An asteroidal origin for water in the Moon

Jessica J. Barnes¹, David A. Kring², Romain Tartèse¹,³, Ian A. Franchi¹, Mahesh Anand¹,⁴ & Sara S. Russell⁴

The Apollo-derived tenet of an anhydrous Moon has been contested following measurement of water in several lunar samples that require water to be present in the lunar interior. However, significant uncertainties exist regarding the flux, sources and timing of water delivery to the Moon. Here we address those fundamental issues by constraining the mass of water accreted to the Moon and modelling the relative proportions of asteroidal and cometary sources for water that are consistent with measured isotopic compositions of lunar samples. We determine that a combination of carbonaceous chondrite-type materials were responsible for the majority of water (and nitrogen) delivered to the Earth–Moon system. Crucially, we conclude that comets containing water enriched in deuterium contributed significantly <20% of the water in the Moon. Therefore, our work places important constraints on the types of objects impacting the Moon ~4.5–4.3 billion years ago and on the origin of water in the inner Solar System.
Lunar sample studies have focused on the measurement of H (reported as equivalent amounts of OH or H$_2$O) in lunar volcanic glass beads$^{1-3}$, melt inclusions$^{4,5}$ andapatite in lunar basalts and highlands samples$^{6-8}$. From this compilation of work the bulk silicate Moon (BSM) is estimated to contain between $\sim$10 and 300 p.p.m. H$_2$O$^{9,10}$. A few of these studies reported the identification of a primordial H-isotopic signature$^{2,5}$, corresponding to Earth-like $\delta^2$H values between $\sim -200$ and $\sim +180$‰ (where $\delta^2$H = [(D/H)$_{\text{sample}}$/(D/H)$_{\text{SMOW}}$] - 1) $\times$ 1,000; SMOW: standard mean ocean water). Therefore, the similar nature of water (the term water is hereafter used to refer to H$_2$O equivalent) in the Earth and Moon suggests that water locked up inside the Moon was either inherited directly from the proto-Earth or delivered to the Earth–Moon system shortly after the formation of the Moon (Fig. 1) through impacting carbonaceous chondrite (CC)-type asteroids, since bulk D/H ratios for most CC-types$^{11}$ are consistent with those of terrestrial$^{12,13}$ and lunar water (Fig. 2).

Models for the differentiation of the Moon invoke the presence of a lunar magma ocean (LMO) and place the lifetime of this LMO to between $\sim 10$ and 200 Ma after the Moon-forming event (as reviewed by Elkins-Tanton et al.$^{14}$), which necessitates that volatile accretion occurred relatively early in the Moon’s geological history (Fig. 1). The final dregs of the LMO, enriched in incompatible elements such as potassium (K), rare-earth-elements (REEs) and phosphorous (P)—collectively termed urKREEP—should have contained the vast majority of the lunar water, as OH would have been incompatible in the crystallizing mantle cumulates and the crust$^{10}$. Lunar samples with a significant KREEP component, such as Mg-suite rocks and KREEP basalts$^{7,8}$, are characterized by H-isotopic compositions that are similar to those estimated for the mantle source regions of picritic glasses and mare basalts$^{6,9}$, suggesting that the crystallization of the LMO did not result in significant fractionation of the H isotopes of water. To retain volatiles in the LMO, a conductive lid is required, to have prevented significant loss of water via degassing of H-bearing species, and is consistent with the formation of an early anorthosite crust a few kilometres thick in the first few thousand years of the Moon’s history$^{14}$. It is likely that the lunar crust then grew by continuous underplating of more anorthositic materials over a period of between $\sim 10$ and $\sim 200$ million years until the LMO completely solidified, leading to the mantle cumulate overturn (see review by Elkins-Tanton et al.$^{14}$). This time period between lunar accretion and the overturn of mantle cumulates permits any water (and other volatiles) accreted to the LMO to be incorporated into the mantle source regions of mare basalts and picritic glasses ($> \sim 100$ km deep$^{15}$), and the urKREEP liquid provided that impactors were able to breach the lunar crust. Crystallization of an insulating crust likely started only after $\sim$80% LMO crystallization$^{14}$. During its initial growth the crust was likely hot and tenuous and perhaps even re-melted if tidal heating played an important role$^{14}$, meaning not only that impactors could have reached the LMO melt pool but also that many early impact structures could have been erased during crustal underplating and modification. Therefore, volatile delivery through the earliest lunar crust into the LMO could have balanced out any potential loss of volatiles (accreted or indigenous) by degassing (before $\sim$80% solidification).

