ABSTRACT
We study orbital and physical properties of Trojan asteroids of Jupiter. We try to discern all families previously discussed in literature, but we conclude there is only one significant family among Trojans, namely the cluster around asteroid (3548) Eurybates. It is the only cluster, which has all of the following characteristics: (i) it is clearly concentrated in the proper-element space; (ii) size-frequency distribution is different from background asteroids; (iii) we have a reasonable collisional/dynamical model of the family. Henceforth, we can consider it as a real collisional family.

We also report a discovery of a possible family around the asteroid (4709) Ennomos, composed mostly of small asteroids. The asteroid (4709) Ennomos is known to have a very high albedo p_N ≃ 0.15, which may be related to a hypothetical cratering event which exposed ice (Fernández et al. 2003). The relation between the collisional family and the exposed surface of the parent body is a unique opportunity to study the physics of cratering events. However, more data are needed to confirm the existence of this family and its relationship with Ennomos.

Key words: celestial mechanics – minor planets, asteroids – methods: N-body simulations.

1 INTRODUCTION
Trojans of Jupiter, which reside in the neighbourhood of \(L_4\) and \(L_5\) Lagrangian points, serve as an important test of the planetary migration theory (Morbidelli et al. 2005). Their inclination distribution, namely the large spread of \(I\), can be explained as a result of chaotic capture during a brief period when Jupiter and Saturn encountered a 1:2 mean-motion resonance. Moreover, the Late Heavy Bombardment provides the timing of this resonant encounter \(\approx 3.8\) Gyr ago (Gomes et al. 2005). It is thus important to understand the population of Trojans accurately.

There are several unresolved problems regarding Trojans, however, for example the number of families, which is a stringent constraint for collisional models. Roig et al. (2008) studied as many as ten suggested families, using relatively sparse SLOAN data and spectra. They noted most families seem to be heterogeneous from the spectroscopic point of view, with one exception — the C-type Eurybates family. As we argue in this paper, the number of families (with parent-body size \(D \gtrsim 100\) km) is indeed as low as one.

Another strange fact is the ratio of \(L_4\) and \(L_5\) Trojans. Szałó et al. (2007) used SLOAN colour data to reach fainter than orbital catalogues and estimated the ratio to \(N(L_4)/N(L_5) = 1.6 \pm 0.1\). There is no clear explanation for this, since the chaotic capture as a gravitational interaction should be independent of size or \(L_4/L_5\) membership. Any hypothesis involving collisions would require a relatively recent disruption of a huge parent body, which is highly unlikely (O’Brien and Morbidelli 2008, D. O’Brien, personal communication). This is again related to the actual observed number of Trojan families.

Brož and Vokrouhlický (2008) studied another resonant population, the so called Hilda group in the 3/2 mean-motion resonance with Jupiter, and reported only two families: Hilda and Schubart with approximately 200 and 100 km parent bodies. This number might be in accord with low collisional probabilities, assuming the Hilda family is very old and experienced the Late Heavy Bombardment (Brož et al. 2011).

Levison et al. (2009) compared the observed distribution of D-type asteroids and the model of their delivery from transneptunian region. They found a good match assuming the D-types (presumably of cometary origin) are easy-to-disrupt objects (with the strength more than 5 times lower than that of solid ice). Note that Trojan asteroids are a mixture of C- and D-type objects and we have to discriminate between them with respect to collisional behaviour.

All of the works mentioned above are a good motivation for us to focus on asteroid families in the Trojan population. The paper is organised as follows. First, we describe our data sources and methods in Section 2. A detailed study of
2 METHODS

2.1 Resonant elements

We use the symplectic SWIFT integrator (Levison & Duncan 1994) for orbital calculations. Our modifications include a second order scheme of Laskar & Robutel (2001) and online digital filters, which enable us to compute suitable resonant proper elements: libration amplitude \(d\) of the \(a-a'\) oscillations, where \(a\) is the osculating semimajor axis of an asteroid and \(a'\) that of Jupiter, eccentricity \(e\) and inclination \(\sin I\). (In figures, we usually plot a mean value \(\bar{a}\) of semimajor axis plus the libration amplitude \(d\).) We employ their definition from Milani (1993). The source of initial osculating elements is the AstOrb catalogue, version JD = 2455500.5 (Oct 31st 2010).

There are actually two independent filters running in parallel: in the first one, we sample osculating elements every 1 yr, compute mean elements using the filter sequence B, B with decimation factors 3, 3 (refer to Quinn, Tremaine & Duncan 1991) a store this data in a buffer spanning 1 kyr. We then estimate the liberation frequency \(f\) by a linear fit of \(\phi(t) = \lambda - \lambda' - \chi\), where \(\lambda, \lambda'\) are the mean longitudes of an asteroid and Jupiter and \(\chi = \pm 60^\circ\) for \(L_4\) or \(L_5\) respectively. The revolution of angle \(\phi(t)\) must not be confined to the interval \([0,360^\circ]\), of course. The amplitude of \(d\) is computed for the already known \(f\) by a discrete Fourier transform. Finally, an off-line running-average filter with a window 1 Myr is used to smooth the data.

