increasing availability of large, openly available datasets and advanced computational tools propels the field toward this aim\(^3\). Yet, with bigger and deeper data volumes, neuroscientists are confronted with a paradox: while big-data neuroscience approaches the realm of population neuroscience, we remain challenged by understanding how individual data variability echoes the singularity of the self\(^3\)\(^2\)\(^8\)\(^9\).

This epistemological question has become particularly vivid with recent research showing that individuals can be differentiated from a cohort via their respective neural fingerprints derived from structural magnetic resonance imaging (MRI)\(^1\)\(^3\)\(^1\)\(^4\), functional MRI (fMRI)\(^1\)\(^2\)\(^6\)\(^8\)\(^9\), electroencephalography (EEG)\(^1\)\(^7\)\(^9\), or functional near-infrared spectroscopy (fNIRS)\(^2\)\(^0\). Neural fingerprints are associated with individual differences in intelligence test performance, working memory, and attention\(^2\)\(^1\)\(^2\)\(^3\)\(^4\)\(^5\)\(^6\). Most published work so far is methodologically based on inter-individual similarity measures of functional connectivity—understood as statistical dependencies between ongoing signals across brain regions in task-free awake conditions\(^2\)\(^5\)\(^2\)\(^6\). As defining features of neural fingerprints, yet, the indirect coupling between hemodynamic and neural brain signaling interrogates the neurophysiological nature of brain fingerprints.

In electrophysiology, ongoing brain dynamics at rest are rich and complex\(^2\)\(^6\) and have long been considered a nuisance, a by-product of neural noise\(^2\)\(^7\)\(^9\). Recent experimental evidence, spurred by systems neuroscience models, indicates that spontaneous brain activity captured using electrophysiological techniques expresses similar resting-state connectomes as fMRI and influences conscious, sensory processes\(^3\)\(^0\)\(^3\)\(^1\)\(^3\)\(^2\). Ongoing neurophysiological activity varies considerably between individuals and across the lifespan. One instance is the inter-individual variability of prominent features of human brain neurophysiological activity, such as the alpha rhythm (8–12 Hz) peak frequency\(^3\)\(^3\)\(^3\)\(^4\). Previous EEG fingerprinting work was restricted to scalp data, and therefore, provided limited neuroanatomical insight\(^1\)\(^7\)\(^1\)\(^8\)\(^9\). Another distinctive aspect of electrophysiology is the contamination of recordings by artifacts of different natures including environment and instrument noise, muscle contractions, eye and head movements, which can be distinctive of individuals and can bias fingerprinting with non-neural signal features. Overall, the unique signature components of fast neurophysiological brain dynamics across individuals remain unchartered.

In this work, we use resting-state recordings of magnetoencephalography MEG\(^3\)\(^5\) from a cohort of participants to identify neurophysiological features of individual differentiation. We both derive measures of functional organization (i.e., functional connectivity) inspired by fMRI neural fingerprinting approaches, and spectral signal markers that are proper to the wider frequency spectrum of brain signaling accessible to neurophysiological data. Our data exemplify that individual differentiation based on connectome features is akin to previous fMRI reports, and further demonstrate that we can equally differentiate individuals with simpler measures of the spatial distribution of neurophysiological spectral signal power. In addition, individual differentiation is achieved with recordings as short as 30 seconds and is robust across recordings preformed weeks after their baseline reference data was collected. Together, our work extends the notion of a neural fingerprint to the fast and large-scale resting-state dynamics of electrophysiology.

**Results**

We used MEG data from 158 participants available from the Open MEG Archives OMEGA\(^6\). Data collected on multiple days were available for a subset of these participants (\(N = 47\); mean duration between consecutive sessions: 201.7 days; Fig. 1). The participants were both healthy and patient volunteers (ADHD and chronic pain) spanning in age from 18–73-years old (see Supplemental Information). T1-weighted structural MRI volumes were available from OMEGA for all participants and were used to produce source maps of resting-state brain activity\(^3\)\(^6\). We derived several neurophysiological signal features from MEG brain source time series summarized within the Desikan-Killiany atlas—68 regions of interest (ROIs) parcellating the entire cortical surface\(^3\)\(^7\). The MEG features comprised powerspectral-density estimates (PSD) within each of the 68 ROIs\(^3\)\(^7\), and 68 × 68 functional connectomes (FC) between these ROIs. The approach is illustrated in Fig. 1 and the FC and PSD methodological details are provided in “Methods”.