Studies that have modelled the flux of impactors to the Moon posit that it was likely that the time period between lunar accretion and differentiation received relatively fewer impact events than during the late heavy bombardment (LHB) (for example, Morbidelli et al.$^{16}$), but importantly this was not a quiescent time. Indeed, there are $\sim 12$ preserved Pre-Nectarian lunar basins that have excavations depths around or greater than 34–45 km (ref. 17), which corresponds to the current estimates for lunar crustal thickness based on observations by the GRAIL spacecraft$^{18}$. This demonstrates that large impacts occurred early in the Moon’s history (albeit infrequently compared with the LHB epoch$^{19}$). In summary, the time interval for water delivery to the LMO, hereafter referred to as the late accretion window ‘LAW’, is conceptually restricted to between time zero (Moon formation) and up to $\sim 200$ Ma thereafter. Importantly, the bulk of lunar water was delivered during LAW, which is distinct from a much younger basin-forming epoch on the Moon that is commonly referred to as the LHB, lunar cataclysm, or inner Solar System cataclysm$^{16,20-22}$.

It has been suggested that water could have been accreted together with the Moon-forming material in the so-called ‘cold start’$^9$. Whilst it is plausible that some water may have been retained since the Moon’s formation$^{23}$, it is highly unlikely that all of BSM water (up to 300 p.p.m. H$_2$O) was accreted in this manner and survived LMO processing. Therefore, we envisage two scenarios that can account for the bulk water inventory of the Moon, the first that water was accreted solely during the LAW and no water was inherited from the Moon-forming material (scenario 1), and the second that a portion (we consider up to 25%) of the BSM water was accreted with Moon-forming materials and was then supplemented by water delivery during the LAW (scenario 2).

**Figure 1** | Cartoon showing the possible time windows and scenarios for the accretion of volatiles to the lunar interior. Volatiles were accreted to the Moon during its formation (a) and/or continuously delivered by impacting bodies during the ca. 10–200 million years of crystallization of the lunar magma ocean (b). This graphic is not to scale.
In this study we utilize estimates of the water content of the BSM and its H-isotopic composition together with the current database for the bulk water contents of chondritic meteorites (Table 1, see Methods section), to determine the amount of water added to the early Moon by impacting objects. We consider a range of possible accretion scenarios during LAW to investigate the implications for the mass of water accreted and populations of accreting objects. This is constrained by the estimates for the proportion of lunar mass that was likely added post-lunar core-formation from studies of highly siderophile elements (HSEs) in lunar basalts (up to 0.02% lunar mass) and highly volatile elements in mare basalts and picritic glasses (up to 0.4% lunar mass). Our results indicate that carbonaceous chondrite types of impactors were the most important contributors of water to the lunar interior and that comets (with heavy water, Fig. 2) played a very small role.

Results
Mass of asteroidal materials added during the LAW. Based on the BSM water estimates of McCubbin et al. (10–100 p.p.m. H₂O), and Chen et al. and Hauri et al. (~100–300 p.p.m. H₂O), we have calculated the amount of material supplied by chondritic impactors to accrete ~100 and 300 p.p.m. bulk H₂O for LMO depths of 400 and 1,000 km (to match the various LMO depths estimated in previous studies), and have recast these estimates into the context of how much lunar mass each would represent (Table 2 and Fig. 3). The types of carbonaceous chondrites are defined in the caption accompanying Fig. 2.

