In many areas of the brain, neural spiking activity covaries with features of the external world, such as sensory stimuli or an animal’s movement. Experimental findings suggest that the variability of neural activity changes over time and may provide information about the external world beyond the information provided by the average neural activity. To flexibly track time-varying neural response properties, we developed a dynamic model with Conway-Maxwell Poisson (CMP) observations. The CMP distribution can flexibly describe firing patterns that are both under- and overdispersed relative to the Poisson distribution. Here we track parameters of the CMP distribution as they vary over time. Using simulations, we show that a normal approximation can accurately track dynamics in state vectors for both the centering and shape parameters ($\lambda$ and $\nu$). We then fit our model to neural data from neurons in primary visual cortex, “place cells” in the hippocampus, and a speed-tuned neuron in the anterior pretectal nucleus. We find that this method outperforms previous dynamic models based on the Poisson distribution. The dynamic CMP model provides a flexible framework for tracking time-varying non-Poisson count data and may also have applications beyond neuroscience.

1 Introduction

Although many models of neural activity assume that neurons respond with stable responses to external sensory stimuli or movements, there is substantial evidence that neural spiking activity changes over time due to adaptation and plasticity (Brown et al., 2001; Lesica et al., 2007) as well as...
spontaneously (Rokni et al., 2007; Tomko & Crapper, 1974). At the same time, a neuron’s spiking responses on individual trials can be highly variable, even in the controlled settings with constant stimuli. In most previous research, trial-to-trial neural variability is assumed to be Poisson distributed. However, spike count distributions can be substantially more or less variable than Poisson (Maimon & Assad, 2009; Amarasingham et al., 2006; DeWeese et al., 2003; Kara et al., 2000), and that the variability also appears to change over time in many cases (Churchland et al., 2010, 2011). Here we introduce a dynamic model with Conway-Maxwell Poisson observations that can describe non-Poisson spike statistics and track changing response properties.

Variability appears to be an increasingly important feature of neural responses and can act as a signature of decision making (Churchland et al., 2011), movement preparation (Churchland et al., 2006), or stimulus onset (Churchland et al., 2010). Although systems neuroscience has a long history of studying how external variables influence mean firing rates, less is known about response variability. Neural activity changes on different timescales, and distinguishing changes in variability from changes in the mean response based on sparse, spike observations is a nontrivial statistical challenge (DeWeese & Zador, 1998). Statistical tools to accurately track the sources of variability within a given experiment may be useful for understanding neural systems. There has been substantial work developing dynamic Poisson models (Brown et al., 2001; Eden et al., 2004), as well as other Poisson models that can account for fluctuating response properties with latent or observed variables (Czanner et al., 2008; Smith & Brown, 2003). Several models of neural activity with non-Poisson observations have also been described (DeWeese et al., 2003; Gao et al., 2015; Pillow & Scott, 2012), including a static model with Conway-Maxwell Poisson observations (Stevenson, 2016). Each of these models, however, whether static or dynamic, assumes a fixed mean-variance relationship (i.e., fixed dispersion parameters). Here, to flexibly track how neural variability might change over time, we explicitly consider changes in both the mean and dispersion.

Here we develop a dynamic GLM with Conway-Maxwell-Poisson (CMP) observations. The CMP distribution can account for both over- and underdispersion in spike count data. To get the closed-form posterior for state vectors with CMP likelihood, we fit the model using a global gaussian approximation (Laplace approximation). Since the state-space of the dynamic model has Markovian structure, inference is efficient with this approximation, and we estimate the process noise by maximizing the predictive likelihood. After illustrating the proposed method in simulations, we apply it to neural activity from primary visual cortex, place cells in the hippocampus and a speed-tuned neuron in anterior pretectal nucleus. The dynamic CMP model can track changes in both the mean and variance of neural responses and outperforms previous Poisson models.
2 Methods

Here we consider a dynamic GLM with Conway-Maxwell Poisson (CMP) observations to describe time-varying spike counts. We first introduce the model. Although the CMP distribution allows us to flexibly model non-Poisson variability, one major challenge with using this model is that there are no closed-form posteriors for the CMP likelihood. Here, we fit the model using a global gaussian approximation, and we discuss several additional technical challenges that arise when using the CMP distribution with a dynamic GLM. Code is available at https://github.com/weigcdsb/COM_POISSON.

2.1 Dynamic Conway-Maxwell Poisson Model. A count observation $y$, such as the spike count for a neuron, is assumed to follow the CMP distribution, with parameters $\lambda$ and $\nu$. The probability mass function (pmf) of CMP distribution is

\[
P(Y = y|\lambda, \nu) = \frac{\lambda^y}{(y!)^\nu} \cdot \frac{1}{Z(\lambda, \nu)},
\]

where $Z(\lambda, \nu) = \sum_{k=0}^{\infty} \frac{\lambda^k}{(k!)^\nu}$ is the normalizing constant. The shape parameter $\nu \geq 0$ controls different dispersion patterns: equi- ($\nu = 1$), over- ($0 \leq \nu < 1$) or under-dispersion ($\nu > 1$). Three common distributions occur as special cases: the Poisson ($\nu = 1$), the geometric ($\nu = 0$, $\lambda < 1$), and the Bernoulli ($\nu \to \infty$).