Participant differentiation was performed across pairs of MEG data segments taken from either the same (within-session differentiation) or a repeated session (between-session differentiation) using two distinct datasets (Fig. 1a) and based either on FC or PSD features (referred as connectome and spectral fingerprinting, respectively). The within-session challenge with longer data segments was considered to assess the baseline performances of the MEG fingerprinting approaches proposed. The more challenging situations developed in the present report concern individual differentiation from shorter 30 s time segments within or between recording sessions. For each pair of participants, the Pearson’s correlation coefficient between their respective features (i.e., FC or PSD) was the corresponding entry in the group correlation matrix (see Supplemental Information). The fingerprinting procedure for each participant proceeded via a lookup operation through the corresponding row of the correlation matrix; the index of the column featuring the largest correlation coefficient determined the predicted (anonymous) identity of the individual in the cohort. Thus, if a given individual’s data features from the first dataset were most correlated to the data features from their second dataset, the individual would be correctly differentiated. Note that taking the maximum along the rows or columns simply switches which dataset is used for deriving the differentiation features (e.g., differentiating individuals using dataset 1 from features derived from dataset 2; results for all possible combinations of datasets are reported in Supplemental Information). The overall accuracy of the neural fingerprinting procedure was computed as the proportion of participants correctly differentiated. We ran three types of differentiation challenges: within-session fingerprinting consisted of the differentiation between 158 participants (i.e., the datasets were from same-day recordings split in half); a between-session differentiation challenge for a subset of 47 participants for whom the datasets were from two separate days; and a between-session differentiation using considerably shorter data segments (30 s) (Fig. 1a). We conducted the differentiation challenges using either broadband MEG data or band-limited versions within the typical frequency bands used in neurophysiology. We also derived a differentiability score for every participant, which indicates the saliency of the differentiation of any given individual in the tested cohort (see “Methods”).

**Within-session connectome and spectral data differentiate individuals.** Within-session MEG connectome and spectral fingerprinting achieved 94.9% and 96.2% participant differentiation accuracy, respectively (Fig. 2). This outcome was robust to switching datasets (Supplemental Information). While previous work\(^1\)\(^2\) reported that data reduction strategies improved fingerprinting performances, this was not the case with our data. Data reduction strategies only marginally improved individual differentiation, as explained in Supplemental Information.
Therefore, tested whether such individual information unrelated to respective head positions in the MEG sensor array and individual brain activity contributed substantially to individual differentiation from MEG source maps. We found that differentiation performances of imaging kernels as those used for each session pseudo brain maps of empty-room sensor data using the same in an identical fashion to participants brain data. We produced data. The implication is that imaging kernels designs are based on these results against variables of nointerest and possible confounds.

Fig. 1 Neural fingerprinting analysis pipeline and definition of differentiability. a Schematic of exemplar MEG data divided into datasets used in each of the specified differentiation challenges. (i) Within-session challenge: the session data was split in half to generate segments of equal duration; (ii) Between-sessions challenge: differentiation was performed using data recorded on two separate days; (iii) Between-session shortened challenge: data recorded on two different days were split into three 30 s segments. b Schematic of the data analysis pipeline: source modeling was first performed before extracting features from each region of the Desikan-Killiany atlas. These features were vectorized and subsequently used to fingerprint individuals, yielding a participant correlation matrix. c Features for the between-session challenge from an exemplar subject. Left panel depicts amplitude envelope correlation (AEC) functional connectivity matrices across two datasets; both matrices feature the Pearson correlation coefficients between all 68 regions of the Desikan-Killiany atlas. Right panel plots the power spectrum density estimates from two regions of the atlas, across two datasets. d Differentiability was derived for each participant as the z-score of their correlation to themselves, relative to the correlation between themselves and the rest of the cohort. A participant with a high correlation to themselves and low correlations to others was qualified as highly differentiable. An individual highly correlated to both themselves and many others in the cohort was qualified as less differentiable.

