Abstract. The measurements of the azimuthal anisotropy of $\varphi$ meson in the U+U and Au+Au collisions at the Relativistic Heavy-Ion Collider (RHIC) are reported. The centrality dependence of the Fourier coefficients $v_2$, $v_3$, $v_4$ and $v_5$ is presented for $\varphi$ meson at midrapidity ($|\eta| \leq 1.0$), in U+U and Au+Au collisions at $\sqrt{s_{NN}} = 193$ and 200 GeV, respectively. The $\eta$-sub event plane method is used with a $\eta$ gap of 0.1 to suppress the non-flow effects. A strong centrality dependence is observed for the $\varphi$ meson elliptic flow ($v_2$), whereas no clear centrality dependence is observed for $v_3$, $v_4$ and $v_5$. Ratios of the Fourier coefficients, $v_3/v_2$ and $v_4/v_2^2$ as a function of transverse momentum ($p_T$) are also presented. A systematic comparison of the Fourier coefficients for the two systems U+U and Au+Au is discussed.

1. Introduction

Azimuthal anisotropy is an important tool for studying the properties of the hot and dense matter created in high energy heavy-ion collisions at the Relativistic Heavy Ion Collider (RHIC) [1]. It describes the momentum space anisotropy of produced particles in non-central heavy-ion collisions, which is expected to be caused by the pressure gradient developed in the early stages of collisions. The azimuthal distribution of the produced particles can be expanded as a Fourier series [2],

$$\frac{dN}{d\phi} \propto 1 + \sum_{n=1}^{\infty} 2v_n \cos [n(\phi - \psi_{RP})]$$

(1)

where $\phi$ is the azimuthal angle and $\psi_{RP}$ is the reaction plane angle. The reaction plane is defined by the beam direction and impact parameter vector between the two colliding nuclei. The reaction plane angle $\psi_{RP}$ is not measurable directly, so the Fourier coefficients are determined with respect to the estimated event plane angle ($\psi_n$) as $v_n = \langle \cos n(\phi - \psi_n) \rangle$. The observed $v_n$ coefficients are then corrected for event plane resolution.

The $\varphi$ meson is the lightest bound state of a strange ($s$) and an anti-strange ($\bar{s}$) quark, and is considered as a clean probe for the study of the properties of the matter created in heavy-ion collisions. The $\varphi$ meson has a life time of $\sim 42$ fm/c [3]. $\varphi$ meson generally decays outside the fireball therefore its decay daughters do not undergo significant re-scattering in the hadronic phase. In addition, the hadronic interaction cross-section of the $\varphi$ meson is expected to be small compared to the other hadrons [4]. Although the generation of the azimuthal anisotropy is an early time phenomenon, its magnitude might still be affected by the late stage hadronic interactions. Due to the above properties of the $\varphi$ meson, its $v_n$ coefficients are relatively...
unaffected by late stage interactions \[5, 6\]. Therefore \(\varphi\) meson \(v_n\) could reflect the collective motion of the partonic phase. This makes the \(\varphi\) meson a clean probe for the study of the properties of the matter created in heavy-ion collisions \[7\].

2. Data Analysis

The data analyzed were recorded with the STAR experiment at RHIC during 2011 and 2012 for Au+Au collisions at \(\sqrt{s_{NN}} = 200\) GeV and U+U collisions at \(\sqrt{s_{NN}} = 193\) GeV, respectively. The minimum bias triggered events with a primary collision vertex position along the longitudinal beam direction (\(V_z\)) within 30 cm from the center of the detector are selected for this analysis. An additional cut on the transverse position of the primary vertex radius (\(V_r < 2.0\) cm) from the center of the beam pipe has also been used to minimize effects of beam pipe interactions. The total number of events analyzed are \(\sim 562\) million and \(\sim 293\) million for Au+Au and U+U collisions, respectively. The STAR’s Time Projection Chamber (TPC) \[8\] and Time Of Flight (TOF) \[9\] detectors were used for particle identification. The TPC is capable of tracking charged particles within \(|\eta| < 1.0\) and has full azimuthal coverage. The TPC detector measures the momentum of the charged tracks as well as the specific ionization energy loss. This energy loss information is then used to identify the individual tracks by comparing them with the theoretical predictions using Bichsel functions \[10\]. The TOF detector measures the time taken by a track to traverse the distance from the primary vertex to the TOF detector. The TOF also has full azimuthal coverage and works within \(|\eta| < 0.9\). \(\varphi\) mesons are identified using the invariant mass technique from their decay to \(K^+\) and \(K^-\) with branching ratio of 48.9%. The mixed event technique has been used for combinatorial background estimation \[11\].

