(Received 13 February 2020; accepted 9 April 2020; published 26 May 2020)

The velocity distribution of a hot ionic beam can be filtered with a narrow stimulated Raman process to prepare a colder subensemble, as substantiated in this theoretical analysis. Using two counterpropagating far-detuned lasers, we can define a \( \pi \) pulse for the resonant velocity to transfer atoms within the linewidth of the Raman resonance between the ground states of a \( \Lambda \) system. Spontaneous emission from the two single-photon resonances, as well as the ground-state decoherence induced by laser noise, diminishes the efficiency of the filter. From a comprehensive master equation, we obtain conditions for the optimal frequency pair of lasers and evaluate the filter performance numerically as well as analytically. If we apply this analysis to current \( ^{40}\text{Ca}^{+} \) ion experiments, we obtain a sensitivity for measuring high ion acceleration voltages on the ppm level or below.

I. INTRODUCTION

“The wonderful blue opalescence of the Mediterranean Sea” is one of the phenomena that Raman attributes to the effect he discovered [1–3] a century ago. Inelastic two-photon scattering, as we know it today, has found innumerable applications from solid-state spectroscopy and enhanced microscopic imaging [4] to actively cooling atoms with velocity-selective coherent population trapping [5]. It is our aim to extend the use of Raman transitions for spectroscopy on fast ion beams with several-keV kinetic energy. We propose a Raman velocity filter to selectively prepare the population of a metastable state for subsequent precision spectroscopy.

A. Motivation

In the context of fast ion and atom beams, collinear laser spectroscopy [6–8] allows us to perform investigations of optical transitions with high resolution and sensitivity. The salient feature is the kinematic compression of the velocity width due to the electrostatic acceleration that reduces the Doppler width of initially hot thermal samples to the typical natural linewidth of allowed optical dipole transitions [6]. This and the fast transport of the ions make it the ideal tool to study short-lived isotopes with lifetimes in the millisecond range that are produced at online facilities [9,10]. Such investigations are usually performed to determine nuclear ground-state properties such as spins, charge radii, and electromagnetic nuclear moments [10–13]. Collinear laser spectroscopy has also been used for ultratrace analysis of long-lived isotopes at very low abundance [14] and was proposed as a technique to measure high voltages \( U \) with very high precision by Doppler velocimetry [15–17].

While the kinematic compression of collinear laser spectroscopy can produce spectra with resolution close to the limit of the natural linewidth, this is not always the case. Especially if the ions are generated in a plasma, e.g., in an electron-cyclotron resonance source, or in a region with strong electric fields such as a liquid metal ion source, a substantial residual broadening can remain. Moreover, the ground state of the ion is not always the most appropriate initial level for the spectroscopy. An excited metastable level might be better suited for the purpose of an experiment, for example, if the transition from this level can provide atomic hyperfine fields with better accuracy or a higher angular momentum provides the possibility to determine the nuclear spin. In such cases population transfer has already being used for collinear laser spectroscopy [18] but only while the ions are stored in a linear Paul trap filled with buffer gas to accumulate and store the ions. Pulsed lasers address ions of all velocity classes and efficiently excite them into a higher-lying state that has a decay branch into the metastable state to be addressed by collinear laser spectroscopy after ejection from the trap. Such a scheme often suffers from various decay paths into a multitude of levels after the resonant excitation. In a Raman transition, population is transferred between two levels without real occupation of a third level with potential leakage into dark states. Only a single experiment has reported a Raman transition in collinear laser spectroscopy so far: In [19] a transition between two hyperfine components of \( \text{Y}^{+} \) was induced using a single laser beam which was frequency modulated with an electro-optic modulator.

Here we investigate theoretically the possible use of Raman transitions in collinear laser spectroscopy to selectively transfer ions from the ground state to a higher-lying metastable state. Beams from different lasers have to be used to bridge the large excitation energy. We are particularly interested in the usage of the Raman scheme as a velocity filter.
to prepare ions with a very narrow velocity distribution in an excited state to perform afterward high-resolution collinear laser spectroscopy on this excited population. As a potential application for such a scheme, we have addressed high-voltage measurements using Ca$^+$ ions. We investigate the influence of interaction time, atomic velocity, laser linewidth, and laser intensity on the excitation efficiency. Our results suggest that Raman transitions can be used with the available laser beams to considerably improve the measurement accuracy with Ca$^+$ ions for high-voltage measurements. This approach will be tested experimentally in the near future and might become the basis for further improvements of laser-based high-voltage measurements, which is of great interest for several applications, e.g., the neutrino mass measurement of the KATRIN experiment [20–22].

B. Spectroscopic high-voltage measurements

Recently, it was demonstrated that an accuracy $s = \Delta U/U$ of at least a few ppm can be reached for high voltages up to 20 kV [23] in laser spectroscopic high-voltage measurements. This is very close to the performance of the world’s best high-voltage dividers [20,21]. In the corresponding measurements two transitions in calcium, shown in Fig. 1, have been employed. The $|g\rangle = (4s^2S_{1/2}) \rightarrow |e\rangle = (4p^2P_{3/2})$ resonance transition was first used to transfer population from the ionic ground level into the metastable level $|m\rangle = (3d^2D_{5/2})$ via a sequential stimulated absorption and spontaneous emission cycle. For this process laser 1 is counterpropagating to the ion beam and the laser frequency determines the longitudinal velocity of the ions required to match the Doppler-shifted resonance condition. Afterwards, the ions are accelerated and the velocity of those ions that are in the metastable state is determined with a second laser tuned to the Doppler-shifted $|m\rangle \rightarrow |e\rangle$ transition. The resonance is observed using the fluorescence light emitted in the subsequent decay into the ground state. The frequencies in the laboratory frame of both lasers are measured with a frequency comb and are used to calculate the shift in frequency and the corresponding acceleration voltage.

While an $s = 5$ ppm uncertainty level has been achieved by now, we are investigating other approaches that promise even higher accuracy for high-voltage measurements. One of the critical issues using the Ca$^+$ ionic beam is the remaining transverse emittance of the beam. Due to the 23-MHz width of the resonance transition, ions with small angles relative to the laser beam direction might also be excited and the angle with respect to the laser beam might be changed during the acceleration with the high voltage to be measured; however, measures to avoid this have been taken: The ion optics of the acceleration region has been designed to suppress such effects by accelerating in the focal region and shaping the beam afterward again into a beam with similar parameters (size and opening angle) as before. A second point is that several excitations are often needed to transfer the ion from the ground state to the metastable state, which is accompanied by uncontrollable recoil effects due to the momentum transfer in absorption and emission.

C. Raman velocimetry

Here we elaborate on the possible use of Raman transitions between $|g\rangle$ and $|m\rangle$ by applying a co- and a counterpropagating laser beam, as depicted in Fig. 2, to reduce corresponding uncertainties with the existing excitation scheme. The advantage is that the selectivity of the narrow Raman transition with respect to the atoms’ initial velocity as well as to the angle between the laser direction and the atoms’ movement is considerably higher than for the allowed dipole transitions used so far. This will provide better control of the initial conditions of the atoms prepared in the metastable state before the acceleration. The theoretical treatment is based on the experimental boundary conditions at the collinear apparatus for laser spectroscopy and applied sciences at TU Darmstadt, where the previous high-voltage measurements were performed. However, the derived models are universally applicable to three-level $\Lambda$ systems together with fast atomic motion.

D. Structure of the article

This article is organized as follows. In Sec. II we present the experimental setup and formulate an appropriate master equation in the classical kinetic regime in Sec. II B. Section III contains analytical models and their results for the population transfer into the metastable state, matching the numerical results. Therewith we can answer the question if the achieved transferred population into the metastable state is sufficient for the realization of optical high-voltage measurements with spectroscopic precision.

FIG. 2. Two counterpropagating lasers with wave number vectors $k_1 = -k_1 e_i$ and $k_2 = k_2 e_i$ interact with the ions, which move with velocity $v = v e_i$ parallel to laser 2. Wave numbers and scalar velocities are positive quantities $k_i, v > 0$.

II. ION-LASER INTERACTION

The Raman spectroscopy is formed with two counterpropagating laser beams that interact with $^{40}$Ca$^+$, moving with velocity $v$ in the same direction as laser 2 (cf. Fig. 2).