We also ran the differentiation procedure for each of the typical frequency bands of electrophysiology to understand whether the expression of certain ranges of brain rhythms would be more specific of individual differentiation. We bandpass filtered MEG signals in the delta (1–4 Hz), theta (4–8 Hz), alpha (8–13 Hz), beta (13–30 Hz), gamma (30–50 Hz), and high gamma (50–150 Hz) frequency bands before running the same within-session fingerprinting procedure using the resulting narrowband signals. Narrowband connectome fingerprinting yielded differentiation accuracy scores of 98.7% for delta, 100% for theta, 99.4% for alpha, 100% for beta, 98.7% for gamma, and 94.9% for high gamma. Narrowband spectral fingerprinting produced differentiation accuracies of 94.9% for delta, 95.6% for theta, 95.6% for alpha, 96.2% for beta, 96.2% for gamma, and 97.5% for high gamma. These results are summarized Fig. 2a. MEG fingerprinting is robust against physiological, artefactual, and demographics confounds. We investigated the robustness of these results against variables of no interest and possible confounds. We first processed each individual session’s empty-room recordings in an identical fashion to participants brain data. We produced pseudo brain maps of empty-room sensor data using the same imaging kernels as those used for each session’s participant brain data. The implication is that imaging kernels designs are based on information that are specific of each participant, such as their respective head positions in the MEG sensor array and individual anatomy brain features that constrain MEG source maps. We, therefore, tested whether such individual information unrelated to brain activity contributed substantially to individual differentiation from MEG source maps. We found that differentiation performances were considerably reduced using empty-room data (<20% across all tested models; Fig. 2). These results based on source maps were corroborated by the low fingerprinting performances obtained by using empty-room sensor data only (<5% across all tested models; Supplemental Information).

We then performed Pearson correlation analyses between differentiability scores and recording parameters, typical MEG artifacts, and demographic variables. There was no association between the duration of scans and differentiability for connectome (r = −0.02, p = 0.75) and spectral (r = 0.02, p = 0.8) fingerprinting (Supplemental Information). Further, none of the tested MEG artifacts due to eye movements, heartbeats, and head motion were related to individual differentiation from either connectome or spectral fingerprinting. Indeed, differentiability was not correlated to motion (connectome: r = 0.06, p = 0.5; spectral: r = −0.01, p = 0.9), cardiac (connectome: r = 0.05, p = 0.6; spectral: r = 0.07, p = 0.4), or ocular (connectome: r = −0.09, p = 0.3; spectral: r = −0.05, p = 0.5) artifacts (Fig. 2b).

Lastly, we further hypothesized that fingerprinting performances may have been skewed by sample heterogeneity in terms of data from healthy vs. patient participants. Yet, there were <1% differences in differentiation accuracy after restricting fingerprinting to healthy participant data (Supplemental Information). We also verified that participant demographics such as age, sex, and handedness did not contribute to differentiability either (Supplemental Information).

MEG fingerprinting is robust over time. We tested whether participants who underwent MEG sessions on separate days were differentiable from datasets collected weeks to months apart (with
Differentiability scores were not correlated with the time between MEG sessions (connectome: $r = 0.08$, $p = 0.65$). We further challenged MEG individual differentiation between sessions days apart using shorter data segments. We extracted three 30 s segments from the between-session data on each day (Fig. 1a) and ran the same fingerprinting procedures as above. Differentiation performances from connectome fingerprinting remained high across all 30 s segments tested (Fig. 3c) using broadband MEG signals (differentiation accuracy 83.8%). Performance of spectral fingerprinting was decreased (differentiation accuracy: 61.6% Fig. 3c). We observed similar discrepancies in performance robustness between connectome and spectral fingerprinting using narrowband signals (Fig. 3), especially in the delta, theta, and alpha bands. We report results obtained from using sensor data only and for the within-session shortened challenge in Supplemental Information.