In the second filter, we compute proper eccentricity \(e\) and proper inclination \(\sin I\) by sampling osculating elements (1 yr step), computing mean elements using a filter sequence A, A, B and decimation factors 10, 10, 3, and then we apply a frequency modified Fourier transform (Nesvorný & Šidlichovský 1997), which gives us the relevant proper amplitudes.

The values of the resonant elements agree very well with those listed in the AstDyS catalogue by Knežević & Milani (see Figure 1). There are only few outliers, probably due to a different time span of integration. We computed proper elements for 2647 \(L_4\) and 1496 \(L_5\) Trojan asteroids. This sample is roughly twice larger than previously analysed. The ratio of populations valid for \(H \lesssim 15\) mag asteroids is thus \(N(L_4)/N(L_5) \approx 1.8\).

The overall distribution of Trojans in the \((d,e,\sin I)\) space is shown in Figure 2. Note there is only one cluster visible immediately in the bottom-left panel — around \((3548)\) Eurybates. The reason is its tight confinement in inclinations \((\sin I = 0.125 \text{ to } 0.135)\).

1 Equivalently, we may compute the amplitude \(D\) of mean longitudes \(\lambda - \lambda'\). Anyway, there is a linear relation between \(d\) and \(D\).

2 The data are available in an electronic form on our web site [http://sirrah.troja.mff.cuni.cz/~mira/mp/](http://sirrah.troja.mff.cuni.cz/~mira/mp/) We use also one-apparition orbits for the purposes of physical studies. Of course, orbital studies require more precise multi-apparition data.
Eurybates — the only asteroid family among Trojans?

3

L4 Trojans

L5 Trojans

Figure 2. The resonant elements \((a \equiv \bar{a} + d, \sin I)\) and \((e, \sin I)\) for \(L_4\) and \(L_5\) Trojans. The crosses indicate relative sizes of bodies, taken either from the AstOrb catalogue or computed from absolute magnitude \(H\) and geometric albedo \(p_V\). In this plot, we assumed \(p_V = 0.058\) for \(L_4\) Trojans and 0.045 for those in \(L_5\) (it corresponds to medians of known \(p_V\)’s). The asteroids (3548) Eurybates in \(L_4\) and (4709) Ennomos in \(L_5\), around which significant clusters are visible, are shown in red. Moreover, the asteroid (9799) 1996 RJ in \(L_4\), which is surrounded by a small cluster, is denoted by a blue circle. (This cluster is so tight, that its members are located inside the circle on the \((e, \sin I)\) plot.)

al. 2006) and it makes the 1996 RJ cluster a particularly interesting case with respect to collisional dynamics. Because one has to use slightly different methods for studies of such young families we postpone a detailed analysis to a next paper.

Let us compare Trojan clusters to the well known asteroid families in the outer Main Belt (Figure 4). Most families (e.g., Themis, Koronis, Eos) exhibit a steady increase of \(N\) until they merge with another families or the entire outer Main Belt. Eurybates, Aneas and 1988 RG10 are the only Trojan clusters which behave in a similar fashion. The Veritas family (dynamically young, Nesvornỳ et al. 2003) exhibits a different behaviour — for a large interval of \(v_{\text{cutoff}}\) the number of members \(N\) remains almost the same, which indicates a clear separation from the background population. With respect to the \(N(v_{\text{cutoff}})\) dependence, the Ennomos cluster is similar to Veritas.

2.3 Size-frequency distribution

At first, let us assume a single value of albedo for all family members. It is a reasonable assumption if the family is of collisional origin. We can then calculate sizes from absolute magnitudes and construct size-frequency distributions. Figure 5 shows a comparison of SFD’s for the clusters detected by the HCM and for the whole population of \(L_4\) and \(L_5\) Trojans.

\[\text{Figure 4.} \quad \text{The } N(v_{\text{cutoff}}) \text{ dependence for seven outer main-belt families. If we would consider only a subset of asteroids brighter than } H = 15 \text{ mag, which is an approximate observational limit for Trojans, the } N(v_{\text{cutoff}}) \text{ dependencies would be qualitatively the same, only slightly shifted to larger cut–off velocities.}\]
A slope $\gamma$ of the cumulative distribution $N(>D) \propto D^\gamma$ is an indicative parameter. For $L_4$ and $L_5$ Trojans it equals to $-2.0 \pm 0.1$ and $-1.9 \pm 0.1$ in the intermediate size range 15 to 60 km. (These numbers are compatible with the study of Yoshida & Nakamura 2008.) The slope is steeper at larger sizes. The uncertainties are mainly due to a freedom in selection of the size range and the difference between $L_4$ and $L_5$ SFD’s does not seem significant. The clusters have typically similar slope as background (within 0.1 uncertainty), thought sometimes the results are inconclusive due to small number of members. The Eurybates family with $-2.5 \pm 0.1$ slope is on the other hand significantly steeper than the mean slope of the whole Trojan population. There are two more groups which exhibit a relatively steep slope, namely Laertes in $L_4$ ($\gamma = -3.1$) and 1988 RG$_{10}$ in $L_5$ ($\gamma = -2.6$).