A. Ironic velocity distribution

In the beamline, ions get accelerated by a high voltage $U$. For the typical value $U = 14$ kV, one can estimate the mean velocity $\bar{v}$ from energy conservation

$$eU = \frac{mv^2}{2}.$$ (1)

For singly charged $^{40}$Ca$^+$, one finds a mean velocity of $\bar{v} = 260$ km s$^{-1} = 8.7 \times 10^4 c$, which is much smaller than the speed of light $c$ and justifies a nonrelativistic treatment.

Due to technical reasons, the ensemble emerges with an artificial velocity distribution $f(v)$, which is depicted in Fig. 3. It exhibits an initial residual velocity spread $\Delta v_1 = 10$–100 m s$^{-1}$ (FWHM). The spectroscopy is performed in an interaction zone of length $L = 1.2$ m. This gives a mean transit time $\bar{t} = L/\bar{v} = 4.62 \mu$s. Due to the velocity spread, an interaction time spread $\Delta \tau/\bar{t} = \Delta v_1/\bar{v}$ arises. For the maximal velocity width $\Delta v_1 = 100$ m s$^{-1}$, one finds a time spread $\Delta \tau = 1.7$ ns, which is negligible. In the short time of the spectroscopy pulse, we can neglect binary interactions or other charge effects.

Due to the large momentum uncertainty $m\Delta v_1 \gg \hbar k_z$ compared to the photon momentum recoil, we disregard mechanical light effects. Therefore, the position $z$ and the momentum of the particle $p = mv$ can be treated as parameters. Consequently, observables are obtained by static averaging over the initial phase-space distribution. At first, we will assume that the laser and the ion beam are spatially homogeneous. This is rectified in Sec. III C 3, when we consider spatial variations.

B. Optical Bloch equations

We assume a closed three-level system for the electronic structure of the ions, consisting of the ground-state manifold $4s^2S_{1/2}$, the excited state $4p^2P_{3/2}$, and the metastable state $3d^2D_{3/2}$, depicted in Fig. 1. The lifetime $\tau_{\text{avg}} = 1.168 (7) \text{ s}$ of the metastable state is much longer than the duration of the spectroscopy and therefore it is considered as stable. Further calcium data and laser parameters are provided in Tables I and II.

To model the interaction, we use the rest frame of an ion moving with velocity $v$. Thus, the laboratory frame laser frequencies get Doppler shifted

$$\omega_i' = \omega_i - k_i \cdot v = \left( \frac{\omega_i + k_1 v}{\omega_i - k_2 v}, \frac{\omega_i + k_1 v}{\omega_i - k_2 v}, \frac{\omega_i + k_1 v}{\omega_i - k_2 v} \right),$$ (2)

using the vacuum dispersion $\omega_i = c k_i$. Furthermore, we assume that the ions and lasers propagate exactly in the $z$ direction with no relevant transversal inhomogeneity. This leads to an effective one-dimensional description with the effective $\Lambda$ Hamilton matrix

$$\mathcal{H}_{ij} = \hbar \left( \begin{array}{ccc} \Delta_1 & \frac{\Delta_2}{2} & 0 \\ \frac{\Delta_2}{2} & 0 & \frac{\Delta_3}{2} \\ 0 & \frac{\Delta_3}{2} & \Delta_2 \end{array} \right).$$ (3)

It is based on the electric dipole interaction in the rotating-wave approximation [25] with basis states sorted as $i \in \{g, e, m\}$. The strength of the dipole interaction is measured

TABLE I. Parameters for $^{40}$Ca$^+$ transitions between the states $|g\rangle$, $|e\rangle$, and $|m\rangle$, of the configurations $4s^2S_{1/2}$, $4p^2P_{3/2}$, and $3d^2D_{3/2}$.

by the Rabi frequency $\Omega_1 = -\epsilon d_{ge} E_i / \hbar$, with dipole matrix element $d_{ge}$, laser polarization $\epsilon_i$, and electric field amplitude $E_i$. The detunings of laser 1 ($\Delta_1$) and laser 2 ($\Delta_2$) define the one- ($\Delta$) and two-photon detuning ($\delta$), following from the energy diagram in Fig. 1.

$$\begin{align*}
\Delta_1 &= \omega_1 + k_1 v - \omega_{eg} = \Delta_{1,0} + k_1 v, \\
\Delta_2 &= \omega_2 - k_2 v - \omega_{em} = \Delta_{2,0} - k_2 v \equiv \Delta, \\
\delta &= \Delta_1 - \Delta_2,
\end{align*}$$

(4)

denoting transition frequencies as $\omega_{ij} = \omega_i - \omega_j$. Herein we will frequently consider the limit of weakly saturated transitions. This is conveniently captured by the saturation parameters. This is conveniently captured by the saturation parameters. This is conveniently captured by the saturation parameters. This is conveniently captured by the saturation parameters. This is conveniently captured by the saturation parameters.

An ensemble of ions interacting with lasers in free space establishes an open quantum system and must be described by a master equation for the semiclassical density operator $\hat{\rho}(t; z, v)$,

$$\dot{\hat{\rho}} = -\frac{i}{\hbar} [\hat{H}, \hat{\rho}] + (\hat{L}_{eg} + \hat{L}_{em} + \hat{L}_{gg} + \hat{L}_{mm}) \hat{\rho},$$

(6)

with the Lindblad operators (cf. Appendix A)

$$\hat{L}_\delta \hat{\rho} \equiv \frac{\Gamma_\delta}{2} (2\delta \hat{\rho} \delta^\dagger - \delta^\dagger \delta \hat{\rho} - \hat{\rho} \delta^\dagger \delta).$$

(7)

The first term of the master equation describes the coherent dynamics. The second and third terms represent spontaneous transitions to the ground state $|g\rangle$ and metastable state $|m\rangle$ with decay rates $\Gamma_{eg}$ and $\Gamma_{em}$, respectively. The fourth and fifth terms consider ground-state dephasing due to finite laser linewidths $\Gamma_{gg}$ of laser 1 and $\Gamma_{mm}$ of laser 2 [26–31]. If one represents the master equation in a basis and

arranges the matrix elements of $\rho = \rho_{ij}$ as a list accordingly (cf. Appendix B), one obtains

$$\dot{\rho}(t; v) = L(v) \rho(t; v).$$

(8)

Explicitly, these optical Bloch equations (OBEs) read

$$\begin{align*}
\dot{\rho}_{ee} &= -\Gamma_{ee} \rho_{ee} + \frac{i}{2} (\Omega_1^2 \rho_{eg} + \Omega_2^2 \rho_{em} - \text{H.c.}), \\
\dot{\rho}_{eg} &= \Gamma_{eg} \rho_{ee} + \frac{i}{2} (\Omega_1 \rho_{eg} - \Omega_1^* \rho_{ge}), \\
\dot{\rho}_{em} &= \Gamma_{em} \rho_{ee} + \frac{i}{2} (\Omega_2 \rho_{me} - \Omega_2^* \rho_{em}),
\end{align*}$$

(9)

denoting transitions. This is conveniently captured by the saturation parameters. This is conveniently captured by the saturation parameters. This is conveniently captured by the saturation parameters. This is conveniently captured by the saturation parameters. This is conveniently captured by the saturation parameters.

for the populations and

$$\begin{align*}
\dot{\rho}_{eg} &= (i \Delta_1 - \Gamma_1) \rho_{eg} + \frac{i}{2} \{\Omega_1 (\rho_{ee} - \rho_{gg}) - \Omega_2 \rho_{mg}\}, \\
\dot{\rho}_{em} &= (i \Delta_2 - \Gamma_2) \rho_{em} + \frac{i}{2} \{\Omega_2 (\rho_{ee} - \rho_{mm}) - \Omega_1 \rho_{gm}\}, \\
\dot{\rho}_{gm} &= -(i \delta + \gamma) \rho_{gm} + \frac{i}{2} [\Omega_2 \rho_{ge} - \Omega_1 \rho_{em}],
\end{align*}$$

(10)

for the coherences $\rho_{ij} = \rho_{ij}$, with composite rates $\Gamma = \Gamma_{eg} + \Gamma_{em}$, $\Gamma_1 = (\Gamma + \Gamma_{gg})/2$, $\Gamma_2 = (\Gamma + \Gamma_{mm})/2$, and $\gamma = (\Gamma_{gg} + \Gamma_{mm})/2$.