In scenario 1, for example, between 3.94 × 10¹⁶ kg (~1 p.p.m. H₂O) and 2.05 × 10¹⁶ kg H₂O (~52 p.p.m. H₂O) could have been accreted by CI-type CCs into a 400-km-deep LMO to remain below the addition threshold of <0.02% lunar mass (Table 1). In fact, using this <0.02% lunar mass threshold prohibits the addition of 300 p.p.m. H₂O by asteroids alone (Table 2). On the other hand, the accretion of up to 0.4% lunar mass in some cases, allows for the addition of H₂O in amounts greater than the high-end of BSM H₂O estimates (Table 2).

Importantly, because equilibrated ordinary (OC) and enstatite chondrites (EC) contain very little water (Table 1) the mass of such types of chondritic material added to accrete even 10 p.p.m. H₂O greatly exceeds the mass constraints imposed by HSE and highly volatile element abundances (Table 2). As a consequence, although ECs are considered an ideal geochemical match for the BSM and the bulk silicate Earth, and Os isotope signatures may suggest a large contribution of OC- and EC-type objects in materials accreted to the Earth–Moon system during late accretion, it is clear that these types of objects are unlikely to have contributed significant amounts of H₂O to the lunar interior. The accretion during the LAW of CC material is consistent with the impact of CC-type asteroids during the LHB. HSE data have been interpreted to mean that EC and OC impactors also played an important role during the LHB, which may reflect a change in impactor populations over the first ~500 million years of the Moon’s evolution and, thus, dynamical mixing of material in the Solar System. The same data have also been interpreted, however, to represent a mixture of OC and CC impactors together with differentiated iron impactors, in which case CC asteroids remained an important source of impactors.

Assessing the contribution of cometary water during LAW.

The first scenario in this study assumes that the Moon accreted completely dry or that any primordial water was completely lost very early in the Moon’s history, and that late-accretion delivered all of the water in the BSM. Considering a BSM of 100 p.p.m. H₂O (the most recent BSM water estimates overlapping at this

CC, carbonaceous chondrite; EC, enstatite chondrites; HSE, highly siderophile element; HVE, highly volatile element; LMO, lunar magma ocean; OC, ordinary chondrites.

Mass of bulk chondritic material, and corresponding percentage (%) of lunar mass (LM), required for the addition of 10, 100, and 300 p.p.m. H₂O in 400- and 1,000-km-deep LMO during the late accretion window (LAW) for different types of carbonaceous, enstatite and ordinary chondrites. Also included is the maximum amount of water that would be added to the Moon for accretion of 0.02% lunar mass (adhering to HSE abundance constraints24,25) and for up to 0.4% lunar mass (adhering to the upper limit defined by HVEs4,9) assuming scenario 1.

*Indicates cases where accretion of chondritic material results in H₂O abundances higher than BSM H₂O estimates.
of water ($H_2O$), $D_i$ refers to the initial H-isotopic composition of the water in the LMO, $H_2O_{LA}$ refers to the mass of water added during LAW (kg), $fH_2O$ is the proportion (fraction of amount added during LAW) of water accreted by a given type of impactor denoted with A or B, respectively, and all other parameters are the same as in equation (1).

Mixing of water from CI-type CCs with water from CO, CM, CV-type CCs and DDK comets in different proportions can yield final $\delta D$ values $< +100\%$ (Table 3), satisfying isotopic constraints. If deuterium-enriched comets were involved in the addition of water during LAW then up to $\sim 14\%$ $H_2O$ could have originated from Oort cloud-type comets and $\sim 5\%$ $H_2O$ from DEK comets if the remaining water is assumed to come from CI-type chondrites (Fig. 5a), proportions that increase to $\sim 7$ and $\sim 19\%$ $H_2O$ originating from DEK and Oort cloud comets, respectively, if the remaining water came from CM-type chondrites (Fig. 5b and Table 3). Significantly, in the case where CO-type CCs dominated the impactor population (Fig. 5c) up to $\sim 27\%$ $H_2O$ could have been contributed by Oort cloud-like comets and up to $\sim 10\%$ $H_2O$ from DEK comets (Table 3). In addition, we considered that the LMO underwent some degassing before prior to late addition (see Methods section) and found that the results limit the amount of initial water present before late addition (assuming degassed H-isotopic composition of $\sim +800\%$ (ref. 8)), which further restricts the amount of water contributed by D-rich comets (Table 4).