We should be aware, however, that even the background exhibits a trend with respect to inclinations (see Figure 3). Slope $\gamma$ typically decreases with inclination $I$, which is especially prominent in case of the $L_4$ cloud. We have to admit if we compare the Eurybates family to its surroundings only ($\sin I = 0.1$ to 0.15), the difference in slopes is not so prominent. An interesting feature of the $L_5$ cloud is a dip in the interval $\sin I = 0.05$ to 0.1. This corresponds to the approximate location of the 1988 RG$_{10}$ group.

The ($\sin I$) dependence among Trojans is not unique. E.g. low-inclination bodies in the J3/2 resonance also have the SFD steeper than background ($\gamma = -2.5 \pm 0.1$ versus $-1.7 \pm 0.1$), without any clear family and a few big interlopers. May be, this feature reflects different source reservoirs of low- and high-inclination bodies among Trojans and J3/2. It may be also in concert with a colour–inclination dependence reported by Szabó et al. (2007).

We also test albedo distributions dependent on size, since the measurements by Fernández et al. (2009) suggested small Trojans are significantly brighter and thus smaller. Large asteroids have $p_V = 0.044 \pm 0.008$ while small $p_V = 0.12 \pm 0.06$. This is a significant change of the SFD, which occurs around the size $D \geq 30$ km. The SFD thus becomes shallower below this size, e.g. for Eurybates we would have $\gamma = -1.6$ and for $L_4$ Trojans $\gamma = -1.5$, so the SFD’s become comparable with respect to the slope. Thought, as we stated above, for a real collisional family we expect the

$$N(v_{\text{cutoff}})$$ is flat. Size-frequency distribution is not very sensitive to this selection anyway.

### Table 1. List of nine members of the $(9799)$ 1996 RJ cluster and their proper $(a, e, \sin I)$ and osculating $(\Omega_{\text{osc}}, \varpi_{\text{osc}})$ elements and absolute magnitude $H$. Note the distribution of nodes and perihelia is not entirely uniform. Asteroids with short-arc orbits (<60 days) are denoted by a * symbol.

| number | designation | $a$  | $e$  | $\sin I$ | $\Omega_{\text{osc}}$ | $\varpi_{\text{osc}}$ | $H$/mag |
|--------|-------------|------|------|----------|-----------------------|-----------------------|--------|
| 9799   | 1996 RJ     | 5.2252 | 0.0412 | 0.5269 | 115.4                | 259.6                | 9.9    |
| 89938  | 2002 FR$_4$ | 5.2324 | 0.0394 | 0.5274 | 70.0                  | 23.1                  | 12.5   |

| 2005   | MG$_{24}$   | 5.2275 | 0.0404 | 0.5252 | 172.3                | 236.5                | 13.1   |
| 2008   | OW$_{22}$   | * 5.2276 | 0.0401 | 0.5274 | 53.7                  | 340.9                | 13.9   |
| 2009   | RA$_{17}$   | * 5.2258 | 0.0409 | 0.5272 | 257.7                | 194.5                | 13.7   |
| 2009   | RK$_{61}$   | * 5.2305 | 0.0407 | 0.5260 | 56.4                  | 5.6                  | 12.8   |
| 2009   | SR$_{30}$   | 5.2362 | 0.0409 | 0.5258 | 103.6                | 22.0                  | 13.3   |

Figure 3. Left panel: The dependence of the number of family members $N$ on the cut–off velocity $v_{\text{cutoff}}$ computed by the hierarchical clustering method. Only clusters among $L_4$ Trojans are included in this plot. Middle panel: The same $N(v_{\text{cutoff}})$ dependence for $L_5$ Trojans. Right panel: Artificial clusters selected from random distribution of asteroids generated in the same volume of the $(d, e, \sin I)$ space.
albedo distribution to be rather homogeneous and independent of size.

2.4 Colour and spectral data

We used the Sloan Digital Sky Survey Moving Object catalogue version 4 (SDSS-MOC4) to check the families are spectrally homogeneous, as we expect. Due to a larger uncertainty in the \( u \) colour in SDSS-MOC4, we used the color indices \( a^* \) and \( i - z \), where \( a^* = 0.89(g - r) + 0.45(r - i) - 0.57 \) (defined by Parker et al. 2008).

The result is shown in Figure 7. It is clearly visible that the distribution of the Eurybates family in the space of \( (a^*, i - z) \) colours is different from the Trojan background. On contrary, the 1988 RG\(_{10} \) group covers essentially the same area as the background. The Aneas is only slightly shifted towards larger \( a^* \) and \( i - z \) with respect to the background. There is a lack of data for the Ennomos group — three bodies are not sufficient to compare the colour distributions.