### C. Resonance conditions

The objective for using the stimulated Raman transition is to filter a velocity group $v_R$ from the ionic ensemble with a resolution below the natural linewidth. From energy conservation (cf. Fig. 1) and the ac Stark-shifted eigenfrequencies $\Delta_r (5)$, one obtains the kinematic condition for the two-photon resonance as

$$\delta(v_R) = \Delta_1 - \Delta_2 = 0.$$  

(11)

Thus, the Doppler-shifted laser frequencies must match the ac Stark-shifted transition frequencies of the ground states (5).
This defines the Raman resonance velocity

\[ v_R = - \frac{\delta_0}{k_1 + k_2} + \frac{|\Omega_2|^2 - |\Omega_1|^2}{4(k_1 + k_2)\Delta}, \]  

where \( v_{R,0} = -\delta_0/(k_1 + k_2) \) is the dominant contribution and around the Raman resonance we can approximate

\[ \frac{\Omega^*_{i,j}(v)}{\Delta_i(v)} \approx \frac{\Omega^*_{i,j}}{\Delta}, \quad \Lambda \equiv \Delta_i(v_{R,0}) = \frac{\Delta_{\text{eg},0}k_1 + \Delta_{1,0}k_2}{k_1 + k_2} \]

within the limit of weak saturation. It is interesting to recognize the magic spot \( |\Omega_1| = |\Omega_2| \), where second-order energy shifts cancel in (12). There are also two rogue resonances at velocities \( v_1 \) and \( v_2 \), where each laser couples resonantly to the excited state

\[
\Delta_1(v_1) = 0, \quad v_1 = -\Delta_{1,0}/k_1, \\
\Delta_2(v_2) = 0, \quad v_2 = \Delta_{2,0}/k_2.
\]

The width and strength of the resonances are determined by the OBEs (9) and (10). From the linkage pattern of Fig. 4, one obtains three pathways to reach state \( |m\rangle \), starting at \( |g\rangle \). Perturbatively, the initial growth rate \( r_m = \rho_{mm}(t = 0) \) of the metastable state reads (cf. Appendix B)

\[
r_m = \frac{\Gamma_1 s_i}{\Gamma} \left[ \Gamma_{em} + \Gamma_{eg} s_j \left( 1 + \frac{v}{\gamma^2 + \delta^2} \left( \frac{\Delta_{\text{eg}}}{\Gamma_1} - \frac{\Delta_{\text{eg}}}{\Gamma_2} \right) \right) \right],
\]

where we generalize the saturation parameter from the coherent limit to \( s_i = |\Omega_i|^2/2(\Gamma_i^2 + \Delta_i^2) \), now broadening the resonances with the linewidths \( \Gamma_i \). The first two resonances occur spontaneously at \( \Delta_1 = 0 \) and \( \Delta_2 = 0 \), while the last two describe the stimulated Raman process at the two-photon resonance \( \delta = 0 \). Due to laser noise, it acquires the finite linewidth \( \gamma \). This growth rate \( r_m \) is schematically depicted in Fig. 3 together with the stationary solution \( \rho_{mm}^\infty \) (B5), also derived in Appendix B. The narrow stimulated Raman resonance at \( v_R \) is clearly distinguishable from the resonance of laser 1 at \( v_1 \), where \( |e\rangle \) gets populated followed by spontaneous emission into \( |m\rangle \). This process limits the velocity determination, due to the broad tail. Therefore, it is called the rogue resonance in the following. In contrast to the rate \( r_m \), the stationary solution \( \rho_{mm}^\infty \) suppresses the resonance at \( v_2 \), because stimulated emission is compensated with stimulated absorption.

### D. Isolating resonances

The positions of the resonances are controlled by the laser frequencies. Obviously, the Raman resonance at \( v_R \) should be within the ion velocity distribution, also depicted in Fig. 3. In contrast, the rogue resonances at \( v_1 \) should be spread far apart. Therefore, we want to determine laser frequencies such that the resonance separations

\[
\beta_i = \frac{v_i - v_{R,0}}{c}.
\]

are maximized. First, for a given Raman resonance velocity \( v_{R,0} \) (12), one obtains a linear frequency relation

\[
\omega_2(\omega_1; v_{R,0}) = \frac{\omega_1 \alpha_+ - \omega_{\text{eg}}}{\alpha_-}, \quad \alpha_{\pm} = 1 \pm \frac{v_{R,0}}{c},
\]

where we disregard ac frequency shifts, deliberately. Second, the distances between the resonances

\[
\beta_1(\omega_1) = \frac{\omega_{\text{eg}}}{\omega_1} - \alpha_+, \\
\beta_2(\omega_1) = \alpha_- \left( 1 - \frac{\omega_{\text{eg}}}{\omega_1 \alpha_+ - \omega_{\text{eg}}} \right)
\]

are now functions of \( \omega_1 \), which is depicted in Fig. 5. The requirement of positive laser frequencies \( \omega_L(\omega_1) > 0 \) leads to a lower limit for \( \omega_1 > \omega_\text{eg}/\alpha_- \). For ultraviolet to near-infrared frequencies \( |\beta_2| > |\beta_1| \). Therefore, we only need to maximize the distance \( \beta_1 \), within the range \( -\alpha_+ < \beta_1 < \alpha_+ \omega_{\text{eg}}/\omega_{\text{eg}} \). For detunings \( |\Delta_{1,0}| < 1 \) THz, the hyperbolic shape of the distance

\[
\beta_1(\Delta_{1,0}) = -\frac{v_{R,0}}{c} - \frac{\Delta_{1,0}}{\omega_{\text{eg}}} + \frac{\Delta_{1,0}^2}{\omega_{\text{eg}}^2} + \cdots
\]

is almost linear. Then the maximal distance of \( \beta_1 \) is only limited by the available laser powers and interaction time. The time should last at least for one \( \pi \) pulse \( t_\phi \) (32) of a Raman transition, where maximal population transfer is achieved. This time will be derived in the next section and is proportional to the Doppler-shifted one-photon detuning \( \Delta \).
and antiproportional to the laser power. Therefore, $\Delta$ is also depicted in Fig. 5(b) and the values of $\Delta_{1,0}$ for the parameter sets A and B (cf. Table II) are highlighted. These parameter sets lead to two distinct velocity distances $c\beta^A = 400 \text{ m s}^{-1}$ and $c\beta^B = 1200 \text{ m s}^{-1}$, keeping $\Delta$ small enough for the experimentally given interaction time and provided laser power. The distances to resonance 2 are $c\beta^A_2 = 867 \text{ m s}^{-1}$ as well as $c\beta^B_2 = 2601 \text{ m s}^{-1}$.

### III. Time-Resolved Population Transfer

In principle, we want to optimize the population transfer from the initial state $|g\rangle$ to the metastable state $|m\rangle$. Therefore, the velocity averaged quantum expectation value of the observable $\hat{\delta}_{mm}$,

$$\langle m(t, v) \rangle_v = \int_0^\infty dv \, f(v) \text{Tr}[\hat{\delta}_{mm} \hat{\rho}(t; v)],$$

(22)

should be maximized. The uncertainty of the voltage measurement is defined by the logarithmic derivative (1),

$$s = \frac{\Delta U}{U} = \frac{2\Delta \nu}{\nu_R}. \quad (23)$$

The smallest uncertainties are obtained for minimal velocity widths $\Delta \nu$ of the transferred metastable-state population. Both objectives require the solution of the OBEs (8),

$$\rho(t; v) = V(v)e^{\Delta \nu \sigma \Delta \nu}V(v)^{-1} \rho(t = 0; v), \quad (24)$$

and

$$L(v)V(v) = V(v)\Lambda(v), \quad (25)$$

for each velocity within the distribution $f(v)$. Here $\Lambda_i$ are the eigenvalues and $V(v)$ is the eigenmatrix of the Liouvillian matrix $L(v)$.

We have implemented a numerical procedure to solve these equations for all velocities and obtain averages. We refer to this as the exact solution. However, in order to get insights in the underlying physical mechanisms, we will discuss in the following simple approximations that match the exact solution very well. These approximations emphasize the relevance of the individual processes contributing cumulatively to the exact result.

#### A. Stimulated Raman transition

For far-detuned lasers $\Delta \gg \Gamma_i$, the excited state stays nearly unpopulated, and spontaneous emission is not an issue. Hence, in a small regime around the resonant velocity $v_R$, the dynamics can be approximated by an effective two-level system, consisting of the ground and metastable states. This describes the process of the stimulated Raman transition.