**Discussion**

To a first order, a dominantly asteroidal source of water accreted during the LAW is similar to the dominant source inferred for the subsequent basin-forming epoch of the Moon, based on geochemical and mineralogical markers, implying that asteroids and not comets dominated the impactor population hitting the Moon during its first 500 million years of geological history. Although the source of objects delivered to the Earth–Moon system may have largely remained the same, the dynamical delivery could have been much different, as the basin-forming epoch appears to have been characterized by asteroids with higher impact velocities compared with those during the early accretional epoch (LAW) (Bottke et al. and references therein). We note that the accretion of CC-type material during

![Figure 3](image3.png)

**Figure 3** | Mass of chondritic material added during late accretion compatible with BSM water estimates. This figure shows the mass of the different types of chondritic material accreted (kg) to the Moon to add 10 (circles), 100 (squares) and 300 p.p.m. $H_2O$ (diamonds), respectively, to a 400-km-deep LMO, and the corresponding amount in terms of lunar mass. The mass constraints imposed by HSE (0.02% lunar mass added) and highly volatile element abundances (up to 0.4% lunar mass added) are indicated by the dashed lines. Where: CI-type carbonaceous chondrites (CCs) are Ivuna-like, CO are Ornans-like, CV are Vigorano-like, CM are Mighei-like and CR are Renazzo-like, respectively.

![Figure 4](image4.png)

**Figure 4** | An example of a two-component mixing model for scenario 1 considering that CI type CCs were dominant during the LAW. This model assumes 100 p.p.m. $H_2O$ in BSM, equivalent to $3.94 \times 10^{18}$ kg of $H_2O$ for a 400-km-deep LMO. The plot shows the resultant $\delta D$ value and D/H ratios of the water mixture versus the amount of water (kg) supplied by CI-type carbonaceous chondrites as an example (results in Table 3). The bar underneath the x-axis shows how the mass of water is related to % of water mixed. Only final H-isotopic compositions below $+100\%$ (denoted by the blue box) are acceptable within the constraints of the model (see Methods). Where: CI-type carbonaceous chondrites (CCs) are Ivuna-like, CV are Vigorano-like CO are Ornans-like, CM are Mighei-like and CR are Renazzo-like, respectively. Note that it only takes a couple of per cent contribution of water from Oort or DEK comets to produce H-isotope compositions outside of the model limits. DDK, deuterium-depleted Kuiper belt comets; DEK, deuterium-enriched Kuiper belt comets; Oort, average H-isotopic composition of Oort cloud comets.

Max. maximum; LL initial, lower limit (1% BSM $H_2O$) of $H_2O$ initially in lunar magma ocean; UL initial, upper limit (25% BSM $H_2O$) of $H_2O$ initially in the lunar magma ocean.

Showing the maximum proportions (%) of water permitted from deuterium-enriched Kuiper belt (DEK) and Oort cloud comets assuming the rest of lunar water was delivered by CC-type asteroids.
Figure 5 | Two-component mixing models for scenario 2 considering that CI or CM or CO-type CCs dominated the impactor population during the LAW. The resultant δD value of each water mixture (‰) versus the amount of water (kg) supplied by (a) CI-, (b) CM- and (c) CO-type carbonaceous chondrites. Table 3 also gives results from mixes with CV-type CCs. This model assumes that the LMO initially contained between 1% (dashed black lines) and 25% (solid black lines) of the BSM water (100 ppm H₂O) with a δD value of −200‰. Only final H-isotopic compositions < +100‰ are acceptable within the model constraints (denoted by the black boxes). Where: CI-type carbonaceous chondrites (CCs) are Ivuna-like, CO are Ornans-like, CV are Vigorano-like, CM are Mighei-like and CR are Renazzo-like, respectively.
the LAW, that is required to account for the lunar H-isotope and water abundances in the lunar interior, is distinct from a late veneer dominated by EC- and OC-type objects that has been inferred from Os isotope studies of terrestrial rocks. This dichotomy could imply that either the largest impactors that preferentially impacted the Earth due to stochastic accretion were OC- and EC-type objects, while the population of smaller impactors included abundant CC objects that preferentially impacted the Moon, or that while the accreting objects had OC- and EC-type Os isotope signatures, they had CC-type water abundances and H-isotope signatures, consistent with other evidence that support the presence of planetesimal-types that are not represented in modern meteorite falls.