Alternatively, we may use principal component analysis of the SDSS colour indices. We use only data with uncertainties smaller than 0.2 mag, which resulted in 70,887 records. We calculated eigenvalues \( (\lambda_1, \lambda_2, \lambda_3) = (0.173, 0.0532, 0.0249, 0.0095) \), corresponding eigenvectors and constructed the following three principal components (Trojanová 2010):

\[
\begin{align*}
PC_1 &= 0.235 \,(u - g) + 0.416 \,(g - r) + 0.598 \,(g - i) \\
&\quad + 0.643 \,(g - z), \\
PC_2 &= 0.968 \,(u - g) - 0.173 \,(g - r) - 0.147 \,(g - i) \\
&\quad - 0.106 \,(g - z), \\
PC_3 &= 0.078 \,(u - g) + 0.601 \,(g - r) + 0.330 \,(g - i) \\
&\quad - 0.724 \,(g - z),
\end{align*}
\]

which have a clear physical interpretation: \( PC_1 \) corresponds to an overall slope, \( PC_2 \) is a variability in the \( u \) band, and \( PC_3 \) a depth of the 1\( \mu \)m absorption band. The Eurybates family is different from Trojans in all three principal components (mean \( PC_1 \) of the Eurybates members is smaller, \( PC_2 \) and \( PC_3 \) larger). The Aneas group has the same distribution of \( PC_2 \) and \( PC_3 \) as Trojans and the 1988 RG\(_{10} \) group is similar to Trojans even in all three components.

Hence, we confirm the Eurybates family seems distinct in color even in the fourth version of the SDSS-MOC. This fact is consistent with previous work of Roig et al. (2008), who used third version of the same catalogue and classified Eurybates family members as C-type asteroids.

Finally, note that De Luise et al. (2010) pointed out an

---

Figure 5. Left panel: size distributions of L\(_4\) Trojans and the following clusters (there is a selected cut-off velocity in the parenthesis): Eurybates (\( v_{\text{cutoff}} = 50\, \text{m/s} \)), Laertes (94), Hektor (160), Teucer (175), Simon (163), 1986 WD (120). Right panel: SFD’s of L\(_5\) Trojans and the following clusters: 1988 RG\(_{10} \) (at \( v_{\text{cutoff}} = 130\, \text{m/s} \)), Aneas (150), Asios (155), Panthoos (130), Polydoros (130).

Figure 6. Slopes \( \gamma \) of the size-frequency distributions \( N(>D) \) for L\(_4\) and L\(_5\) Trojans and their dependence on the inclination \( \sin I \). The range of diameters for which the SFD’s were fitted is \( D_{\min} = 12\, \text{km}, D_{\max} = 30\, \text{km} \). Thin lines were calculated for different ranges, which were varied as \( D_{\min} \in (10, 15)\, \text{km}, D_{\max} \in (20, 40)\, \text{km} \). Their spread indicates the uncertainty of \( \gamma \) in a given interval of \( \sin I \). The populations are observationally complete down to \( D \approx 10\, \text{km} \), because the characteristic change of slope due to incompleteness occurs at smaller sizes (see also Yoshida and Nakamura 2008).
absence of ice spectral features at 1.5 and 2.0 μm on several Eurybates members and Yang and Jewitt (2007) concluded the same for (4709) Ennomos. This puzzling fact may indicate that pure ice covers at most 10% of the Ennomos surface.

2.5 Impact disruption model

We use a simple model of an isotropic disruption from Farinella et al. (1994). The distribution of velocities “at infinity” follows the function

\[ dN(v) = C v^2 + v_{\text{esc}}^2 (\alpha + 1)/2, \]

with the exponent \( \alpha \) being a free parameter, \( C \) a normalisation constant and \( v_{\text{esc}} \) the escape velocity from the parent body, which is determined by its size \( R_{PB} \) and mean density \( \rho_{PB} \). The distribution is cut at a selected maximum allowed velocity \( v_{\text{max}} \) to prevent outliers. We typically use \( v_{\text{max}} = 300 \text{ m/s} \). The orientations of velocity vectors in space are assigned randomly. We assume the velocity of fragments is independent on their size.

There are several more free parameters, which determine the initial shape of the family in the space of proper elements: initial osculating eccentricity \( e_i \), initial inclination \( i_i \), as well as true anomaly \( f_i \) and argument of perihelion \( \omega_i \) at the time of impact disruption.

An example of a synthetic family just after disruption and its comparison to the observed Eurybates family is shown in Figure 7. Usually, there is a significant disagreement between this simple model of impact disruption and the observations. Synthetic families usually look like thin ‘filaments’ in the \((d,e,\sin I)\) space, which are curved due to the mapping from osculating elements to resonant ones. On the other hand, observed groups among Trojans are much more spread. However, this only indicates an importance of further long-term evolution by chaotic diffusion and possibly by planetary migration.