We are dealing with laser linewidths $\gamma \sim 10^{2}$ kHz, much larger Rabi frequencies $\Omega \sim 10^5$ MHz and even larger one-photon detunings $\Delta_{0i} \sim 10^3$ GHz. Around the Raman resonance, the two-photon detuning $\delta$ is very small, leading to the inequality

$$\gamma, \delta \ll \Omega_i \ll \Delta_i. \quad (26)$$

We will frequently make use of this relation.

---

Figure 6: Rabi oscillations of the metastable-state population $m(t, v_R)$ (red solid line) for the resonant velocity, together with the velocity averaged population $\langle m(t, v) \rangle_v$ for $\Delta v_i = 50 \text{ m s}^{-1}$ (blue dashed line). Three parameter sets (Table II) are compared: A ($\times$), B$_1$ ($\circ$), and B$_2$ ($\Delta$).

#### 1. Coherent dynamics

The ideal coherent dynamic is described by the Schrödinger equation

$$i\hbar \partial_t |\psi\rangle = (\hat{H} - \sigma |\psi\rangle), \quad (27)$$

with $|\psi\rangle = |\psi_g\rangle + |\psi_e\rangle + |\psi_m\rangle$ and using the Hamilton matrix (3). In order to apply the standard adiabatic elimination methods [32] to eliminate the tiny excited-state population using $\psi_e \ll \Delta \psi_c$, we have to transform to another frame. This can be accomplished by introducing the frequency shift $\sigma = \frac{\Delta \nu}{\Delta} \ll \frac{\Delta}{\Gamma}$, leading only to an unobservable, global, dynamical phase. The resulting effective two-level system reads

$$i\hbar \partial_t \begin{pmatrix} \psi_g \\ \psi_m \end{pmatrix} = \begin{pmatrix} \delta/\Delta & \Omega_2 \\ \Omega_1 & -\delta/\Delta \end{pmatrix} \begin{pmatrix} \psi_g \\ \psi_m \end{pmatrix},$$

(28)

with the Raman Rabi frequency and the ac Stark shifts

$$\Omega_R = \frac{\Omega_1^2 + \Omega_2^2}{2 \Delta} + O\left(\frac{\delta}{\Delta}\right), \quad \omega_{ac} = \frac{||\Omega||^2}{4 \Delta} + O\left(\frac{\delta}{\Delta}\right), \quad (29)$$

using the separation of the frequency scales (26). The two-level dynamics (28) can be solved by diagonalization as stated in Eqs. (24) and (25). For the initial condition $\psi_g(t = 0) = 1$, the metastable-state population reads

$$m_0(t, v) = |\psi_m(t, v)|^2 = \frac{||\Omega||^2}{\Omega_2^2} \sin^2 \left[\frac{\Omega_R t}{\Delta} \right], \quad (30)$$

with the effective detuning $\delta(v) = \Delta_1 - \Delta_2$. For weak saturation solution $m_0(t, v)$ (30) can be simplified with

$$\Omega_R \approx \Omega_R \equiv \frac{\Omega_1^2 + \Omega_2^2}{2 \Delta}, \quad \delta \approx \frac{d}{2} \equiv (k_1 + k_2)(v - v_R). \quad (31)$$

approximating the velocity-dependent Rabi frequencies with their on-resonance values (13). Figure 6 shows Rabi oscillations of the population of the metastable state for the resonant velocity $m(t, v = v_R)$ together with its velocity average $\langle m(t, v) \rangle_v$, calculated with (22). In our calcium experiment, ions emerge from the accelerator with a flat-top velocity...
FIG. 7. The velocity-dependent metastable-state population \( m(t_\pi) \) after a \( \pi \) pulse (\( t_\Delta^A = t_0^B = 4.62 \) \( \mu s \) and \( t_\Delta^B = 0.68 \) \( \mu s \)) is indiscernible for parameter sets A and B. For maximal laser power \( B_2 \) the resonance is broadened as well as shifted. The approximation \( m_0 \) (33) matches the full solution.

Three different laser parameter sets, listed in Table II, are compared, demonstrating the essential impact of different laser frequencies and powers. Parameter sets A and B generate a \( \pi \) pulse for the experimental transit time \( \bar{t} = 4.62 \) \( \mu s \). For the resonant velocity \( \bar{t}(v = v_R) = 0 \), a complete population transfer via the Raman transition is achieved. Applying the approximations for the Raman Rabi frequency and the effective detuning \( (31) \) to the metastable-state population \( m_0(t, v) \) \( (30) \), we obtain the \( \pi \)-pulse duration

\[
\tau_{\pi,0} \equiv \tau_{\pi}(\gamma = 0) = \frac{\theta}{|\Omega_R|}. \tag{32}
\]

Parameter sets A and B differ in the laser frequencies, resulting in vastly different distances between the stimulated and the spontaneous Raman resonances \( B_1^R > B_1^A \), as mentioned in Sec. II C. However, this does not affect the Rabi oscillations and \( (m(t, v))_s \), because for the purely coherent population transfer via the Raman transition the spontaneous one is not an issue at all. The parameter set B2 provides the same laser frequencies as B1, while the maximum laser power, available in the experiment, is applied. Therefore, \( (m(t, v))_s \) is slightly enlarged, effectively due to power broadening. This is apparent in Fig. 7, depicting the velocity dispersion of the metastable-state population after a \( \pi \) pulse. Using approximations \( (31) \) and the expression for the \( \pi \)-pulse time \( (32) \), this population reads

\[
m_0(t_{\pi,0}, v) = \frac{\pi^2}{4} \sin^2\left[\frac{\pi\tilde{\Omega}}{2|\Omega_R|}\right]. \tag{33}
\]

with \( \sin(x) = \sin(x)/x \). It is plotted for B2, matching the exact analytical solution \( (30) \). The \( \sin^2 \) behavior is the typical response to constant interaction. For smooth temporal envelopes the side maxima vanish. The results for A and B show no difference. For B2 the resonance is ac Stark shifted (\( \Omega_1^B \neq \Omega_2^B \)) to \( v_R^B = v_R - \bar{v} = -0.17 \) m\( s^{-1} \) as predicted by (12).

We define the velocity width (FWHM) of \( m_0 \) (33) by the first zero of the sinc function

\[
\Delta v_0(t_{\pi,0}) = \sqrt{3} \frac{|\tilde{\Omega}_R|}{k_1 + k_2}. \tag{34}
\]

For maximal laser power \( \Delta v(t_{\pi}) \) increases from \( \Delta v^B(t_{\pi}) = 4.62 \) \( \mu s \) to \( \Delta v^B(t_{\pi}) = 0.68 \) \( \mu s \). The results of approximation (34) are displayed in square brackets and provide very good predictions.

2. Finite laser linewidths

For finite laser linewidths, the ground-state decoherence must be considered. Adiabatic elimination of the fast coherences \( \rho_{gg} \) and \( \rho_{me} \) in the OBEs \( (9) \) and \( (10) \) leads to the equations of motion in matrix representation \( \dot{\rho} = L\rho \), with \( \rho = (\rho_{gg}, \rho_{gm}, \rho_{mg}, \rho_{mm}) \) and

\[
L = \begin{pmatrix}
0 & i\frac{\gamma}{2} & -i\frac{\gamma}{2} & 0 \\
-i\frac{\gamma}{2} & -\gamma - i\delta & 0 & -i\frac{\gamma}{2} \\
-i\frac{\gamma}{2} & 0 & -\gamma + i\delta & i\frac{\gamma}{2} \\
0 & -i\frac{\gamma}{2} & -i\frac{\gamma}{2} & 0
\end{pmatrix}. \tag{35}
\]

Furthermore, we neglect the spontaneous emission rates as well as population of the excited state. In addition, we exploit the separation of the frequency scales \( (26) \). Applying the initial condition \( \rho_{gg}(t = 0) = 1 \) leads to the solution for the population of the metastable state

\[
m_k(t, v) = \frac{1}{2} + e^{-\beta t}(A \cos \theta t + B \sin \theta t) - e^{2(\theta - \gamma)vC}. \tag{36}
\]

The stationary solution approaches \( \lim_{t \to \infty} m_R = 1/2 \). The complex velocity-dependent frequency \( \theta \) and damping rate \( \beta \) as well as the coefficients \( A, B, \) and \( C \) define damped oscillations (cf. Appendix D).