**Salient neurophysiological features for fingerprinting.** We identified the features which were the most characteristic of individuals for MEG fingerprinting. We derived measures of intraclass correlation (ICC)\(^1\) to quantify how much each feature, such as an edge of the FC connectome or the signal power in a frequency band from an anatomical parcel, contributed to fingerprinting (see “Methods”). This metric was reported in previous brain fingerprinting studies and captures the inter-rater reliability of each participant as their own rater, to identify the neurophysiological signal features that are the most consistent across individuals\(^2,3\). We performed this analysis for both the broadband connectome and the band-specific spectral fingerprinting within-session challenges. The data show that the dorsal attention and visual networks were the most specific across individuals for connectome fingerprinting, in all frequency bands (Fig. 4). Beta-band connectivity of the limbic network was particularly distinctive of individuals. For spectral fingerprinting, theta, alpha, beta, and gamma bands discriminated individuals along midline, parietal, lateral temporal, and visual areas (Fig. 4b). These results are consistent with our narrowband analysis (see Fig. 2a), which
**Fig. 3 Between-session fingerprinting accuracy.** a Differentiation accuracy for connectome and spectral between-session fingerprinting. Fingerprinting performances are similar to those from the within-session challenge. b Pearson correlation analyses did not reveal an association between differentiability and the delay between session recordings (connectome fingerprinting: $r = 0.09, p = 0.5$; spectral fingerprinting: $r = 0.08, p = 0.60$). c Between-session-shortened differentiation accuracy using shorter 30 s data segments collected days apart (average: 201.7 days). Each data point represents one combination of datasets used for fingerprinting (see “Methods” for details). d Scatter plots of all fingerprinting challenges across frequency bands for source (brain) and sensor (scalp) level fingerprinting (Supplemental Information details the results obtained for all sensor data fingerprinting challenges). Source data are provided as a Source Data file.

**Fig. 4 Characteristic features of connectome and spectral fingerprinting.** Intraclass correlation (ICC) for connectome and spectral within-session fingerprinting. a ICC for connectome fingerprinting plotted for each tested frequency band, using network labels from Yeo et al. The most prominent networks for connectome fingerprinting were the Visual, Dorsal Attention, and Limbic networks. b ICC for spectral fingerprinting plotted for each tested frequency band and mapped using the Desikan-Killiany cortical parcellation. The most salient features were the theta, alpha, and gamma band signals expressed in midline structures and the beta band across the cortex.
Neurophysiological fingerprinting features are associated with demographics. Beyond differentiating individuals in a cohort, we tested whether resting-state neurophysiological features could also predict meaningful participant traits, using an exploratory partial-least-squares (PLS) analysis (see "Methods"39). Briefly, PLS explains the structure of the covariance between two observation matrices—here a demographic matrix and a neurophysiological signal matrix composed of ROI-specific connectome of spectral measures—with latent components. PLS analysis of our data revealed three significant latent components, which were distinct for connectome and spectral fingerprinting (Supplementary Information). The first latent component in connectome fingerprinting was related to clinical population ($r = 0.2$, 95% CI $[0.160, 0.3]$) and handedness ($r = 0.2$, 95% CI $[0.1, 0.3]$). This demographic profile was associated with reduced beta-band functional connectivity over the frontal-parietal network (Fig. 5). For spectral fingerprinting, the first salient latent component was related to a younger age ($r = -0.3$, 95% CI $[-0.1, -0.5]$), female ($r = 0.4$, 95% CI $[0.2, 0.5]$) and clinical population ($r = 0.5$, 95% CI $[0.2, 0.5]$). This demographic profile was associated with stronger expressions of broadband neurophysiological signal power in superior parietal regions and the pericalcarine gyrus bilaterally, and reduced neurophysiological signals in the isthmus cingulate (Fig. 5).

**Discussion**

The recent leveraging of large, open fMRI datasets has brought empirical evidence that individuals may be differentiated within a cohort from their brain imaging functional connectivity, inspiring the metaphor of a neural fingerprint. Unlike hand fingerprints, their cerebral counterpart predicts task performance and a variety of traits14,21–24. These intriguing findings require a better understanding of their neurophysiological foundations, which we sought to characterize from direct neural signals captured at a large scale with MEG.

Our data show that individuals can be differentiated in a cohort of 158 unrelated participants from their respective resting-state connectomes and spectral profiles in a range of fast brain signals. MEG fingerprinting was successful using data lengths (30 s) much shorter than those reported for fMRI fingerprinting14,40. Brain electrophysiological signals are rich, complex, and convey expressions of large-scale neural dynamics channeled by individual structural anatomy and physiology41. Indeed, we also showed that MEG fingerprinting is robust across time, making individuals potentially differentiable from data collected days, months, or years apart. Lastly, we characterized whether individual differences in resting-state neural dynamics are graphically meaningful through an exploratory PLS analysis. We showed that both resting-state connectomes and spectra predict latent demographic components. Recent findings corroborate our results, demonstrating individual differences between functional connectivity derived from resting-state electrophysiology42. Future work will be required to replicate and expand these findings in more samples of individuals.