For multiple observations up to $T$ steps, such as simultaneous spike counts from $n$ neurons, denote the counts at time bin $t$ as $y_t = (y_{1t}, \ldots, y_{nt})'$, for $t = 1, \ldots, T$. The corresponding CMP parameters at $t$ are $\lambda_t = (\lambda_{1t}, \ldots, \lambda_{nt})'$ and $v_t = (v_{1t}, \ldots, v_{nt})'$. Previous work has examined the CMP-GLM (Chatla & Shmueli, 2018; Sellers & Shmueli, 2010), and here we focus on the dynamic version of this GLM. The CMP parameters at $t$ are modeled by two log-linear models, $\log \lambda_t = X_t \beta_t$ and $\log v_t = G_t \gamma_t$, with $\beta_t \in \mathbb{R}^p$ and $\gamma_t \in \mathbb{R}^q$, and $X_t$ and $G_t$ denote known predictors. Under the CMP-GLM, the parameters are static. Here, we assume that they progress linearly with gaussian noise.

The observations follow conditionally independent CMP distributions, given the state vector $\theta_t = (\beta_t', \gamma_t')'$,

\[
y_t \sim CMP(\lambda_t, v_t),
\]

\[
\log \lambda_t = X_t \beta_t, \quad \log v_t = G_t \gamma_t,
\]

while the state vector $\theta_t$ evolves linearly with gaussian noise:

\[
\theta_1 \sim N_{p+q}(\theta_0, Q_0),
\]

\[
\theta_t|\theta_{t-1} \sim N_{p+q}(F\theta_{t-1}, Q),
\]

(2.2)
given the initial state mean \( \theta_0 \), covariance \( Q_0 \), linear dynamics \( F \), and process covariance \( Q \).

### 2.2 Inference by Gaussian Approximation.

To fit the model to data, we need to estimate the time-varying state vector \( \Theta_1 = (\theta_1', \ldots, \theta_T') \in \mathbb{R}^{(p+q)T} \). In this section, we first assume \( F \) and \( Q \) are known. Since the observations are CMP distributed, we cannot estimate \( \Theta_1 \) in closed form. Instead, here we approximate it by a multivariate gaussian distribution, \( P(\Theta_1 \mid Y) \approx N(\mu, \Sigma) \), with \( Y = (y_1', \ldots, y_T') \). The parameters of this gaussian are found by a global Laplace approximation:

\[
\mu = \arg\max_{\Theta_1} P(\Theta_1 \mid Y) \quad \text{and} \quad \Sigma = -\nabla\nabla_{\Theta_1} \log P(\Theta_1 \mid Y)_{\Theta_1 = \mu}^{-1}.
\]

The log-posterior is given by

\[
\log P(\Theta \mid Y) = \sum_{t=1}^{T} l_t - \frac{1}{2} (\theta_t - \theta_0)'Q_0^{-1}(\theta_t - \theta_0)
- \frac{1}{2} \sum_{t=2}^{T} (\theta_t - F\theta_{t-1})'Q^{-1}(\theta_t - F\theta_{t-1}),
\]

\[
l_t = l(\theta_t) = \log P(y_t | \theta_t) = \sum_{i=1}^{n} y_{it} \log \lambda_{it} - \nu_{it} y_{it}! - \log Z(\lambda_{it}, \nu_{it}). \tag{2.4}
\]

where \( l(\cdot) \)is the log-likelihood. The log-posterior is concave (Gupta et al., 2014), and the Markovian structure of the state vector dynamics makes it possible to optimize by Newton-Raphson (NR) in \( O(T) \) time (Paninski et al., 2010). After the Newton update, we can further quantify the uncertainty for the CMP parameters and the underlying rates, as in appendix A.

There are several technical challenges involved with performing the Newton update with CMP observations. First, in order to find the gradient and Hessian, we need to calculate moments of \( Y_{it} \) and \( \log Y_{it}! \), which have no closed forms (Shmueli et al., 2005). We can calculate these moments by truncated summation. However, when \( \lambda \geq 2 \) and \( \nu \leq 1 \), truncated summation is computationally costly since we need many steps for accurate approximation. In this case, we approximate the moments using previous (Chatla & Shmueli, 2018; Gaunt et al., 2019) asymptotic results, as in appendix B. A second challenge is that the Hessian is not robust to outliers. Outliers often result in the Hessian being close to singular or even positive-definite. (See details in appendix C.) To ensure robustness, we use Fisher scoring where the observed information is replaced by the expected information. Finally, a third challenge is that the Newton updates take a long time to converge if the initial state estimate is far from the maximum of the posterior, especially when \( T \) is large. To resolve this issue, we use a smoothing estimate with local gaussian approximation as a “warm start.” Forward filtering for a dynamic Poisson model has been previously described in Eden et al. (2004), and here we implement CMP filtering following the same rationale. Let
\( \theta_{t|t-1} = E(\theta_t|y_1, \ldots, y_{t-1}) \) and \( \Sigma_{t|t-1} = \text{Var}(\theta_t|y_1, \ldots, y_{t-1}) \) be the mean and variance for the one-step prediction density and \( \theta_{t|t} = E(\theta_t|y_1, \ldots, y_t) \) and \( \Sigma_{t|t} = \text{Var}(\theta_t|y_1, \ldots, y_t) \) be mean and variance for the posterior density, then the filtering update for step \( t \) is given by

\[
\theta_{t|t-1} = F\theta_{t-1|t-1}, \\
\Sigma_{t|t-1} = F\Sigma_{t-1|t-1}F' + Q, \\
\theta_{t|t} = \theta_{t|t-1} + (\Sigma_{t|t}) \left[ \frac{\partial l_t}{\partial \theta_t} \right]_{\theta_{t|t-1}}, \\
\Sigma_{t|t} = \Sigma_{t|t-1} - \left[ \frac{\partial^2 l_t}{\partial \theta_t \partial \theta'_t} \right]_{\theta_{t|t-1}}.
\]  