In case of the Ennomos group members, they are distributed mostly on larger semimajor axes than (4709) Ennomos, thought isotropic impact disruptions produce fragments distributed evenly on larger and smaller \( a \). May be, it is an indication of an anisotropic velocity field? Or a different parent body of this cluster?

2.6 Planetary migration

If asteroid families are very old, planetary migration might influence their current shape. In order to study of late stages of planetary migration, which is caused by interactions with a planetesimal disk, we construct the following model. We treat the migration analytically within a modified version of the numerical symplectic SWIFT-RMVS3 integrator (Levison & Duncan 1994), which accounts for gravitational perturbations of the Sun and four giant planets and includes also an energy-dissipation term, as described in Brož et al. (2011). The speed of migration is characterised by the exponential time scale \( \tau_{\text{mig}} \) and the required total change of semimajor axis \( a_i - a_\zeta \). We use an eccentricity damping formula too, which simulates the effects of dynamical friction and prevent an unrealistic increase of eccentricities (Morbildelli et al. 2010). The amount of damping is determined by the parameter \( e_{\text{damp}} \).

We try to adjust initial orbital parameters of planets and the parameters of migration in such a way to end up at currently observed orbits. The integration time step is \( \Delta t = 36.525 \text{ days} \) and the time span is usually equal to 3\( \tau_{\text{mig}} \), when planetary orbits almost stop to migrate.

2.7 Inefficient Yarkovsky/YORP effect

On long time scales, the Yarkovsky thermal force might cause significant perturbations of orbits. We use an implementation of the Yarkovsky thermal effect in the SWIFT N-body integrator (Brož 2006). It includes both the diurnal and seasonal variants.

The YORP effect (thermal torques affecting spin states; Vokrouhlický et al. 2006) was not taken into account in our simulations. The reason is that the respective time scale \( \tau_{\text{YORP}} \) is of the order 100 My to 1 Gyr so as a ‘zero’ approximation, we neglect the YORP effect on these “short” time scales and keep the orientations of the spin axes fixed.

For Trojan asteroids captured in a zero-order mean motion resonance, the Yarkovsky perturbation only affects the position of libration centre (Moldovan et al. 2010). Note that the perturbation acts ‘instantly’ — there is no systematic secular drift in eccentricity nor in other proper elements which is an important difference from first-order resonances, where a \( e \)-drift is expected (Brož & Vokrouhlický 2008, Appendix A). This is another reason we do not need a detailed YORP model here.

The thermal parameter we use are reasonable estimates for C/X-type bodies: \( \rho_{\text{surf}} = \rho_{\text{bulk}} = 1300 \text{ kg/m}^3 \) for the surface and bulk densities, \( K = 0.01 \text{ W/m/K} \) for the surface

---

\(^6\) If we use a size-dependent relation for velocities similar to Vokrouhlický et al. (2006), our results do not change much, because the overall shape of the velocity distribution is quite similar to the size-independent case.

\(^7\) Only very young clusters like the Karin family (Nesvorný et al. 2002) exhibit this kind of a ‘filament’ shape.
thermal conductivity, \( C = 680 \text{ J/kg for the heat capacity, } \)
\( A = 0.02 \) for the Bond albedo and \( \epsilon_{IR} = 0.95 \) for the thermal emissivity.

## 3 ASTEROID FAMILIES AND INSIGNIFICANT GROUPS

In this section, we briefly discuss properties of selected clusters: Eurybates, Ennomos, Aneas and 1988 RG\textsubscript{10}. We focus on these four clusters, since they seem most prominent according to our previous analysis.

### 3.1 Eurybates family

The Eurybates family can be detected by the hierarchical clustering method for cut-off velocities \( v_{\text{cutoff}} = 38 \) to 78 m/s, when it merges with Menelaus (see Figure \textbf{8}).

Yet, we do not rely just on the HCM! Another selection criterion we use is a ‘meaningful’ shape of the family and its changes with respect to \( v_{\text{cutoff}} \).

A very important characteristic of the Eurybates family at low values of \( v_{\text{cutoff}} \) is a tight confinement of inclinations (\( \sin I \) within 0.01). It breaks down at \( v_{\text{cutoff}} \approx 68 \text{ m/s} \), so we consider this value as an upper limit. The Eurybates family is also confined in semimajor axis, being approximately twice smaller than other groups.

The diameter of the parent body is \( D_{\text{PB}} \approx 97 \text{ km} \) for albedo \( p_V = 0.055 \) if we sum the volumes of the known bodies. Of course, in reality it is slightly larger due to observational incompleteness. If we prolong the slope of the SFD \( \gamma = -2.5 \) down to zero we obtain \( D_{\text{PB}} \approx 110 \text{ km} \).

The geometric method of Tanga et al. (1999) gives an upper limit \( D_{\text{PB}} \approx 130 \text{ km} \).

Spectral slopes of family members are rather homogeneous and correspond to C/P-types (Roig et al. 2008).