On the basis of combined N isotopes and C/N ratios, the lunar interior seems to be best matched with CO-type CCs. In terms of N, we can estimate the amount of N delivered to the LMO based on our calculations of the mass of chondritic material added during LAW for each chondrite type (Table 2, restricted to consideration of material added to achieve a BSM with 100 p.p.m. H2O), and the average N contents in the different chondrite types (Table 1). Results yield N contents for the BSM of ~0.95 to 2.21 p.p.m. for LMO depths of 400 and 1,000 km (Table 5), which is consistent with an average of ~1 p.p.m. N in the lunar mantle as estimated by Furi et al. If minimal fractionation of 15N/14N occurred during basalt ascent and eruption, then the N-isotopic composition measured in mare basalts of between ~-2 and +27% (refs 37,38) should reflect the isotopic composition of the lunar mantle source regions from which the basalts were derived. If all of the N in the LMO was added during LAW (scenario 1) then mixing of Cl-, CM-, CO- and CV-type CCs provide suitable matches for the origin of lunar N (Methods section and Table 1) and restrict cometary contribution of N to as much as ~5% (Table 5). This is comparable to scenario 2, where considering the lowest mare basalt δ15N value of ~-2% (ref. 37) to represent the N-isotopic signature of N accreted with Moon-forming materials before LAW, then up to ~6% N could have been delivered by comets (Table 5). Still using scenario 2 but considering that the isotopic signature of N accreted when the Moon formed was consistent with that of the primordial Earth mantle, which is thought to be as low as ~-40% (reviewed by Furi and Marty), increases the possible cometary contribution to a maximum of ~8% of total lunar interior N.

Therefore, it appears that in order to add the appropriate amounts of H2O and N to the lunar interior during LAW, while keeping the H- and N-isotopic compositions in line with sample measurements, requires the contemporaneous accretion of the various types of CCs (mostly CO, CI, CM and CV), together with < ~20% cometary input.

The very-low apparently indigenous lunar δD values of ~ -600‰ reported by Robinson et al. are quite anomalous. In fact, such low values have yet to be observed in terrestrial rocks, the lowest δD values being ~ -220‰ for Earth’s depleted upper mantle. Therefore, such low values reported for an intrusive lunar rock could potentially indicate the presence of a proto-solar component (δD value of ~ 900‰ (ref. 42)) in the lunar mantle, in a similar way that has been used to explain Earth’s noble gas record and recent data from primitive terrestrial basalts. If this source is indeed required to explain the extremely low H-isotopic compositions observed, then this signature must have been added to the Moon from either material accreted from the proto-Earth or by the impactor involved in the formation of the Moon. Alternatively, such a low δD value could have arisen from contamination of a water-poor magma by solar wind-derived H present in the lunar regolith during magma ascent and emplacement.

The mantles of the early-Earth the Moon and Mars all seem to be characterized by water with remarkably similar H-isotopic compositions, suggesting that the same types of accreting objects as those modelled here for the Moon delivered a vast majority of the water to the rocky planets in the inner Solar System. Likewise, isotopic analyses of differentiated meteorites suggest that the interior of the eucrite parent body, probably the asteroid 4-Vesta, contained water characterized by H-isotopic signatures indistinguishable to that of the terrestrial planetary objects in the inner Solar System (Fig. 2).