(2.5)

Here, to again ensure robustness, we use Fisher scoring when updating the state covariance. We then find smoothed estimates using a backward pass (Rauch et al., 1965). Although doing smoothing is fast, the estimates can be inaccurate, especially when there are large changes in the state vector. In the forward filtering stage, the gaussian approximation at each step \( t \) is conducted locally at the recursive prior \( \theta_{t|t-1} \). This will be statistically inefficient when the recursive prior is too far away from the posterior mode or when there is a large change in the state vector. Moreover, Fisher scoring reduces the efficiency of the smoother even further. The smoother provides reasonable initial estimates, but estimation accuracy is substantially improved by using Newton’s method to find the global Laplace approximation for the posterior.

### 2.3 Estimating Process Noise.

For the applications to neural data examined here, we assume that \( F = I \). However, we still need to estimate the process noise \( Q \). When \( n \) is small, especially when \( n = 1 \), different \( Q \) values will have a substantial influence on estimation. One possible way to estimate \( Q \) is to use an expectation-maximization (EM) algorithm as in Macke et al. (2011). However, using the Laplace approximation for \( \Theta \) during the E-step breaks the usual guarantee of nondecreasing likelihoods in EM and may lead to divergence. To avoid that, we could sample the posterior directly by MCMC. However, the lack of closed-form moments for the CMP distribution makes sampling computationally intensive. Here, to estimate \( Q \) robustly and quickly, we instead assume \( Q \) is diagonal and estimate it by maximizing the prediction likelihood in the filtering stage, as in Wei & Stevenson (2021).

### 3 Results

#### 3.1 Tracking the Mean and Dispersion of Spike Counts over Time.

To illustrate how the dynamic CMP model can track both time-varying
mean and dispersion, we simulated a neuron with a time-varying tuning curve, where the response to 100 evenly spaced hypothetical visual stimuli shifts over 100 trials. Here, the neuron’s tuning curve is determined by a linear combination of cubic B-spline basis functions with equally spaced knots. The stimulus that evokes the highest average response, the “preferred orientation,” is initially 80 degrees, but shifts over the course of the experiment, and the response amplitude also increases over time (see Figure 1A). Meanwhile, the dispersion pattern also changes: the responses are initially overdispersed relative to a Poisson distribution and then become under-dispersed (see Figure 1B). Noisy observations are sampled from the Conway-Maxwell Poisson distribution at each time (see Figure 1C), mimicking the types of experimental observations collected during adaptation experiments in primary visual cortex (Dragoi et al., 2000). We then fit the
Figure 2: Constant mean with fluctuations in dispersion. (A) The first two panels show the true mean firing rate and the simulated observations. The last panel shows the fitted mean response. (B) Although the mean response is constant, the Fano factor varies across the trial (black line). The colored lines show the fitted result.

simulated spike observations using the same predictor variables as the generative model: the covariates for $\lambda_t$ capture the tuning curve with $X_t$ as a 10-knot cubic spline basis expansion of the orientation, and the covariate for the shape parameter $\nu_t$ does not depend on the stimulus orientation $G_t$. The fitted results match the ground truth well for both the mean (see Figure 1C) and Fano factors (variance-to-mean ratio, see Figure 1D).

This model-based approach provides estimates of tuning curves and dispersion at each time point. In cases where the tuning curve and variability change simultaneously, this approach can efficiently track both. By using the model with CMP observations, rather than Poisson or negative-binomial observations, the Fano factor can be both less than 1 (under-dispersed) and more than 1 (over-dispersed).

Changes in tuning have been widely documented in systems neuroscience due to changing environment and spontaneous nonstationarity. Changes in variability also occur, but they have been less well studied. With the CMP model, the mean and dispersion are both tracked, and so changes in variability can occur even when the mean is stable. To illustrate this potential, we simulated a neuron whose mean firing rate is controlled to be constant but whose Fano factor varies over time. Here $X_t$ is a 5-knot cubic B-spline basis expansion of the orientation and $G_t = 1$. The model recovers the true mean firing rate (see Figure 2A) and captures the fluctuations in variance (see Figure 2B) at the same time. However, the estimated Fano factor is somewhat oversmoothed when the process noise $Q$ is optimized by maximizing the predictive likelihood (see section 2.3).

Although dynamic Poisson models have been applied in some neuroscientific settings, when spike counts are not Poisson distributed, the model estimates can be biased. Since the dispersion influences estimates of the process noise $Q$, estimates of the mean in the dynamic Poisson model can be affected by over- or under-dispersion. To illustrate this interaction here,
Figure 3: Dynamic CMP and dynamic Poisson estimates differ. Simulated overdispersed place cell spiking is generated by the dynamic CMP model with $\nu_t = 0.1$. (A) We then fit dynamic CMP and dynamic Poisson models with $X_t$, a 2-knot B-spline expansion for position ($G_t = 1$ for the CMP). (B) When evaluating the response at the true preferred position for each run, the dynamic Poisson estimates are biased (underestimated) and the uncertainty is also underestimated. The solid line gives the MAP estimates of mean firing rate, and the dashed lines show 1 SD credible intervals. The standard deviations of dynamic CMP estimates are calculated using the truncated summations (see details in appendix B), while the standard deviations for the dynamic Poisson model are from a log-normal distribution.

we simulate a place cell from the hippocampus whose “place field” drifts over time. The true mean is determined by a gaussian function where the preferred position varies over time. The spike counts are then generated by CMP distributions, here over-dispersed with constant shape parameter $\nu_t = 0.1$. We fit 1000 observations randomly sampled from 100 runs of a linear track. We find that in this data-limited regime, the dynamic Poisson model and the dynamic CMP model give substantially different estimates of the time-varying place field (see Figure 3A). The dynamic Poisson model in this case underestimates the firing rate at the true preferred position and under-estimates the uncertainty (see Figure 3B).