### 3.2 Ennomos group

The cluster around (4709) Ennomos can be recognised for a wide interval of cut-off velocities \( v_{\text{cutoff}} \in (69, 129) \text{ m/s} \) when it stays compact and confined in inclinations (\( \sin I = 0.451 \) to 0.466). Very probably, there are several interlopers, because we can count 4 to 10 asteroids in the surroundings, i.e., in the same volume of the \( (d, e, \sin I) \) space (see Figure \textbf{9}). Since small bodies dominate the Ennomos group we suspect large bodies might be actually interlopers.

A very intriguing feature is a high albedo of (4709) Ennomos \( p_V \approx 0.15 \) measured by Fernández et al. (2003). Apart from other explanations, the authors speculated it may result from a recent impact which covered the surface with pristine ice. If true the relation between the fresh surface and the collisional family might be a unique opportunity to study cratering events.

We cannot exclude a possibility that (4709) Ennomos is actually an interloper and the family is not related to it at all. Nevertheless, our hypothesis is testable: family members should exhibit a similarity in spectra and albedos. The only information we have to date are SDSS colours for three members: 98362, 2005 YG\textsubscript{204} are probably C-types and 2005 AR\textsubscript{72} is a D-type. In case new data become available we can remove interlopers from our sample and improve our analysis.

The size distribution of the Ennomos group is barely constrained, since small bodies are at the observational limit. Moreover, removal of interlopers can change the SFD shape completely (from \( \gamma = -1.4 \) to \( -3.2 \) or so). The minimum parent body size is about \( D_{\text{PB}} \approx 67 \text{ km} \) if all members have high albedo \( p_V = 0.15 \).

### 3.3 Group denoted Aneas

The Aneas group looks like a middle portion of the \( L_5 \) cloud with approximately background density. It spans whole range of semimajor axes, as background asteroids do.

The minimum size of a hypothetical parent body is \( D_{\text{PB}} = 160 \) to 170 km (for albedo \( p_V = 0.055 \) to 0.041). This size is very large and an impact disruption of such body is less probable (see Section \textbf{4.4}). The size-frequency distribution is shallow, with approximately the same slope as background.

According to Roig et al. (2008) the colours are rather homogeneous and correspond to D-types, with \( \sim 10\% \) of probable interlopers.

### 3.4 Group denoted 1988 RG\textsubscript{10}

The group around asteroid (11487) 1988 RG\textsubscript{10} again looks like a lower portion of the \( L_5 \) cloud at low inclinations, with \( \sin I \in (0.06, 0.1) \). The SFD is steeper (\( \gamma = -2.6 \pm 0.1 \) than...
surroundings in $L_5$ and the resulting parent body size $D \approx 60 \text{ km}$ is relatively small. The colours seems heterogeneous (Roig et al. 2008) and we can confirm this statement based on the new SDSS-MOC version 4 data.

The remaining clusters (Hektor, Teucer, Sinon, 1986 WD, Laertes, Asios, Polydoros, Panthoos, etc.) may be characterised as follows: (i) they have a density in $(d, e, \sin I)$ space comparable to that of background (surroundings); (ii) when identified by the HCM their semimajor axes span the whole range of Trojan region; (iii) the slopes of their SFD’s are comparable to the background; (iv) they are often inhomogeneous with respect to colours (according to Roig et al. 2008). These reasons lead us to a conclusion that these clusters are not necessarily real collisional families.

4 LONG-TERM EVOLUTION OF TROJAN FAMILIES

4.1 Evolution due to chaotic diffusion

We try to model long-term evolution of the Eurybates family. At first, we generate a synthetic family (consisting of 42 bodies) by an impact disruption of the parent body with required size. Then we integrate the synthetic family and compare it at particular time to the observed Eurybates family. The time span of the integration is 4 Gyr.

The main driving mechanism is slow chaotic diffusion (the Yarkovsky effect is present but inefficient in the Trojan region). Initially, the spread of inclinations of the synthetic family is consistent with the observed one. On the other hand, the shape in $(a, e)$ elements is clearly inconsistent.

Since the inclinations evolve only barely we focus on the evolution of in the $(a, e)$ plane (see Figure 10). The point is the synthetic family, namely the ‘filament’ structure, has to disperse sufficiently. After 500 Myr it is still recognisable but after 1 Gyr of evolution it is not. So we may constrain the age of the Eurybates family from 1 to 4 Gyr.

A similar analysis for the Ennomos group indicates that chaotic diffusion is faster in this region (given the large inclination) and the most probable age thus seems to be from 1 to 2 Gyr. Beyond 2 Gyr the inclinations of the synthetic family become too large compared to the observed Ennomos group, while the eccentricities are still compatible.

We try to model Areae and 1988 RG10 groups too (see Figure 11). In these two cases, there is a strong disagreement between our model and observations. The observed groups are much larger and chaotic diffusion in respective regions is very slow. Even after 4 Gyr of orbital evolution, the synthetic family remains too small.