**Connectome and spectral neurophysiological fingerprints.** Our results highlight two sets of brain-wide electrophysiological features that contributed to successful fingerprinting: connectome and spectral measures across the neurophysiological frequency spectrum. Overall, connectome and spectral fingerprinting with MEG performed equivalently to fMRI approaches, achieving...
overall differentiation rates above 90%, with robust individual differentiation over time and against noise12,14,43.

We found that for connectome fingerprinting, the anatomical regions the most characteristic of individuals differed between MEG and fMRI. While fMRI highlighted the default-mode network and the fronto-parietal resting-state networks, MEG connectome fingerprinting emphasized functional connectivity within limbic and visual networks as contributing to individual specific neurophysiological signatures. In contrast, both MEG and fMRI fingerprinting emphasize the importance of the dorsal attention network14. These observations are not mutually exclusive, considering the different nature of brain signals captured by the respective modalities. One possible interpretation—requiring further investigation—is that the fast neurophysiological signals that contribute to differentiation with MEG have hemodynamic counterparts that are not as salient in fMRI as the fingerprinting networks reported so far. Nevertheless, our data indicate that neurophysiological signals in the beta band contribute to the highest differentiation accuracy amongst all other typical bands. This finding is compatible with previous work reporting that correlated amplitude changes of MEG brain signals are related to the microstructure of white matter tracts and reveal, with the same amplitude envelope correlation method as used here, MEG resting-state brain networks that align with fMRIs.44,45. Beta-band activity also emerges from recent literature as a signalling vehicle of re-afferent “top-down” communications in brain circuits16,47. One can therefore speculate that beta-band signals would convey electrophysiological representations of internal cognitive models that are by essence intimately specific of each individual35.

Such brain signal amplitude signatures are further emphasized by the ability of simple spectral brain maps to enable MEG fingerprinting. Within- and between-session spectral fingerprinting were achieved with remarkable accuracy (>90%) with broadband MEG brain signals or restricted to the typical bands of electrophysiology. Spectral differentiation based on signals from the faster bands (gamma and high-gamma) was overall the most robust longitudinally and against using shorter data segments. This observation is consistent with the width of (high) gamma frequency bands spanning broader ranges (here between 30–50 Hz and 50–150 Hz) than slower bands such as delta (1–4 Hz), theta (4–8 Hz) and alpha (8–12 Hz). The spectral estimates averaged across the broader (high) gamma bands were, therefore, the most robust against using shorter data segments. The reduced number of sliding time windows available over shorter data durations increased the variance of the summary statistics extracted to derive the spectral fingerprints from the signals defined over narrower bands. The higher frequency bands were less affected because the larger number of frequency bins involved in the extraction of their summary power statistics tended to compensate the higher empirical variance of spectral estimates from a lesser number of observations over time. Connectome fingerprinting was more immune against using shorter data durations. The underlying approach indeed did not require spectral transformations but resorted to a bank of narrowband filters applied over the original duration of MEG recordings before the resulting filtered signals were segmented in shorter epochs for the fingerprinting challenges. The consequence is that the number of data points used for all narrowband signals was identical across all frequency bands, yielding moderate variability in differentiation performances compared to those obtained with the spectral approach. Another point of robustness for connectome fingerprinting is that connectivity weights between network nodes may fluctuate very slowly over time in task-free brain activity: Florin and Baillet30 reported fluctuation rates of 0.01 Hz in MEG, indicating typical time cycles of 100 s—a duration substantially longer than the 30 s shortest time window used here. Over longer periods of time though, such as in the between-session challenge, spectral fingerprinting outperformed its connectome counterpart. We note a slight increase of spectral differentiation accuracy in the between-session challenge (e.g., +1.6% for broadband fingerprinting) compared to within-session, which was a statistical fluctuation due to using a smaller sample of participants.