3.2 Application to Experimental Data. We next applied our method to three publicly available data sets of extracellular spike recordings: (1) Utah array recordings of visually evoked activity from anesthetized macaque primary visual cortex (V1 data), (2) multi-shank silicon probe recordings from hippocampus of a rat running back and forth on a linear maze (HC data), and (3) a speed-tuned neuron recorded from the anterior pretectal nucleus (APN) of an awake mouse (APN neuron).

3.2.1 V1 Data. In the V1 data set. CRCNS pvc-11 (Kohn & Smith, 2016), anesthetized macaque monkeys viewed full-field sinusoidal grating movies while neural activity was recorded by a 96-channel “Utah“ array. Extracellular spiking activity was recorded on each electrode, and spike waveform
Dynamic CMP Models for Spike Counts 1195

segments were sorted by hand with modified competitive mixture decomposition methods (Shoham et al., 2003). Here we use data from one animal (monkey 1) viewing a movie of drifting sinusoidal gratings with 100 different drift directions presented in pseudorandom order (300 ms each, 30 s movie in total), and the movie was repeated 120 times. Here we analyze spike counts following each stimulus presentation from the period 50 to 350 ms after stimulus onset, considering the response delay. (For further details on how the data were obtained, see Kelly et al., 2010, and Smith & Kohn, 2008.)

As with many neurons in visual cortex, the responses of the neurons in this data set are tuned to the stimulus direction. Neurons respond to some directions of stimuli more than others, but the spike counts from trial to trial are highly variable. Here, we are specifically interested in tracking changes in tuning curves and changes in variability over time. Figure 4A shows responses from one example neuron with a preferred direction around 240 degrees. This neuron is somewhat direction insensitive and also responds with increased spiking to stimuli moving in the opposite direction, around 70 degrees. After fitting the dynamic CMP model to these data, we find that the tuning curve itself appears mostly stable, but the overall firing rate increases over the course of the recording (see Figure 4B). At the same time, the Fano factor decreases over the course of the recording (see Figure 4C).

Although the data here are structured in 120 trials, the data are collected sequentially, and we model nonstationary at the level of individual observations. For the predictors $X_t$ and $G_t$, we use cubic B-spline basis functions with periodic boundary conditions over the grating directions. Results for the example neuron use 5 and 3 equally spaced knots for $X_t$ and $G_t$, respectively. Fitting the model with half of the data (in a speckled hold-out pattern) gives patterns for the mean response (see Figure 4B) and Fano factor (see Figure 4C) that are similar to those using the full data. However, since the model-based approach provides a continuous estimate of the state vectors, the Fano factor estimated by the dynamic CMP model differs from a simple estimate of the Fano factor calculated using a sliding window (see Figure 4C).

We then compare the performance of multiple models on data from all 74 neurons in this recording (see Figure 4D). We assess four dynamic models: (1) dynamic CMP, with 5 knots for $X_t$ and 3 knots for $G_t$, denoted as $d$CMP-(5,3); (2) dynamic CMP with $G_t = 1$, $d$CMP-(5,1); (3) dynamic CMP with constant $\nu_t$, $d$CMP-(5,1) (fit by coordinate descent), and (4) a dynamic Poisson model, $d$Poi-(5). In addition, we assess three static models: (1) static CMP, sCMP-(5,3); (2) static CMP with $G_t = 1$, sCMP-(5,1); and (3) static Poisson, sPoi-(5). The held-out log-likelihoods relative to a homogeneous static Poisson model show that the CMP-based models, both dynamic and static, outperform the Poisson-based models (see Figure 4D). The dynamic models perform slightly better than the corresponding static models on
Figure 4: Modeling nonstationary spiking from visual cortex. (A) The spike counts of one example neuron from V1 in response to drifting grating stimuli with different drift directions presented over 120 trials. Two preferred directions (estimated by the CMP model) are marked by the dashed lines. (B) Estimated mean for the dynamic CMP model dCMP-(5,3) when fit to all the data and only half of the observations (held out in a speckled pattern). (C) Fano factor estimates for the two models, along with a direct estimate from 15-trial sliding windows, at the two preferred directions. Dashed lines denote ±1 standard deviation around the window estimates, obtained by Bayesian bootstrapping. (D) Model comparison for all 74 neurons in the V1 data set. In these models, 4 are dynamic and the remaining 3 are static, with different noise distributions (Poisson versus CMP) and bases. The training and test log-likelihood ratios (bits/spike) with respect to a homogeneous static Poisson model are shown for all neurons in gray lines. The solid orange lines and numbers denote the medians, and the dashed lines show the first and third quartiles.

The best performance on test data comes from modeling nonstationarity and stimulus dependence with the full dynamic CMP model dCMP-(5,3). However, the benefit of adding nonstationary shape parameter
(dCMP-(5)-ν versus dCMP-(5,1)) and of adding stimulus-dependent shape parameter (dCMP-(5,1) versus dCMP-(5,3)) tend to be small for these data.