The only free parameter which may substantially change our results is the initial velocity distribution. Theoretically, the distribution might have been strongly anisotropic. However, we cannot choose initial velocities entirely freely, since their magnitude should be comparable to the escape velocity from the parent body, which is fixed by the size $D_{PB}$ and only weakly dependent on a-priori unknown density $\rho_{PB}$.

Another solution of this problem is possible if we assume families are very old and they experienced perturbations due to planetary migration.

4.2 Stability during planetary migration

The major perturbation acting on Trojans are secondary resonances between the libration period $P_{J1/1}$ of the asteroid in the $J1/1$ mean-motion resonance with Jupiter and the period $P_{J1-2S}$ of the critical argument of Jupiter–Saturn 1:2 resonance (Morbidelli et al. 2005)

\[
P_{J1/1} = nP_{J1-2S},
\]

where $n$ is a small integer number. Typical libration periods are $P_{J1/1} \simeq 150 \text{ yr}$ and $P_{J1-2S}$ changes as planets migrate (it decreases because Jupiter and Saturn recede from their mutual 1:2 resonance)\footnote{Another source of instability might be a secondary resonance with $P_{2J-3S}$ (the so called Great Inequality period) thought it is}

\[
D_{KS} = 0.20 \text{ and } p_{KS}(>D) = 0.32, \text{ which indicates a reasonable match.}
\]

\footnote{We verified these estimates by a 2-dimensional Kolmogorov–Smirnov test of the $(a, e)$ distributions: initially the KS distance is $D_{KS} = 0.30$ and the probability $p_{KS}(>D) = 0.02$, which means the distribution are incompatible. At $t = 1$ Gyr, the values are...}
Eurybates — the only asteroid family among Trojans?

Figure 10. Orbital evolution of the synthetic family and its comparison with the observed Eurybates family. Left panel: the situation in the \((a, e)\) plane at 500 Myr. Middle panel: the situation after 4 Gyr. Chaotic diffusion disperses the synthetic family in course of time (see shaded tracks of particles). Right panel: the \((a, \sin I)\) plane at the same time. Inclinations evolve only barely.

Figure 11. Evolution of the synthetic family over 4 Gyr versus the observed Aneas group. Chaotic diffusion is slow and it seems impossible to match the large spread of the observed group even after 4 Gyr.

All synthetic families are strongly unstable when \(P_{1J-2S} \approx 150\) yr and even during later stages of migration with \(P_{1J-2S} \approx 75\) yr the eccentricities of family members are perturbed too much to match the observed families like Eurybates or Ennomos (see Figure 12). There are practically no plausible migration scenarios — regardless of time scale \(\tau_{\text{mig}}\) — which would produce a sufficiently compact group, unless Jupiter and Saturn are almost on their current orbits. We tested \(\tau_{\text{mig}} = 0, 3, 30\) Myr and even for \(\Delta aJ \equiv a_{3J} - a_{1J}\) as small as \(-0.08\) AU and \(\Delta aS = +0.25\) AU the perturbation was too strong. The reason is that one has to avoid \(n = 2\) secondary resonance to preserve a low spread of a synthetic family.

Let us conclude if any of Trojan families was created during planetary migration and if the migration was smooth (exponential) the family cannot be visible today. However, we cannot exclude a possibility that final stages of migration were entirely different, e.g. similar to the ‘jumping-Jupiter’ scenario (Morbidelli et al. 2010).

Figure 12. Evolution of a synthetic family during late phases of planetary migration \((\tau_{\text{mig}} = 30\) Myr in this case). Top panel: the state at 0 Myr, middle: 100 Myr, bottom: the respective orbital evolution of Jupiter and Saturn. The family is almost destroyed and it is definitely incompatible with the observed Eurybates family.

4.3 Families lost by the ejection of fragment outside the resonance

We studied a possibility that some families cannot be identified because the breakup occurred at the outskirts of the stable libration zone and some fragments were ejected outside the \(J1/1\) resonance. We thus chose 30 largest asteroids near the edge of the \(L_4\) libration zone and we simulated breakups of these asteroids which create families with 30 fragments each. We assumed the diameter of all parent bodies equal to \(D_{\text{PB}} = 100\) km and their density \(\rho_{\text{PB}} = 1.3\) g cm\(^{-3}\). The breakups always occurred at the same geometry \(f_{\text{imp}} = 0^\circ\), \(\omega_{\text{imp}} = 30^\circ\). After the breakup, we calculated proper elements of the family members and plotted their distribution (see Figure 13). We can see all 30 synthetic families can be easily identified. In most cases, more than 95\% of family members remained within the stable libration zone. We can

\(\copyright\) 2010 RAS, MNRAS 000, 1–11
thus conclude that the ejection of fragments outside the libration zone does not affect the number of observed families among Trojans.