On average across all source fingerprinting challenges reported herein, and despite successful fingerprinting across lower frequency bands (delta 54.4%, theta 62.3%, alpha 65.5%), performances were markedly better using high-frequency signal components (beta 82.0%; gamma 82.5%; high gamma 77.9%). Gamma and faster activity have long been associated with concurrent and colocalized hemodynamic fluctuations48,49. Because they may be seen as dual manifestations of BOLD signaling used in fMRI fingerprinting, this may explain why these signals contributed robustly to MEG brain fingerprinting in our data. However, gamma-band and faster brain signals are on average weaker in amplitude and therefore may be masked by contamination from artifacts and noise50–52. The preprocessing applied to our data attenuated such nuisance to a point where individuals were not differentiable from typical sources of signal contamination such as individual head motion behavior.

Although a rhythm of prominent amplitude in humans during rest, alpha-band activity (8–12 Hz) was not particularly specific to differentiate individuals in the cohort. In that respect, our data is aligned with previous MEG works on resting-state connectomes extracted from neurophysiological MEG signals, which did not report on a salient role of alpha activity in driving inter-regional connectivity30,44. We argue that the spatial topography of alpha resting activity may be relatively stereotypical across individuals, involving thalamo-cortical loops that project focally to the parieto-occipital junction, with limited variability across individuals.6 In task, alpha activity has been related to attention orienting, alertness and anticipation, and the registration of (multimodal) sensory information, thereby reflecting transient mental states32,53–56 rather than individual traits.

The data also indicates that MEG fingerprinting is robust against typical recording artifacts that may be idiosyncratic of individuals and therefore, could have confounded fingerprinting. Session environmental conditions captured by empty-room MEG recordings were not sufficient to differentiate individuals within or between sessions. The participant’s anatomical and head-position information embedded in their respective MEG source imaging kernels were also not sufficient to differentiate individuals. Note that head position changed between sessions. Further studies are required to clarify how these results may vary depending on the type of MEG source modeling adopted. We anticipate little influence of the type of source model used though, based on evidence that beamforming kernels are mathematically equivalently to other major classes of linear source estimation38. Future work should corroborate these results with regards to fingerprinting. The choice of connectivity measure to derive electrophysiological connectomes may also influence fingerprinting38. We look forward to current progress in electrophysiological brain connectomics to put forward measures of network connectivity informed by mechanistic principles and emerging as a standard metrics in the field to confirm and expand present fingerprinting results39.

While our present data show robust longitudinal fingerprinting performances, future work involving more participants with multiple MEG visits is required to both replicate these observations and investigate whether individual deviations from baseline fingerprints could be early signals of asymptomatic
We hope the remarkable ability to fingerprint individuals from the present electrophysiological features serves as a stepping stone for future investigation, which may include multimodal noninvasive assessments based on MEG, combined with, e.g., fMRI and/or EEG.

**Neural fingerprints of individual traits.** Our data suggest that individual differences in resting-state neurophysiological functional connectivity and spectral power relate to latent demographic clusters. These observations are in line with previous fMRI work that showed that connectomes are predictive of individual differences in attention, working memory, and intelligence test performance. For instance, connectivity patterns between the default mode and the dorsal attention networks predict attentional behavior during the task and self-reported mind wandering. Overall, a possible conceptual framework is that task-free neural dynamics are the signatures of an individual scaffold of brain functions that is predictive of task behavior. This view is also that of the spontaneous trait reactivation hypothesis wherein the organization of the human cortex at rest (manifested e.g., by functional connectivity) is a window into the self’s unique traits and abilities. Early evidence indeed suggests that functional connectivity and brain activity are associated with personality traits and even inter-personal closeness in social networks.

Yet, the mechanistic implementation of these intriguing observations remains elusive. Inter-individual variability in the distribution of synaptic weights across the cerebral, shaped through lifetime experiences according to Hebbian principles, may account—at least in part—for connectome fingerprinting. The heritability of functional connectivity has also been discussed, especially for a variety of brain networks (e.g., dorsal and ventral attention network and the default mode network). Heritability of brain spectral characteristics is also actively discussed. This emerging literature and the empirical evidence of brain fingerprinting certainly motivate more research on new, fascinating questions about the biological nature of the self.