3.2.2 HC Data. In the HC data set, CRCNS hc-3 (Mizuseki et al., 2013), a rat was running back and forth along a 250 cm linear track. Extracellular spiking activity was recorded in dorsal hippocampus using multishank silicon probes. Spikes were automatically sorting using KlustaKwik, followed by manual adjustment (Rossant et al., 2016). Here we use data from one 66 minute recording session (ec014-468) and analyze spike counts in 200 ms bins. (For further details on how the data were obtained, see Mizuseki et al., 2014.)

As with many neurons in hippocampus, the responses of the neurons in this data set are tuned to the rat’s position along the track. Neurons spike at specific locations, but the place fields can also shift over time, and the spike counts from run to run are highly variable. Figure 5A shows an example from one neuron with two place fields where the location and firing within the place field vary over the course of the recording. Compared to the data from V1, neural responses of place cells in hippocampus tend to be sparser and more selective. Many place cells also tend to be direction tuned, spiking only when the animal is running in one direction down the track but not the other. We thus fit the data using a dynamic CMP model with 12 equally spaced knots for $X_t$ with a circular representation of position, and let $G_t = 1$.

For this example neuron, the dynamic CMP model accurately tracks the time-varying place field (see Figure 5B). We then evaluate the fitted Fano factors at the peaks of the two place fields (see Figure 5C). Compared to the example from the V1 data, the spiking of this example place cell is much more highly dispersed. The Fano factors vary over time and are also specific in both position and running direction. We then compare model performance on 78 neurons from this recording (19 neurons were excluded due to sparse spiking patterns). In these data, the dynamic models are generally better than the static models (see Figure 5D). Within groups of dynamic or static models, CMP-based models are consistently better than the Poisson-based models.

3.2.3 APN Neuron. To illustrate a case where the dynamic CMP provides a qualitatively better description of neural activity compared to previous models, we show results from one neuron recorded from the Allen Institute Visual Coding Neuropixels data set. (See the detailed data description in Siegle et al., 2021.) Here, when examining tuning to running speed, we found a neuron in APN, whose responses were speed tuned, increasing firing with increasing running speed (see Figure 6A), but also highly under-dispersed relative to a Poisson distribution (Fano factor <1). We analyzed spike counts in 200 ms bins for the 160 minute recording (ecephys_session_id 719161530, unit_id 950917034) and fit the spiking
Figure 5: Modeling nonstationarity in hippocampal spiking activity. (A) Spike counts of an example neuron from the hippocampus recorded while a rat was running back and forth on a linear maze. The blue lines show the animal’s position over time. The black circles denote spike counts with the radius of each circle corresponding to number of spikes. (B) The heat map shows fitted mean firing rate for the dynamic CMP model dCMP-(12,1). The colored lines show peaks for two place fields, chosen based on the model fit. (C) The estimated Fano factors at the two place field peaks, with each running direction (+ versus −) shown separately. (D) The training and test log-likelihood ratios (bits/spike) with respect to a homogeneous static Poisson model for 78 neurons (gray lines). Here the test set log-likelihood ratios are calculated using 5% of the data held out in a speckled pattern. The red solid lines and numbers denote median values, while the dashed lines show the first and third quartiles.

Evaluating all of the data and averaging over time, the neuron is significantly under-dispersed (Fano factors less than 1), and both the mean response and dispersion appear tuned to running speed (see Figure 6B). However, we found that this neuron’s speed tuning is somewhat nonstationary, with the baseline firing rate shifting over time (see Figure 6C). Within individual segments of the recording, the Fano factor is much lower than the Fano factor evaluated for the entire recording. Moreover, the Fano factor within each chunk does not show a strong relationship to running speed.

activity for the whole session using the dynamic CMP model. Here we use a nonlinear function of the running speed $v_t$ for the $X_t = [1 f(v_t)] (f(v) = v/(1 + 0.1v))$ and $G_t = [1 v_t]$. 

Evaluating all of the data and averaging over time, the neuron is significantly under-dispersed (Fano factors less than 1), and both the mean response and dispersion appear tuned to running speed (see Figure 6B). However, we found that this neuron’s speed tuning is somewhat nonstationary, with the baseline firing rate shifting over time (see Figure 6C). Within individual segments of the recording, the Fano factor is much lower than the Fano factor evaluated for the entire recording. Moreover, the Fano factor within each chunk does not show a strong relationship to running speed.
Figure 6: Modeling a speed-tuned neuron in mouse anterior pretectal nucleus with the dynamic CMP model. Here we analyze a 160 minute recording of a neuron from APN, with spike counts calculated in 200 ms bins. The whole session was evenly partitioned into chunks for visualization. (A) Spike counts and mouse running speed for the recording session. (B) The spiking activity and Fano factor as a function of speed for the whole session. Dots denote results from observed spike counts. Error bars denote 95% confidence intervals from Bayesian bootstrapping. Red lines denote fits from the dynamic CMP model averaged over time. (C) The top row shows 2D histograms for spiking counts versus running speed for each chunk. The second row shows corresponding model fitted densities (averages within each chunk). The lines show predicted average spike counts (tuning curves) for each chunk. (D) There is substantial variation in the tuning curves across chunks, and the Fano factor tends to be smaller on individual chunks than in the overall recording.

speed (see Figure 6D). This suggests that the apparent relationship between running speed and the overall Fano factor is a by-product of the nonstationarity. Using the static CMP model may be able to describe the under-dispersion of these responses but would miss this key feature of the data by assuming that the tuning curve is static. The dynamic Poisson model, on the other hand, is able to describe the nonstationary in the tuning curve but cannot describe the under-dispersion of these data, since the Poisson model always assumes Fano factor $= 1$.