3. The \( \pi \) pulses for underdamped oscillations

The solution (36) includes regimes from underdamping to overdamping, depending on the ratio \( \eta = \sqrt{3}\tilde{\Omega}_R/\gamma \). For \( \eta > 1 \) and \( v = v_R \), the coefficient \( C(v_R) = 0 \). The oscillation frequency \( \theta \) and damping rate \( \beta \) are real. In order to maximize the population transfer, we define a \( \pi \)-pulse time \( t_{\pi} \) for the resonant velocity \( v = v_R \) from the condition \( m_R(t_{\pi}, v_R) = 0 \) and obtain

\[
t_{\pi} = \frac{1}{\theta} \cos^{-1}\left(\frac{A\theta + B\theta}{\sqrt{(A^2 + B^2)(\theta^2 + \beta^2)}}\right)
\approx \frac{\pi}{\theta} \frac{2\sqrt{3}\pi\xi}{\gamma(\xi^2 + 1 + \eta^2)},
\]

\[
\xi = \left[1 - \frac{\eta^2}{2}(1 - \sqrt{4\eta^2 - 3})\right]^{1/3}, \tag{37}
\]

using again the approximations \( \Omega_R \approx \tilde{\Omega}_R \) and \( \delta \approx |d| \) \( (31) \). In the limit \( \gamma = 0 \), we recover \( t_{\pi,0} \) \( (32) \). For \( t_{\pi} \), an upper bound for the velocity width of \( m_R(t_{\pi}, v) \) is given by the FWHM of

\[
e^{2(\theta - \gamma)vC} \approx 1 - \frac{d^2}{2}\xi^2 + d^2 \exp\left[\frac{Dt_{\pi}}{1 + Ed^2}\right], \tag{38}
\]

052512-7
where $\xi^2 = y^2(\eta^2 - 1)/3$ and $D$ and $E$ are velocity-independent functions, given in Appendix D. We get

$$\Delta v_R(t_\pi) = \frac{2}{k_1 + k_2} \sqrt{p + \sqrt{p^2 + q}},$$

$$p = \frac{\xi^2 E - D t_\pi - \ln(2)}{2 \ln(2) E}, \quad q = \frac{\xi^2}{\ln(2) E}.$$  (39)

using $\ln(d^2 + \xi^2) = \ln(d^2) + \xi^2 d^2 + O((\xi^2/d^2)^2)$. Together with the lower bound, provided by the limit of vanishing laser linewidths $\Delta v_0$ (34), the width is constrained by

$$\Delta v_0(t_\pi) \leq \Delta v(t_\pi) \leq \Delta v_R(t_\pi)$$  (40)

for arbitrary $\eta > 1$.

4. Limit of large laser linewidths

In the limit $t \gg 1/\gamma$ of large laser linewidths and long interaction times, the populations of the ground and metastable state can be approximated with the solutions of the rate equations derived from the two-level system with adiabatic elimination, using $\dot{\rho}_{gg} \ll \gamma \rho_{gg}$.

$$\dot{\rho}_{gg}(\rho_{mm}) = r \left( \begin{array}{cc} -1 & 1 \\ 1 & -1 \end{array} \right) \left( \begin{array}{c} \rho_{gg} \\ \rho_{mm} \end{array} \right).$$  (41)

The decay rate $r = y/\sqrt{\Omega_R^2/(\gamma^2 + d^2)} < \gamma$ involves the approximations $\Omega_R \approx \Omega_R$ and $\delta \approx d$ (31) and the solution reads

$$m_{RE}(t, v) = \frac{1}{2} (1 - e^{-rt}).$$  (42)

The velocity width of $m_{RE}$ follows with

$$\Delta v_{RE}(t) = \frac{2y}{k_1 + k_2} \sqrt{\frac{r_0 f}{\ln(1 + \tanh \frac{\xi^2}{2} d^2)}} - 1,$$  (43)

where $\Delta v_{RE}(t) \gg y/(k_1 + k_2) \forall v_0, t$. The rate equation limit is a good approximation when the transient part in (36) vanishes, which is the case if $\gamma t \gg 1$, because $\gamma/2 < \delta < \gamma$.

5. The $\pi$ pulses for overdamped oscillations

For $\eta < 1$, the solution $m_{RE}$ (42) is overdamped with $m_{RE}(t) \sim 1/2 V t$. Therefore, we define the time of a $\pi$ pulse, when $m_{RE}(v = v_R)$ is saturated after several decay times $t_\pi = n/r_0$ with $n > 1$. We choose $n$ by the condition $m_{RE}(v = v_R)$, leading to

$$t_\pi = \frac{2\pi V}{\sqrt{3} f \Omega_R^2}, \quad 0 < \eta \leq 1.$$  (44)

B. Spontaneous Raman transition

The atomic transition between the ground and the excited state can be coupled resonantly, depending on the frequency of laser 1 and the ion velocity. In this limit, the population transferred into the metastable state can be approximated with the solutions of the rate equations for the ground, excited, and metastable states, approximating the steady state of all coherences. Therewith, the OBEs (9) and (10) simplify to

$$\partial_t \left( \begin{array}{c} \rho_{gg} \\ \rho_{mm} \end{array} \right) = \left( \begin{array}{cc} -R_1 & 0 \\ 0 & -R_2 \end{array} \right) \left( \begin{array}{c} \rho_{gg} \\ \rho_{mm} \end{array} \right) + \left( \begin{array}{c} \rho_{eg} \\ \rho_{ee} \end{array} \right) \left( \begin{array}{c} \rho_{eg} \\ \rho_{ee} \end{array} \right),$$  (45)

with $R_i = \Gamma_i (\Omega_i)^2/(4\Delta_i^2 + \Gamma_i^2)$. Additionally, we approximate $\rho_{gg}(t) \approx 0$, being important only in the regime of the transfer via the Raman transition. For $t > 1/\Gamma$ the population of the metastable state reads

$$m_{sp}(t, v) = \frac{\Gamma_{ee} + 1}{R_1 + \Gamma_{em} + 3} (1 - e^{-rt}),$$

$$r = \frac{R_1 \Gamma_{em} + R_2 (\Gamma_{ee} + 3R_1)}{\Gamma + 2(R_1 + R_2)}.$$  (46)

C. Maximizing the population transfer

After studying the individual population transfer into the metastable state via the stimulated Raman transition $m_{R}$ (36) and the spontaneous population transfer $m_{sp}$ (46) separately, we will analyze the total population transfer now. We assume that we can incoherently combine both processes, as long as they do not interfere. The ad hoc analytical ansatz

$$m_{ana}(t, v) = m_{R}(t, v) + m_{sp}(t, v),$$

$$w = m_{R}(t_\pi, v_R) + m_{sp}(t_\pi, v_R)$$  (47)

supercoses the populations such that $m_{ana}(t_\pi, v_R) = 1$.

1. Vanishing laser linewidths

Using the numerical solutions of the OBEs (9) and (10), we can calculate the population distributions over a wide velocity range, depicted in Fig. 8. The approximation $m_{ana}$ (47) clearly matches the numerical results. The rogue resonance of spontaneous population transfer, located at $v_\lambda^i = 400$ m s$^{-1}$ and $v_\lambda^f = 1200$ m s$^{-1}$, is clearly distinguishable from the narrow Raman resonance at $v_R^i = v_R^f \approx 0$ m s$^{-1}$. Obviously parameter sets B are more favorable, because here it can be ensured that for wider velocity distributions of the ions the transferred population into $|m\rangle$ remains less influenced by the tail of the rogue resonance as for A. However, for
FIG. 9. Velocity-dependent difference between the metastable-state populations, considering (m) and neglecting (m0) spontaneous emission effects, after $t_\omega$.

all parameter sets there is indeed a small deviation to the reference $m_0$ (30), considering exclusively the coherent transfer via the Raman transition. This difference is depicted in Fig. 9. For A the deviation and especially the roughly constant offset besides the Raman resonance is clearly larger than for B1 and B2, because of a smaller separation of the rogue to the Raman resonance $\beta_1^A < \beta_1^B$. However, with enlarging the laser power B2, especially the reduction exactly on the Raman resonance is, as expected, slightly enlarged again. Nevertheless, the velocity width of the transferred population is quasi purely defined by the width of the Raman transition $\Delta \nu_{\text{R}} = \Delta B_{\text{R}}$, showing no differences from the results of Sec. III A 1 [cf. $\Delta \nu_{\text{R}}(t_{\pi,0})$ (34) and Fig. 7].