### 4.4 Collisional rates

We can estimate collisional activity by means of a simple stationary model. Trojan–Trojan collisions play a major role here, because Trojans are detached from the Main Belt. In case of Eurybates, the target (parent body) diameter \( D_{\text{target}} = 110 \text{ km} \), the mean impact velocity \( V_{\text{imp}} = 4.7 \text{ km/s} \) (Dell’Oro et al. 1998), the strength \( Q_{\text{PB}} = 10^2 \text{ J/kg} \) (Benz & Asphaug 1999) and thus the necessary impactor size (Bottke et al. 2005)

\[
d_{\text{disrupt}} = \left(2Q_{\text{PB}}/V_{\text{imp}}^2\right)^{1/3} D_{\text{target}} \approx 23 \text{ km}.
\]

Number of \( \geq 23 \text{ km} \) projectiles among \( L_4 \) Trojans is \( n_{\text{project}} = 371 \) and we have \( n_{\text{target}} = 8 \) available targets. An intrinsic collision probability for Trojan–Trojan collisions \( P_i = 7.8 \times 10^{-18} \text{ km}^{-2} \text{ yr}^{-1} \) (Dell’Oro et al. 1998) and corresponding frequency of disruptions is

\[
f_{\text{disrupt}} = P_i D_{\text{target}}^2 n_{\text{project}} n_{\text{target}} \approx 7 \times 10^{-11} \text{ yr}^{-1}.
\]

Over the age of the Solar System \( T_{\text{SS}} \approx 4 \text{ Gyr} \) (after the LHB), we have a very low number of such events \( n_{\text{events}} = T_{\text{SS}} f_{\text{disrupt}} \approx 0.28 \). This number seems to be in concert with only one \( D \geq 100 \text{ km} \) family currently observed among Trojans\(^{10}\). In a less-likely case, the material of the Eurybates parent body was very weak and its strength may be at most one order of magnitude lower, \( Q_{\text{PB}} \approx 10^4 \text{ J/kg} \) (see Leinhardt & Stewart 2009, Bottke et al. 2010). We then obtain \( d_{\text{disrupt}} \approx 10 \text{ km} \) and \( n_{\text{events}} \approx 1.0 \), so the conclusion about the low number of expected Trojan families remains essentially the same.

The parent body of Aneas group is 1.5 larger and consequently the resulting number of events is more than one order of magnitude lower. On the other hand, clusters with smaller parent bodies \( (D_{\text{PB}} \ll 100 \text{ km}) \) or significantly weaker \( (Q_{\text{PB}} \ll 10^3 \text{ J/kg}) \) might be more frequent.

During the Late Heavy Bombardment epoch we may assume a substantial increase of collisional activity (Levison et al. 2009). Hypothetical old families were however probably ‘erased’ due to the late phases of planetary migration (see Section 3.2) unless the migration time scale for Jupiter and Saturn was significantly shorter than the time scale of the impactor flux from transneptunian region which is mainly controlled by the migration of Uranus and Neptune.

### 5 CONCLUSIONS

Increasing number of Trojan asteroids with available proper elements enables us to get new insights into this important population. Essentially, new faint/small asteroids filled the ‘gaps’ in the proper-element space between previously known clusters and today it seems most clusters are rather comparable to background. One should be aware that the number of families among Trojans may be low and one should not take the number of \( \approx 10 \) families as a rule.

Only the C-type Eurybates family fulfils all criteria to be considered a collisional family. This is probably also true for the newly discovered Ennomos group. Moreover, there might be a potentially interesting relation between the high-albedo surface of \((4709)\) Ennomos and the collisional family thought we do not have enough data yet to prove it independently (by colours, spectra or albedos).

Note there may exist clusters among Trojans which are not of collisional origin. They may be caused by: (i) differences in chaotic diffusion rates; (ii) \( a/c \)-dependent efficiency of original capture mechanism; or (iii) it may somehow reflect orbital distribution in source regions.

We cannot exclude a hypothetical existence of old families which were totally dispersed by dynamical processes, e.g., by perturbations due to planetary migration which is especially efficient in the Trojan region.

Finally, note there seem to be no D-type families anywhere in the Solar System — neither in the Trojan region, nor in the \( J_3/2 \) (Brož et al. 2011) and Cybele regions (Vokrouhlický et al. 2010). May be, the D-type parent bodies are too weak and the target is completely pulverized during a collision? This might have important implications for collisional models of icy bodies.

### ACKNOWLEDGEMENTS

We thank David Vokrouhlický, David Nesvorný, Alessandro Morbidelli and William F. Bottke for valuable discussions on the subject. We also thank Lenka Trojanová for his review which helped to improve the final version of the paper. The work has been supported by the Grant Agency of the Czech Republic (grant 205/08/P196) and the Research Program MSM0021620860 of the Czech Ministry of Education. We acknowledge the usage of computers of the Observatory and Planetarium in Hradec Králové and Observatory and Planetarium of Prague.

---

\(^{10}\) A similar stationary estimate valid for the Main Asteroid Belt gives the number of events 12 while the number of observed families with \( D_{\text{PB}} \geq 100 \text{ km} \) is about 20 (Durda et al. 2007). These two numbers are comparable at least to order-of-magnitude.