4 Discussion

Here we introduced a dynamic CMP model to track changes in both the mean and dispersion of neural spikes over time. A global Laplace approximation with a smoothing-based initialization can provide accurate and computationally efficient model estimates. In both simulations and applications with experimental data, we find that this model out-performs previous static and dynamic Poisson models and may thus be a useful tool for understanding the role of variability in neural systems. While many studies have characterized noise (DeWeese et al., 2003; Deweese & Zador,
2004; Taouali et al., 2016) or nonstationarity (Tomko & Crapper, 1974; Wu & Hatsopoulos, 2008) separately, modeling changes in the mean-variance relationship directly may allow us to more closely examine the role of variability in the brain.

The original motivation for the development the CMP distribution is from industrial research on queuing theory where production resources are allocated in a state-dependent way to meet demand (Conway & Maxwell, 1962). Although spiking neurons may not be exactly analogous to production queues, they are multi-input, single-output, resource-limited nonlinear systems. Previous studies have proposed that resources in neurons may be dynamically allocated across dendrites (Acharya et al., 2022) and that neural networks may share some features with queued, packet-switching systems (Luczak et al., 2015).

The extent to which the dynamic CMP model can predict neural responses more accurately than the dynamic Poisson model or static non-Poisson models depends on the neural activity itself. Here with the V1 data we found a 6% improvement in test log-likelihood ratios between the dynamic and static CMP, while in the HC data, there is a 35% improvement. The extent of spontaneous changes in neural responses is somewhat unclear; some evidence suggests that neurons can be relatively stable in some circumstances (Chestek et al., 2007; Stevenson et al., 2011; Dickey et al., 2009), but variability appears to differ across brain areas (Mochizuki et al., 2016). More accurate spike sorting may account for some degree of instability (Steinmetz et al., 2021), and the degree of spontaneous changes may also depend on the brain area (Rule et al., 2019). However, neurons do clearly change both their average responses and dispersion in many situations.

Although the current model works well for fitting neural spikes, there are some potential improvements. First, the state transition matrix $F$ is currently assumed to be known and is fixed to $I$ for convenience in our simulations and experimental analysis. This does not allow for interactions between state vectors and may limit the usage in some situations. However, when using a Laplace approximation for the state vectors, $F$ can be estimated using the EM algorithm as in Macke et al. (2011). Second, although the CMP distribution can flexibly model over- and under-dispersed data, the assumed mean-variance relationship may not be appropriate in some cases. To more flexibly model the dispersion for single observations, it may be useful to instead consider the generalized count (GC) distribution (del Castillo & Pérez-Casany, 2005), which includes the CMP distribution as a special case. This model has been applied in the context of linear dynamical systems, similar to the dynamical factor analysis model, with a fixed dispersion function (Gao et al., 2015). To track fluctuations in dispersion more flexibly, it could be useful to allow the function to vary dynamically similar to $\nu_i$ in the dynamic CMP model here.
The best modeling strategy also likely depends on what researchers want to know about the variability. Omitted variables (Stevenson, 2018; Goris et al., 2014) and history effects (Uzzell & Chichilnisky, 2004) can alter apparent observation noise. For example, in the hippocampus, place cell firing is highly variable on different passes through the field (Fenton & Muller, 1998). This may be partially due to joint selectivity to position, speed, and head direction, as well as the influence of local field potentials. Here, rather than model these distinct covariates assuming Poisson observations, we allow the variability to be non-Poisson and introduce a dynamic GLM with CMP observations. However, doubly stochastic Poisson models (Barbieri et al., 2001) or latent variable models with fixed mean-variance relationships (Gao et al., 2015; Pillow & Scott, 2012) may also be able to account for some differences in the variance over time. Nonetheless, the dynamic CMP model may provide a useful tool for neuroscientists to study the role of variance directly. Since the static CMP model can improve decoding of external variables in some cases (Ghanbari et al., 2019), the dynamic CMP may lead to further improvements in decoding by tracking nonstationarity in neural response properties.

Appendix A: Quantifying Uncertainties

After convergence, we have an approximation of the log-posterior $P(\theta_t|Y) \approx N(\theta_t|\mu_t, \Sigma_t)$, and we can use this approximation to quantify the uncertainty about the CMP parameters, as well as about the mean rate at each time.

The CMP parameters are log-normal-distributed. Let $Z_{it} = \begin{pmatrix} x_{it}' & 0 \\ 0 & g_{it}' \end{pmatrix}$; then $(\lambda_{it}, \nu_{it})' = \exp(Z_{it}\theta_t) \sim \text{Lognormal}_2(Z_{it}\mu_t, Z_{it}\Sigma_t Z_{it}')$. Denote the variance of CMP parameters as $V_{it}$, where for $a = Z\mu$ and $S = Z\Sigma Z'$, $[V]_{mn} = e^{a_m + a_n + 1/2(S_{mm} + S_{nn})} (e^{S_{mn}} - 1)$.