The negative impact of a small distance $\beta_1$ can be further illustrated comparing the velocity averaged population $\langle m(t, v) \rangle_v$ (22) in Fig. 10. Already for the as narrow as possible initial ion velocity distribution with $\Delta v_i = 10$ m s$^{-1}$, the effect of the incoherent population transfer is discernible for A. For $\Delta v_i = 50$ m s$^{-1}$ and A the total transferred population is more than twice the population transferred via the Raman transition. So for A this regime is already unsuitable to properly determine the ion velocity. However, the major portion of $\langle m(t, v) \rangle_v$ for B1 and B2 results still from the narrow Raman transition. In addition, the necessary, larger Rabi frequencies are still reachable, viz., this represents a good working regime for available initial ion velocity widths.

For parameter sets A and B1 the analytical approximation $m_{\text{ana}}$ (47) describes exactly the numerical results. Only for the maximum laser power within B2 are there tiny deviations after the first $\pi$ pulse.

2. Finite laser linewidths

For a finite laser linewidth ($\gamma = \Gamma_{gg} = \Gamma_{mm} = 300$ kHz), the velocity selectivity of the Raman transition is significantly affected. On the one hand, its width is enlarged, so the velocity determination is less exact. On the other hand, even on the resonance $\nu_{\text{R}}$ the maximum transfer efficiency of almost 100% for $t_{\pi}$ cannot be reached any longer. Both effects are visible in Fig. 12(a), depicting the velocity-dependent population of the metastable state after time $t_{\pi,0}$. However, the Raman resonance is still clearly discernible and just as for $\gamma = 0$ the analytic approximation $m_{\text{ana}}$ (47) can predict the numerical full solution. We have foregone plotting the results for parameters A, because they are very similar to B1. However, the differences are not negligible, becoming apparent in Fig. 13(a), where the velocity average $\langle m(t, v) \rangle_v$ is visualized. Again the analytic approximation $m_{\text{ana}}$ (47) gives reliable predictions; only for the maximum laser power and longer times are tiny deviations visible.

The disappearance of Rabi oscillations indicates that the laser linewidths and the interaction time are sufficient to yield the rate equation limit. Only for B2 is the time of a $\pi$ pulse discernible with $t_{\pi}^{B2} = 0.70 \mu$s, slightly different from $t_{\pi}^{B1} = 0.68 \mu$s. The width of the velocity dispersion is $\Delta \nu(t_{\pi}) = 0.42$ m s$^{-1}$, where the analytical approximations $\Delta \nu(t_{\pi,0})$ (34) and $\Delta \nu(t_{\pi})$ (39) provide an appropriate range $\Delta \nu(t_{\pi}) \in [\Delta \nu(t_{\pi,0}), \Delta \nu(t_{\pi})] = [0.34, 0.60]$ m s$^{-1}$. The $\pi$-pulse times for the other parameter sets $t_{\pi}^{B2} \approx t_{\pi}^{B1} = 14.8 \mu$s are much larger than $t_{\pi,0}^{B1} = 6.2 \mu$s, demonstrating the overdamping for A and B1 with $\gamma = 300$ kHz. Hence, we get for the interaction time $\tau = 4.62 \mu$s, $\Delta \nu(t) = [0.22, 0.22, 1.34]$ m s$^{-1}$ for [A, B1, B2], demonstrating the broadening of the Raman transition due to finite laser linewidths and well predicted by the analytical approximation $\Delta \nu_{\text{R}}(\tau) = [0.21, 0.21, 1.38]$ m s$^{-1}$ (43). In this way, in particular for B2, the total amount of the metastable-state population is substantially enlarged. At the same time, the ratio of population transferred into the metastable state via the Raman transition to the whole population

$$\mu = \frac{\langle m_{\text{gs}}(t, v, r) \rangle_{v,r}}{\langle m_{\text{ana}}(t, v, r) \rangle_{v,r}},$$

depicted in Figs. 13(e) and 13(g), remains larger in comparison to the simulations with $\gamma = 0$. The comparison of the parameter sets demonstrates the compelling necessity of a careful choice of laser frequencies, providing a sufficiently large distance between Raman and rogue resonance $\beta_1$, especially for wider velocity distributions of the ions. It is worth mentioning that the ratio $\mu$ decreases with time, more crucial
for the idealized scenario with \( \gamma = 0 \) than for \( \gamma \neq 0 \). Therefore, it is important to carefully choose the interaction time in combination with the laser powers, achieving a significant absolute population amount and simultaneously keeping a reliable ratio, optimally \( \mu \rightarrow 1 \) but at least \( \mu > 0.5 \). To identify the maximum laser powers to reach a prescribed maximum uncertainty of the velocity determination, the widths \( \Delta v(t_e) \) as well as \( \Delta v(\bar{\tau}) \) are depicted in Fig. 11. Indeed, \( \Delta v(t_e) \) (39) provides an upper bound for \( \Delta v(\bar{\tau}) \), and due to \( \gamma \bar{\tau} = 9 \gg 1 \), \( \Delta v_{\text{RE}}(\bar{\tau}) \) (43) matches the actual results \( \Delta v_{\text{ana}}(\bar{\tau}) \) very well. It is worth mentioning that the relative deviation between \( \Delta v_{\text{ana}} \) and \( \Delta v \) of the numerical solution of the OBEs (9) and (10), not depicted here, is in the lower single-digit percentage range with no qualitative difference.

3. Spatial intensity variations

So far we approximate the lasers as plane waves with no spatial dependences. In reality, they are collimated Gaussian laser beams with beam waist \( w_0 \) and

\[
\Omega(r) = \Omega_0 e^{-r^2/w_0^2}.
\] (49)

The ions are also spatially inhomogeneously distributed and assumed to be Gaussian with width \( \sigma \),

\[
g(r) = \frac{1}{2\pi\sigma^2} e^{-r^2/2\sigma^2}.
\] (50)

We average over the cross-sectional area of the ion and the laser beams, assuming that the respective maxima of all are perfectly overlapped

\[
\langle m(t, v, r) \rangle_r = 2\pi \int_0^\infty dr \, r \, g(r) \, m(t, v, r).
\] (51)

We solve this integral numerically with Gauss-Laguerre quadrature [33]. Finally, the population of \( |m| \) is additionally averaged over the velocity distribution according to (22).

We compare two scenarios, the results of which are depicted in Figs. 12 and 13. For \( \sigma \ll w_0 \), the calcium beam is much narrower than the laser beam, corresponding to the case we assumed so far in which all ions experience the same Rabi frequency [Figs. 12(a), 13(a), 13(c), 13(e), and 13(g)]. For \( \sigma = w_0 \), the calcium beam is broader than the laser beam, viz., some ions are not affected at all, representing the current experimental scenario [Figs. 12(b), 13(b), 13(d), 13(f), and 13(h)]. For \( \sigma = w_0 \), essentially, \( \langle m(t_x, v_r) \rangle \) (Fig. 12) and \( \langle m(t, v, r) \rangle \) (Fig. 13) are reduced overall.

The off-axis Rabi frequencies are reduced and therewith the Raman resonance velocity \( v_R \) is shifted. This effect is more crucial, the larger \( \Omega_2 \) is. Averaging over the results for different \( r \), for \( B_2 \) the velocity of maximum transfer efficiency is shifted from \( v_R = v_R - \bar{v} = -0.17 \, \text{m s}^{-1} \) to \( v_R = -0.11 \, \text{m s}^{-1} \). However, the resonance of the Raman transition is still visible. In addition, the considered spatial intensity variations lead to a small reduction of the ratio \( \mu \) (48), primarily for A and \( B_1 \).

IV. CONCLUSION

Our calculations show that ion velocity classes with widths as low as \( \Delta v = 0.2 \, \text{m s}^{-1} \) can be transferred into the
metastable state via the Raman transition, achieving a significant population proportion \( \langle m(t, v, r) \rangle_{v,r} = 10^{-3} - 10^{-2} \). Thereby it is important to carefully choose the laser frequency combination to ensure that the transferred population into the metastable state originates mainly by the Raman process and not by incoherent spontaneous emission processes, when laser 1 couples resonantly to |e⟩. This also supports an initially narrow ion velocity distribution.

For infinitely sharp laser linewidths (\( \gamma = 0 \)) and an ion beam much smaller than the laser beams the smallest FWHMs of the ion velocity distribution in the metastable state can be reached with \( \Delta v(t_{\pi,0}) = [0.05, 0.05, 0.32] \) m s\(^{-1}\), for parameter sets \([A, B_1, B_2]\). With (23) this results in a voltage width \( s = [0.4, 0.4, 2.4] \) ppm on the sub-ppm level for A and B₁. The analytical expressions for the resonance velocity of the Raman transition \( v_R \) (12), the population of the metastable state after applying a \( \pi \) pulse \( m_0(t_{\pi,0}, v) \) (33), and the corresponding FWHM \( \Delta v_0(t_{\pi,0}) \) (34) give reliable predictions.