**Sampling population diversity for personalized interventions.** Robust individual signatures of brain activity may be transformative to neurophysiological phenotyping and population neuroscience. With the increasing availability of multi-omic data repositories, there is a research opportunity to span the diversity of statistical normative characteristics of brain fingerprints across the population in relation to behavior, environmental, and clinical variables. Our study highlights the utility of datasets of individuals who have been scanned on multiple occasions to capture and characterize interindividual variability as meaningful information. Ideally, large databanks of individual variants sampled across multiple dimensions of socio-economic, age, and geographic factors enable normative modeling approaches to establish the risk traits of developing syndromes of, e.g., early cognitive decline, neurodegeneration, or mental illness. Previous work has shown that mental disorders may affect the stability of individual fingerprints over time and therefore points at possible translational applications of the approach. We also foresee that changes over time or lack thereof of a person’s brain fingerprint may also constitute a new class of non-invasive markers of responses to neurological and other treatment in a variety of chronic, neurodegenerative, or acute (e.g., stroke) conditions. Brain fingerprints derived from short, task-free sessions may play a leading role to realize this vision in practice.

Brain fingerprinting may also contribute to future endeavors in establishing how oscillatory dynamics at rest support cognitive functions across the lifespan. MEG brain fingerprinting presents several potential advantages in terms of safety, shorter scan duration, and the immediate proximity of a care person during data collection, especially for special populations.

The methodological approaches proposed herein can, in principle, transfer to EEG fingerprinting, which would be more readily available in clinics. Whether results would be as robust with EEG as MEG remains to be demonstrated. Indeed, EEG source mapping is more prone to contamination from muscle artifacts and is more sensitive to approximations in the biophysical modeling of head tissues, which may compromise further fingerprinting capabilities.

In sum, our study extends the concept of neural or brain fingerprint to fast and large-scale resting-state electrophysiological dynamics, which encapsulate meaningful individual differences in both functional connectivity and neuroanatomical maps of power spectrum characteristics. We are hopeful that the present contribution paves the way to replication and extension using larger open datasets. Many fascinating outstanding questions remain about the physiological meaning of inter-individual variability expressed via neural oscillations and brain network dynamics, and more specifically how these differences associate with behavior and diseases natural history. The research ahead is for future population neuroscience studies.

**Methods**

**The Open MEG Archives (OMEGA).** We used data from the Open MEG Archives (OMEGA) consisting of resting-state MEG recordings acquired using the same MEG system (275 channels whole-head CTF: Port Coquitlam, British Columbia, Canada). The sampling rate was 2400 Hz, with an antialiasing filter applied at 600 Hz cut-off, and built-in third-order spatial gradient noise cancellation (see ref. for details on data acquisition).

We analyzed MEG rest-state data from 158 unrelated OMEGA participants (77 females, 31.9 ± 14.7 years old). Recordings were ~5-min long. Supplementary Table 1 provides details on scanning procedures and Supplementary Table 2 on demographics. A subset of these individuals (N = 47) had recordings over multiple visits (different days) and were used in the between-session fingerprinting characterization. The OMEGA data management protocol was approved by the research ethics board of the Montreal Neurological Institute. We followed the ethical procedure of our local ethics board (the Montreal Neurological Institute).

**MEG data preprocessing and feature extraction.** MEG data were preprocessed using Brainstorm; version Oct-12-2018 in MATLAB 2017b (Mathworks, Inc., Massachusetts, USA) following good-practice guidelines. Unless specified, all steps below were performed using the Brainstorm toolkit, with default parameters. Line noise artifact (60 Hz) along with 10 of its harmonics were removed using a notch filter bank. Slow-wave and DC-offset artifacts were removed using a high-pass FIR filter with a 0.3-Hz cut-off. We derived Signal-Space Projections (SSPs) to remove cardiac and ocular artifacts. We used electro-cardiogram and -oculogram recordings to define signal projectors around identified artifact occurrences. We also applied SSPs to attenuate low-frequency (1–7 Hz) and high-frequency noisy components (40–400 Hz) due to saccades and muscular activity. Bandpass filtered duplicates of the cleaned data were produced for each frequency band of interest (delta: 1–4 Hz, theta: 4–8 Hz, alpha: 8–13 Hz, beta: 13–30 Hz, gamma: 30–50 Hz, and high gamma: 50–150 Hz). Distinct brain source models were then derived for all narrowband versions of the MEG sensor data.