The conditional mean firing rate is $\delta_{it} = E(Y_{it})$, whose variance can be calculated by the delta method:

$$\widetilde{\text{Var}}(\delta_{it}) = \begin{pmatrix} \frac{\partial \delta_{it}}{\partial x_{it}} & \frac{\partial \delta_{it}}{\partial g_{it}} \\ \frac{\partial \delta_{it}}{\partial x_{it}} & \frac{\partial \delta_{it}}{\partial g_{it}} \end{pmatrix} V_{it} \begin{pmatrix} \frac{\partial \delta_{it}}{\partial x_{it}} & \frac{\partial \delta_{it}}{\partial g_{it}} \\ \frac{\partial \delta_{it}}{\partial x_{it}} & \frac{\partial \delta_{it}}{\partial g_{it}} \end{pmatrix}.$$  

$$\frac{\partial \delta_{it}}{\partial \lambda_{it}} = \frac{\partial^2 \log Z_{it}}{\partial \log \lambda_{it} \partial \lambda_{it}} = \frac{\text{Var}(Y_{it})}{\lambda_{it}}.$$  

$$\frac{\partial \delta_{it}}{\partial \nu_{it}} = \frac{\partial^2 \log Z_{it}}{\partial \log \nu_{it} \partial \nu_{it}} = -\text{Cov}(Y_{it}, \log Y_{it}).$$ (A.1)
We can calculate the moments as in appendix B, or we can use simpler approximations: $E(Y) = \lambda^{1/\nu} - \frac{\nu-1}{2\nu}$ when $\nu \leq 1$ or $\lambda > 10^\nu$. Then $\frac{\partial \delta_t}{\partial \lambda_t} \approx \frac{1}{\nu_t} \lambda_t^{1/\nu_t - 1}$ and $\frac{\partial \delta_t}{\partial \nu_t} \approx -\frac{\lambda_t^{1/\nu_t} \log \delta_t}{\nu_t^2} - \frac{1}{2\nu_t^2}$.

Appendix B: Moments Approximation for Conway-Maxwell Poisson Distribution

To estimate the state-vector for the dynamic CMP model, we need to find first and second moments for $Y$ and $\log Y$! For $Y \sim CMP(\lambda, \nu)$,

\[ Z(\lambda, \nu) = \sum_{k=0}^{\infty} \frac{\lambda^k}{(k!)^\nu}, \]

\[ E(Y) = \frac{\partial \log Z}{\partial \log \lambda} = \frac{1}{Z} \sum_{k=0}^{\infty} \frac{k\lambda^k}{(k!)^\nu}, \]

\[ \text{Var}(Y) = \frac{\partial^2 \log Z}{\partial (\log \lambda)^2} = \frac{1}{Z} \sum_{k=0}^{\infty} \frac{k^2\lambda^k}{(k!)^\nu} - E^2(Y) \]

\[ E(\log Y!) = -\frac{\partial \log Z}{\partial \nu} = \frac{1}{Z} \sum_{k=0}^{\infty} \frac{(\log k!)\lambda^k}{(k!)^\nu}, \]

\[ \text{Var}(\log Y!) = \frac{\partial^2 \log Z}{\partial \nu^2} = \frac{1}{Z} \sum_{k=0}^{\infty} \frac{(\log k!)^2\lambda^k}{(k!)^\nu} - E^2(\log Y!), \]

\[ \text{Cov}(Y, \log Y!) = -\frac{\partial^2 \log Z}{\partial \log \lambda \partial \nu} = \frac{1}{Z} \sum_{k=0}^{\infty} \frac{(\log k!)\lambda^k}{(k!)^\nu} - E(\log Y!)E(Y). \quad (B.1) \]

Generally these moments can be calculated by truncated summation. However, when $\lambda \geq 2$ and $\nu \leq 1$, we need many steps for accurate approximation. In this case, we make use of a previous asymptotic results (Chatla & Shmueli, 2018; Gaunt et al., 2019) for efficient calculation. Let $\alpha = \lambda^{1/\nu}$, $c_1 = \frac{v^2-1}{24}$ and $c_2 = \frac{v^2-1}{48} + \frac{c_1^2}{2}$:

\[ Z(\lambda, \nu) = \frac{e^{\nu \alpha}}{\lambda^{\frac{\nu-1}{2\nu}} (2\pi)^{\frac{v-1}{2\nu}} \sqrt{v}} (1 + c_1 (\nu \alpha)^{-1} + c_2 (\nu \alpha)^{-2} + O(\lambda^{-3/\nu})). \quad (B.2) \]

Then the moments can be calculated as follows:

\[ E(Y) = \alpha - \frac{\nu - 1}{2\nu} - \frac{v^2 - 1}{24v^2} \alpha^{-1} - \frac{v^2 - 1}{24v^3} \alpha^{-2} + O(\alpha^{-3}), \]
\[
\text{Var}(Y) = \frac{\alpha}{v} + \frac{v^2 - 1}{24v^3} \alpha^{-1} + \frac{v^2 - 1}{12v^4} \alpha^{-2} + \mathcal{O}(\alpha^{-3}),
\]

\[
E(\log Y!) = \alpha \left( \frac{\log \lambda}{v} - 1 \right) + \frac{\log \lambda}{2v^2} + \frac{1}{2v} + \frac{\log 2\pi}{2}
- \frac{\alpha^{-1}}{24} \left( 1 + \frac{1}{v^2} + \frac{\log \lambda}{v^2} - \frac{\log \lambda}{v^3} \right)
- \frac{\alpha^{-2}}{24} \left( \frac{1}{v^3} + \frac{\log \lambda}{v^4} - \frac{\log \lambda}{v^5} \right) + \mathcal{O}(\alpha^{-3}),
\]