Considering finite laser linewidths, the analytical approximation for the velocity- and time-dependent metastable-state population \( m_{\text{ana}} \) (47) matches the full numerical solution very well. In addition, the approximations for the velocity width after applying a \( \pi \)-pulse \( \Delta v_R(t_{\pi}) \) (39) and in the rate equation limit \( \Delta v_{\text{RE}}(t_{\pi}) \) (43) are also suitable. Therewith, almost exact results for large parameter regimes are possible with small computational effort. Moreover, the presented analytical models lead to physical insights, verified by the numerical results.

Finite laser linewidths lead to a significant broadening of the Raman transition. With \( \gamma = 300 \) kHz the velocity width of \( m \) is enlarged to \( \Delta v(t_{\pi,0}) = [0.22, 0.22, 0.43] \) m s\(^{-1}\), leading to \( s = [1.7, 1.7, 3.3] \) ppm, still on the ppm level. Note that the width of the distribution does not represent the ultimate limit of the determination of the resonance velocity \( v_R \). Therefore, sub-ppm high-voltage measurements are still attainable. The related width in the frequency domain is \( \Delta f = (k_1 + k_2)\Delta v / 2\pi = [0.8, 0.6, 1.6] \) MHz, much smaller than the natural linewidth \( \Gamma_{\pi} = 23.396 \) MHz. The Raman transition therefore has the potential to provide a significant reduction in uncertainty. Moreover, it avoids additional uncertainties caused by varying and unknown momentum transfers in multiple resonant excitations along the 4s \( \rightarrow 4p \) transition and the subsequent spontaneous decay in the current measurement scheme. The momentum transfer during the Raman transition is very small and exactly defined as \( h(k_1 + k_2)^2 / 2m = 69 \) kHz in the direction of laser 2. Therefore, it can be taken into account in the analysis process.

For the velocity acceptance of the Raman transition, we can approximate the maximum angle between ion and laser
beams, where ions can be transferred into the metastable state $\alpha \approx \arccos ((v_k - \Delta v_i)/v_k + \Delta v_i/2)) \approx 6$ mrad for all parameter sets. In comparison, the natural linewidth induces a much larger angle $\alpha' \approx \arccos ((v_1 - \Gamma_{eg}/2k_1)/(v_1 + \Delta v_i/2)) \approx 11$ mrad.

Spatial intensity variations of both the laser beams and the ion beam mainly reduce slightly (less than an order of magnitude) the transfer efficiency for all velocities. Therewith, the velocity width of the transferred population is approximately not affected. Note that for maximum laser powers the velocity of maximum population transfer is slightly shifted in comparison to infinitely large laser beams. However, considering these experimental imperfections, the resonance of the Raman transition is still clearly identifiable. This demonstrates the feasibility of high-voltage measurements using coherent Raman spectroscopy on the ppm level, under realistic conditions. Finally, high-precision collinear laser spectroscopy from metastable states might also profit from such a Raman transition.

**ACKNOWLEDGMENTS**

**APPENDIX A: RAMAN TRANSITION IN INCOHERENT BEAMS**

We consider a Raman transition with counterpropagating lasers $E_i(t, r) = \text{Re}(\xi_i \mathcal{E}_i e^{i (k_i \cdot r - \omega_i t)})$ as shown in Fig. 2. The coordinate $r$ refers to the laboratory frame $S$. Assuming that the ion beam and the lasers are aligned along the $z$ direction, we can specify the ion velocity $v = v_z \hat{e}_z$ and the laser wave vectors $k_1 = -k_z \hat{e}_z$ and $k_2 = k_z \hat{e}_z$. During the interaction of the laser pulses, no relevant transversal motion occurs, which is why we will discuss only the one-dimensional evolution in the $z$ direction.

In the optical domain, the electric dipole interaction in the rotating-wave approximation is dominant [25]. Thus, the Hamiltonian operator of an ion with quantized canonical coordinates $[\hat{z}, \hat{p}_z] = i\hbar$ is

$$H(t) = \frac{\hat{p}_z^2}{2m} + \hbar (\omega_g \hat{d}_{gg} + \omega_m \hat{d}_{mm} + \omega_e \hat{d}_{ee}) + \hbar \left(\hat{d}_{gg} \frac{\Omega_{1} \Omega_{1}}{2} e^{i\phi_{1}} + \hat{d}_{em} \frac{\Omega_{2} \Omega_{2}}{2} e^{i\phi_{2}} + \text{H.c.}\right),$$

(A1)

with phases $\phi_1 = -k_1 z - \omega_1 t$ and $\phi_2 = k_2 z - \omega_2 t$. It accounts for the kinetic and the internal energy of the ion, where $\hbar \omega_i$ is the energy of state $|i\rangle$. The electronic transition operators are $\hat{d}_{ij} = |i\rangle \langle j|$. The complete internal and motion state $\hat{\rho}(t)$ of the ionic beam evolves according to

$$\dot{\hat{\rho}} = -i[H/\hbar, \hat{\rho}].$$

(A2)

One eliminates the ballistic evolution by the transformation $\hat{\rho} = \exp(-i 2 \hat{p}_z^2/2 \hbar) \hat{\rho} \exp(i 2 \hat{p}_z^2/2 \hbar)$. Then the Liouville–von Neumann equation $\dot{\hat{\rho}}'^{'} = -i[H'/\hbar, \hat{\rho}']$ reads

$$H'(t)/\hbar = \omega_g \hat{d}_{gg} + \omega_m \hat{d}_{mm} + \omega_e \hat{d}_{ee} + \left(\hat{d}_{gg} \frac{\Omega_{1} \Omega_{1}}{2} e^{i\phi_{1}} + \hat{d}_{em} \frac{\Omega_{2} \Omega_{2}}{2} e^{i\phi_{2}} + \text{H.c.}\right),$$

(A3)

dow Doppler-shifted phases $\phi'_1 = -k_1 z - (\omega_1 + k_1 \hat{p}_z/m) t$ and $\phi'_2 = k_2 z - (\omega_2 - k_2 \hat{p}_z/m) t$. The motional state of the ionic beam smoothly extends over a large phase-space area $\Delta z \Delta \hat{p}_z \gg \hbar/2$. The recoil momentum $\hbar k_i \approx \Delta \hat{p}_z$ are tiny compared to the momentum width and the recoil energy $\hbar^2(k_i + k_z^2/2m) \ll \hbar \Omega_1$. $\Omega_1 < \Delta \hat{p}_z$ are significant. Hence, we use the classical approximation $(\hat{z}, \hat{p}_z) \to (z, p_z = mv)$ of kinetic theory [26]. Consequently, the full quantum state $\hat{\rho}'(t) = \hat{\rho}'(t; z, v)$ is replaced by an internal state operator denoting the motional variables to the role of parameters. Using the Doppler-shifted frequencies $\omega'_i$ from Eq. (2), the phases read $\phi'_1 = -k_1 z - \omega'_1 t$ and $\phi'_2 = k_2 z - \omega'_2 t$ and the Hamilton operator in the classical approximation $H' \to H'$ is given by

$$H'(t)/\hbar = \omega_g \hat{d}_{gg} + \omega_m \hat{d}_{mm} + \omega_e \hat{d}_{ee} + \left(\hat{d}_{gg} \frac{\Omega_{1} \Omega_{1}}{2} e^{i\phi_{1}} + \hat{d}_{em} \frac{\Omega_{2} \Omega_{2}}{2} e^{i\phi_{2}} + \text{H.c.}\right).$$

(A4)

The remaining optical and spatial oscillations are eliminated by the transformation $\hat{\rho}' = U(t, z) \hat{\rho} U^\dagger(t, z)$, with

$$U(t, z) = e^{-i \omega_0 t - i \phi_1 \hat{d}_{gg} + i \phi_2 \hat{d}_{em}}.$$

(A5)

This results in the Liouville–von Neumann equation for the semiclassical state $\hat{\rho}' = -i[H'/\hbar, \hat{\rho}']$, with

$$H'/\hbar = \Omega_1 \hat{d}_{gg} + \Omega_2 \hat{d}_{mm} + \left(\hat{d}_{gg} \frac{\Omega_{1} \Omega_{1}}{2} + \hat{d}_{em} \frac{\Omega_{2} \Omega_{2}}{2} + \text{H.c.}\right),$$

(A6)

with a one-photon detuning $\Delta_1 = \omega'_1 - \omega_{eg}$ for laser 1 and $\Delta_2 = \omega'_2 - \omega_{em}$ for laser 2. With this approximation for the Hamiltonian evolution, we have essentially disregarded any photon recoil effects. One can apply the same arguments to the spontaneous contributions of the Lindblad equation [26].