Regarding the timing of volatile accretion to the Moon, major constraints are imposed by the time interval between lunar accretion and solidification of the LMO and overturn of mantle cumulates (~10–200 Myr after Moon formation), since there is water in the mantle source regions of the mare basalts and picritic glasses. It is possible that some water with Earth-like H-isotopic characteristics may have been accreted with the Moon-forming material, to explain the H-isotopic composition of water in the source regions for the picritic glasses (that were likely deep enough in the lunar mantle to have escaped processes such as degassing of H2 (ref. 48)). To account for the H-isotopic composition of the primordial lunar mantle and the urKREEP reservoir together, it is necessary that any initial lunar water was complemented by the continuous accretion of water from CC-type objects to the LMO during LAW. Incidentally, late

LMO, lunar magma ocean; max., maximum. N contents based on BSM of 100 p.p.m. H2O.
accretion of material to the Earth–Moon system did not only affect their volatile inventories19 but could also explain the recently identified difference between the bulk silicate Earth and BSM in terms of W isotopes10,21.

In summary, the lunar interior is characterized by an average bulk water content of the order of ~100 p.p.m. based on samples studies8,9,10 and we propose that the majority of this water was delivered during the ca. 100–200 million year-long LMO phase of lunar differentiation, with the possibility that some of this water was inherited proto-Earth-derived materials. This late accretion was dominated by water-rich carbonaceous chondrite asteroids, on the basis of H and N data, likely comprising a mixture of CO-, CI-, CM- and possibly CV-type CCs, with a minor contribution of water from deuterium-rich Oort cloud or Kuiper belt comets (much less than 20% of the total water in the BSM). Our work, therefore, confirms that the inner Solar System received a similar flux of asteroidal and cometary material for much of its early history from 4.5 billion years (this work and Dauphas et al.52) to at least 3.9 Gyr (ref. 20) (LHB).

Methods

Mass balance calculations. For mass balance calculations, we considered a lunar radius of 1,737.4 km, a mantle density of 3,300 kg m\(^{-3}\), and a BSM water content for the BSM of 300 p.p.m. based on samples8,9,10. We then calculated the mass of chondritic material added to the lunar interior that would result in BSM water contents of 10, 100 and 300 p.p.m. H\(_2\)O, and considered both the addition of up to 0.02% lunar mass24,25 and up to 0.4% lunar mass4,9. Note that for a 400-km-deep LMO, a BSM with accretion of material to the Earth–Moon system did not only follow equation (2) and consider an initial amount of water varying between 1% and 25% of the BSM estimate (that is, 1–25 p.p.m. for a bulk BSM water content of 100 p.p.m. H\(_2\)O) characterized by a δ\(_D\) value of ~200% and ~4% of the total water found in the lunar highlands53,54.

The bulk nitrogen content of the Moon and mixing calculations. Using the mass of each type of CC (CI, CO, CM and CV) accreted to an initially dry Moon during LWA (scenario 1) to end up with a BSM containing 100 p.p.m. H\(_2\)O (Table 2), the average N contents for the various types of carbonaceous chondrites (Table 1, data sources53–55), and assuming LMO depths of 400 or 1,000 km, we have estimated the amounts of N added to an initially N-free LMO, that is, the bulk N content of the BSM (Table 5). Note that in some cases (e.g., CV CCs) the mass of chondritic material added, in order to accrete 100 p.p.m. H\(_2\)O, exceeds the mass balance constraints imposed by HSEs. We then employed the mixing models described above for H\(_2\)O to calculate the acceptable proportion of N contributed by comets (with a δ\(_D\) value of ~200% and 30–400 p.p.m. H\(_2\)O, and considered both the addition of up to 0.02% lunar mass24,25 and up to 0.4% lunar mass4,9). For mass balance calculations, we considered a lunar radius of 1,737.4 km, a mantle density of 3,300 kg m\(^{-3}\), and varied the depth of the LMO (Table 1) to remain consistent with the volatile inventory of the Moon.