\[
\text{Var}(\log Y!) = \frac{\alpha(\log \lambda)^2}{v^3} + \frac{\log \lambda}{v^3} + \frac{1}{2v^2}
+ \frac{\alpha^{-1}}{24v^5} \left[ -2v^2 + 4v \log \lambda + (-1 + v^2)(\log \lambda)^2 \right]
+ \frac{\alpha^{-2}}{24v^6} \left[ -3v^2 - 2v(-3 + v^2) \log \lambda + 2(-1 + v^2)(\log \lambda)^2 \right]
+ \mathcal{O}(\alpha^{-3}),
\]

\[
\text{Cov}(Y, \log Y!) = \frac{\alpha \log \lambda}{v^2} + \frac{1}{2v^2} + \frac{\alpha^{-1}}{24} \left( \frac{2}{v^3} + \frac{\log \lambda}{v^2} - \frac{\log \lambda}{v^4} \right)
- \frac{1}{24\alpha^2} \left( \frac{1}{v^2} - \frac{3}{v^4} - \frac{2\log \lambda}{v^3} + \frac{2\log \lambda}{v^5} \right) + \mathcal{O}(\alpha^{-3}). \quad (B.3)
\]

### Appendix C: Gradient and Hessian of the Log-Posterior

We estimate the state vector by maximizing the log-posterior with Newton-Raphson updates. Denote \( f = P(\Theta | Y) \); the \((k + 1)\)th update of NR algorithm is \( \Theta^{(k+1)} = \Theta^{(k)} + [\nabla \nabla_{\Theta} f]^{-1} \nabla_{\Theta} f \). The gradient is:

\[
\nabla_{\Theta} f = \left[ \left( \frac{\partial f}{\partial \theta_1} \right)', \ldots, \left( \frac{\partial f}{\partial \theta_T} \right) \right]',
\]

\[
\frac{\partial f}{\partial \theta_1} = \frac{\partial l_1}{\partial \theta_1} - Q_0^{-1}(\theta_1 - \theta_0) + F'Q^{-1}(\theta_2 - F\theta_1),
\]

\[
\frac{\partial f}{\partial \theta_t} = \frac{\partial l_t}{\partial \theta_t} - Q^{-1}(\theta_t - F\theta_{t-1}) + F'Q^{-1}(\theta_{t+1} - F\theta_t),
\]

\[
\frac{\partial f}{\partial \theta_T} = \frac{\partial l_T}{\partial \theta_T} - Q^{-1}(\theta_T - F\theta_{T-1}),
\]

\[
\frac{\partial l_t}{\partial \theta_t} = \sum_{i=1}^{n} \left( y_{it} - E(Y_{it}) \right) x_{it} \left( E(\log Y_{it}) - \log y_{it} \right) g_{it}. \quad (C.1)
\]
The Hessian matrix is
\[
\nabla^2 \nabla \theta f = \begin{pmatrix}
\frac{\partial^2 f}{\partial \theta_1 \partial \theta'_1} & F' Q^{-1} & 0 & \cdots & 0 \\
Q^{-1} F & \frac{\partial^2 f}{\partial \theta_2 \partial \theta'_2} & F' Q^{-1} & \cdots & : \\
0 & Q^{-1} F & \frac{\partial^2 f}{\partial \theta_3 \partial \theta'_3} & \cdots & : \\
& & \vdots & \ddots & \ddots & \vdots \\
0 & \cdots & \cdots & \cdots & \frac{\partial^2 f}{\partial \theta_T \partial \theta'_T}
\end{pmatrix},
\]

where
\[
\frac{\partial^2 f}{\partial \theta_i \partial \theta'_i} = \frac{\partial^2 l_i}{\partial \theta_i \partial \theta'_i} - Q^{-1} - F' Q^{-1} F,
\]
\[
\frac{\partial^2 f}{\partial \theta_i \partial \theta'_i} = \frac{\partial^2 l_i}{\partial \theta_i \partial \theta'_i} - Q^{-1} - F' Q^{-1} F,
\]
\[
\frac{\partial^2 f}{\partial \theta_T \partial \theta'_T} = \frac{\partial^2 l_T}{\partial \theta_T \partial \theta'_T} - Q^{-1}, \tag{C.2}
\]

where
\[
\frac{\partial^2 l_i}{\partial \theta_i \partial \theta'_i} = \sum_{i=1}^{n} \begin{pmatrix}
A_{it} & B_{it} \\
B_{it}' & C_{it}
\end{pmatrix},
\]
\[
A_{it} = \text{Var}(Y_{it}) x_{it} x_{it}',
\]
\[
B_{it} = -v_{it} \text{Cov}(Y_{it}, \log Y_{it}!) x_{it} g_{it}^g,
\]
\[
C_{it} = v_{it} [v_{it} \text{Var}(\log Y_{it}) - E(\log Y_{it}!) + \log y_{it}!] g_{it}^g g_{it}^{g'} \tag{C.3}
\]

When \( \log y_{it}! \ll E(\log Y_{it}!) \), the Hessian may be ill conditioned or even positive-definite. To ensure the robustness, do Fisher scoring: replace the observed information \(-\nabla^2 \nabla \theta f\) by the expected information \(E(-\nabla^2 \nabla \theta f)\), so that \(C_{it} = v_{it}^2 \text{Var}(\log Y_{it}!) g_{it}^g g_{it}^{g'}\).

The observed information may provide more accurate estimates of the variance at the MAP estimate (Efron & Hinkley, 1978), but these estimates may not be robust. Robustness to outliers is especially necessary for convergence during the optimization of CMP models (Green, 1984; Chatla & Shmueli, 2018).