**APPENDIX B: BLOCH MATRIX**

Representing the master Eq. (6) in the sorted basis $\{|g\rangle, |e\rangle, |m\rangle\}$ and arranging the matrix elements as linear arrays $\rho = (\rho_{gg}, \rho_{ge}, \rho_{em})$, one finds the...
Bloch Eq. (8) with a Bloch matrix

\[ L = \begin{pmatrix} L_{gg} & L_{ge} & 0 \\ L_{eg} & L_{ee} & L_{em} \\ 0 & L_{me} & L_{mm} \end{pmatrix} = i \begin{pmatrix} 0 & \frac{i\Gamma_1}{2} & -\frac{i\Gamma_1}{2} \\ -\frac{i\Gamma_1}{2} & 0 & 0 \\ 0 & 0 & \Delta_1 + i\Gamma_1 \end{pmatrix} \begin{pmatrix} \frac{i\Gamma_1}{2} & 0 & 0 \\ 0 & \frac{i\Gamma_1}{2} & 0 \\ 0 & 0 & \frac{i\Gamma_1}{2} \end{pmatrix} \begin{pmatrix} 0 & 0 & \Delta_2 + i\Gamma_2 \\ 0 & 0 & 0 \\ 0 & 0 & \frac{i\Gamma_1}{2} \end{pmatrix} \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \frac{i\Gamma_1}{2} \end{pmatrix} \begin{pmatrix} 0 & -\frac{i\Gamma_1}{2} & -\frac{i\Gamma_1}{2} \\ 0 & 0 & 0 \\ -\frac{i\Gamma_1}{2} & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & 0 & 0 \\ -\frac{i\Gamma_1}{2} & 0 & 0 \\ 0 & 0 & \frac{i\Gamma_1}{2} \end{pmatrix} \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \].

with \( \delta = \Delta_1 - \Delta_2 \). It exhibits the block structure of two coupled two-level systems. The Bloch equations define an initial value problem with \( \rho(t = 0) = (\rho_g^0, \rho_e^0, \rho_m^0) = (1, 0, 0, 0, 0, 0, 0, 0, 0) \). The Laplace transform

\[ \varrho(s) = \int_0^\infty dt \ e^{-st} \rho(t) \] (B2)

is ideally suited to transform the system of differential equations with initial values to an algebraic equation

\[ \left( \begin{array}{ccc} G^{-1} & -L_{ge} & 0 \\ 0 & G^{-1} & -L_{em} \\ 0 & 0 & G^{-1} \end{array} \right) \left( \begin{array}{c} \rho_g^0 \\ \rho_e^0 \\ \rho_m^0 \end{array} \right) = \left( \begin{array}{c} \rho_g^0 \\ \rho_e^0 \\ \rho_m^0 \end{array} \right), \] (B3)

where \( G^{-1}(s) = (s - L_{ij})^{-1} \) is the resolvent matrix. The formal inversion of the Bloch matrix is facilitated by the block structure and by backward substitution. This leads to the explicit solution

\[ \begin{align*} \rho_g(s) &= G_g(s) \rho_g^0, \\
\rho_e(s) &= G_e(s) L_{eq} \rho_g(s), \\
\rho_m(s) &= G_m(s) L_{me} \rho_e(s), \end{align*} \]

\( \rho_i = (\rho_g, \rho_e, \rho_m) \).

One can find the stationary solution using the final value theorem of the Laplace transformation

\[ \rho_{mm}^\infty = \lim_{t \to \infty} \rho_{mm}(t) = \lim_{s \to 0} s \varrho_{mm}(s). \] (B5)

The Laplace transform can also be used to approximate the initial growth rate \( \rho_{mm}(t = 0) \) of the population of the metastable state. This provides insights into the contributions of different processes of population transfer. Therefore, in Fig. 4 the processes generating population in \( |m\rangle \) are schematically visualized. Following this scheme and starting initially with the whole population in the ground state, the Laplace transform, considering only the initial processes in perturbation theory, denoted by \( \tilde{\varrho}_{mm} \), results in

\[ \tilde{\varrho}_{mm} = G_{mm} \left[ \left( \Gamma_{em} + \frac{|\Omega_1|^2}{2} \text{Re}(G_{me}) \right) \tilde{\rho}_{ee} + \frac{|\Omega_1|^2}{8} \text{Re}(G_{me} G_{mg} G_{eg} G_{gg}) \right], \]

\[ \tilde{\rho}_{ee} = \frac{|\Omega_1|^2}{2} G_{ge} \text{Re}(G_{eg}) G_{gg}. \]

The initial growth rate of the metastable-state population is then given by \( r_m = \lim_{s \to 0} s^2 \tilde{\varrho}_{mm}(s) \).

**APPENDIX C: PARAMETERS**

Relevant spectroscopic data for \(^{40}\text{Ca}^+\) are given in Table I, while laser parameters are specified in Table II. The listed Rabi frequency, defining the interaction strength, can be calculated with the total laser power \( P \) and the effective dipole moment \( d_{\text{eff}} \) to \cite{1999PRA101.52512}

\[ \Omega_0 = \frac{|d_{\text{eff}}|}{\hbar} \sqrt{\frac{4P}{\pi \epsilon_0 c w_0}}, \] (C1)

with the laser beam waist \( w_0 = \text{FWHM}/\sqrt{2 \ln 2} \), the vacuum permittivity \( \epsilon_0 \), and the speed of light \( c \). Due to the nonexistent nuclear spin of the considered level configurations, there is no hyperfine splitting and consequently the lasers interact with the \( J \to J' \) transition. In addition, the lasers are linearly polarized, wherefore they interact only with one (of three) component of the dipole operator and the effective coupling strength is \cite{1999PRA101.52512}

\[ |d_{\text{eff}}|^2 = \frac{1}{2} |\langle J || \epsilon || J' \rangle|^2. \] (C2)

The numerical values of the reduced matrix elements, listed in Table I, can be calculated from the lifetime \cite{1999PRA101.52512}

\[ \frac{1}{\tau} = \frac{w_0^2}{3 \pi \epsilon_0 \hbar c^3} \frac{2J+1}{2J'+1} |\langle J || \epsilon || J' \rangle|^2. \] (C3)
APPENDIX D: COEFFICIENTS OF $m_R$ (36) AND $\Delta V_R$ (39)

The analytic approximation for metastable-state population, transferred via the Raman transition $m_R$, results in (36), with velocity-dependent coefficients

$$\phi = \frac{1}{12} \left( 8y + x + \frac{y}{x} \right), \quad \theta = \frac{x^2 - y}{4\sqrt{3}x}, \quad A = \frac{1}{3} \frac{m + \text{op}}{m^2 + \alpha^2}, \quad B = \frac{1}{3} \frac{m - \text{op}}{m^2 + \alpha^2}, \quad C = \frac{3\alpha^2 \delta^2 / y^2 + [x(x + 2) + y]^2}{6(x^2 + x^2 y + 2y^2)},$$

$$m = \sqrt{3}(x^4 - 4y^2), \quad n = \sqrt{3}(y - x^2)[x(x - 4) + y], \quad o = (x^2 - y^2)^2, \quad p = 4xy(x - 1) - y^2 + x^2[8(1 + 9\delta^2 / y^2) - x(4 + x)],$$

$$x = (z + \sqrt{z^2 - y^2})^{1/3}, \quad y = 4 \left( 1 - \frac{\delta}{\gamma} + \frac{\Omega_R^2}{\gamma^2} \right), \quad z = 8 \left( 1 + \frac{\delta}{\gamma} - \frac{\Omega_R^2}{\gamma^2} \right).$$

The corresponding width $\Delta V_R$ can be analytically approximated for $t_s$, resulting in (39) with coefficients

$$D = 3F(d = 0), \quad E = \frac{d^2}{2} \frac{9F(d = 0)}{3F(d) - 2} \bigg|_{\Omega_R = \Omega_R, d = \Omega}, \quad F = \frac{x^2 + y}{6x} \bigg|_{d = \Omega}. $$