Each individual T1-weighted MRI data were automatically segmented and labeled with Freesurfer. Coregistration with MEG sensor locations was derived using dozens of digitized head points collected at each MEG session. We produced MEG forward head models for each participant using the overlapping spheres approach, and cortical source models with linearly-constrained minimum-variance (LCMV) beamforming, all using Brainstorm with default parameters (2016 version for source estimation processes). We performed data covariance regularization to reduce the effect of variable source depth, the estimated source variance was normalized by the noise covariance matrix. Elementary MEG source orientations were constrained normal to the surface at 15,000 locations of the cortex. Noise statistics for source modeling were estimated from two-minute empty room recordings collected as close as possible in time to each participant’s MEG session. Source timeseries were clustered into 68 cortical ROIs defined from the Desikan-Killiany atlas and dimension-reduced via the first principal component of all signals within each ROI.

Connectome and spectral fingerprinting features were computed from ROI source timeseries. Individual connectomes were derived in all frequency bands from the amplitude envelope correlation (AEC) approach. ROIs timeseries were
Fingerprinting and differentiability. We used a fingerprinting approach directly adapted from fMRI connectome fingerprinting methods\(^{12,14}\), which relies on correlation scoring of individuals between datasets. A given probe participant is differentiated from a cohort by computing all Pearson correlation coefficients between the spectral or connectome features of said probe at one timepoint (e.g., dataset 1) to the entire cohort at a different timepoint (e.g., dataset 2). The entry presenting the highest correlation to the probe determined the probe’s estimated identity, i.e., identified entry in the cohort. This approach was applied between all pairs of participants in the cohort, yielding an asymmetric correlation matrix spanning the cohort. We report scores of differentiation accuracy as the ratio between all other individuals in dataset 2 (i.e., the mean along the 2nd row of matrix $A$), and $\sigma_i$ is the empirical standard deviation of inter-individual features correlations. Thus, if a participant is easily differentiable, its differentiability increases; whereas small differentiability scores indicate a participant that is particularly difficult to differentiate from the rest of the cohort.

Recording artifacts and differentiability. To investigate the effects of recording parameters and artifacts on fingerprinting, we related each individual’s differentiability score to several possible confounds. The duration of each scan was compared to differentiability to verify that longer recordings available from a subset of individuals did not make them easier to differentiate. We also correlated the root mean square (RMS) of signals that measured ocular, cardiac, and head movement artifacts over the duration of the entire recording to participants’ differentiability score.

Partial Least-Squares: MEG features of participant demographics. We conducted a Partial Least-Squares (PLS) analysis with the Rotman-Baycrest PLS toolbox\(^{16}\) in MATLAB 2017b (Mathworks, Inc., Massachusetts, USA). PLS is a multivariate statistical method that relates two matrices of variables (e.g., neural activity and participant demographics) by estimating a weighted linear combination of variables from both data matrices to maximize their covariance. The associated weights can be interpreted neural patterns (e.g., functional connections) and their associated demographic profiles. PLS used singular value decompositions of the z-scored neural activity-demographics covariance matrix. This decomposi- tion yielded orthogonal latent variables (LV) that related to patterns of neural activity (i.e., functional connectivity or spectral power) and demographics. To assess the significance of these multivariate patterns, we computed permutation tests (10,000 permutations). Each permutation shuffled the order of the observa- tions (i.e., the rows) of the demographic data matrix before running PLS on the resulting surrogate data under the null hypothesis that there was no relationship between the demographic and neural data. A p-value for the LVs was computed as the proportion of times the permuted singular values exceeded that of the original data. We explored the first significant LV from the broadband connectivity and spectral fingerprinting features. We also assessed the contribution of each variable in the demographic matrices and neural activity matrices by the bootstrap methods with replacement (10,000 bootstraps). We computed 95% confidence intervals for the demographic weights and bootstrap ratios for the neural weights. The bootstrap ratio was computed as the ratio between each variable’s weight and the bootstrap-estimated standard error.

Data availability

Resting-state data were obtained from the OMEGA repository\(^{5}\). Raw MEG recordings can be accessed by requesting the data (https://www.megcll.ca/bioc/omega-registration). The power spectra and connectomes derived from the preprocessed OMEGA samples and used to differentiate individuals in the present study can be reproduced using the code that has been made available and are available from the corresponding author upon reasonable request. Source data are provided with this paper.