3. Results

3.1. Flow Harmonics \((v_n)\)

The differential flow harmonics \(v_n\) (\(n = 2-5\)) for \(\varphi\) meson as a function of the transverse momentum \((p_T)\) at mid-rapidity (\(|y| < 1.0\)) in Au+Au collisions at \(\sqrt{s_{NN}} = 200\) GeV and U+U collisions at \(\sqrt{s_{NN}} = 193\) GeV for minimum bias events are presented. Figure 1 shows the

![Figure 1](image-url)

**Figure 1.** (Color online) \(\varphi\) meson \(v_n\) as function of \(p_T\) in U+U collisions (a) and Au+Au collisions (b) for minimum bias (0–80% centrality). The different colored bands are the systematic uncertainties and vertical lines are the statistical uncertainties.

\(\varphi\) meson flow coefficients \(v_n\) for Au+Au and U+U. It is observed that the values are comparable between the two collision systems and \(v_2 > v_3 > v_4 > v_5\). The \(v_n\) coefficients as a function of
$p_T$ first increase for $p_T < 2.0$ GeV/c, saturate for intermediate $p_T$ and then decrease for higher $p_T > 3.5$ GeV/c. A similar type of $p_T$ dependence is observed for both systems.

### 3.2. Centrality Dependence

![Graphs showing $v_2$, $v_3$, $v_4$, and $v_5$ as a function of $p_T$ for different centrality bins.](Figure 2)

**Figure 2.** (Color online) $\phi$ meson $v_2$, $v_3$, $v_4$ and $v_5$ as function of $p_T$ in U+U collisions and Au+Au collisions for three different centrality bins ($0 – 10\%$, $10 – 40\%$ and $40 – 80\%$). The different colored bands are the systematic uncertainties and vertical lines are the statistical uncertainties.

Figure 2 shows the centrality dependence of $\phi$ meson flow coefficients $v_n$ for Au+Au at $\sqrt{s_{NN}} = 200$ GeV and U+U collisions at $\sqrt{s_{NN}} = 193$ GeV. Strong centrality dependence is observed for the elliptic flow ($v_2$) in both Au+Au and U+U collisions. We found $v_2$ values higher in peripheral collisions ($40 – 80\%$ centrality) compare to central collisions ($0 – 10\%$ centrality). No clear centrality dependence is observed for other flow harmonics. This can be explained as the higher flow coefficients $v_3$, $v_4$ and $v_5$ are generated due to fluctuations corresponding to the initial states of the colliding nuclei.

### 3.3. Ratio ($v_3/v_2$)

![Graph showing $v_3/v_2$ ratio as a function of $p_T$ for different centrality bins.](Figure 3)

**Figure 3.** (Color online) $v_3/v_2$ ratio as a function of $p_T$ in U+U collisions and Au+Au collisions for three different centrality bins ($0 – 10\%$, $10 – 40\%$ and $40 – 80\%$). Different colored bands are the systematic uncertainties and vertical lines are the statistical uncertainties. The dashed lines are the 4th order polynomial fit to the $v_2$ to get $v_2$ at the $p_T$ corresponding to $v_3$.

Figure 3 shows the ratio of $v_3$ to $v_2$ as a function of $p_T$ for Au+Au and U+U collisions at $\sqrt{s_{NN}} = 200$ GeV and 193 GeV, respectively. We observe the $v_3/v_2$ ratio for $p_T > 1.5$ GeV/c
is constant for both U+U and Au+Au collisions and this is qualitatively consistent with the prediction from hydrodynamic calculations [13].

3.4. Ratio ($v_4/v_2^2$)

![Figure 4](image-url)

Figure 4. (Color online) $v_4/v_2^2$ ratio as a function of $p_T$ in U+U collisions and Au+Au collisions for three different centrality bins (0−10%, 10−40% and 40−80%). The different colored bands are the systematic uncertainties and vertical lines are the statistical uncertainties. The dashed lines are the 4th order polynomial fit to the $v_2$ to get $v_2$ at the $p_T$ corresponding to $v_4$.

Figure 4 shows the ratio of $v_4$ to $v_2^2$ as a function of $p_T$ for Au+Au and U+U collisions at $\sqrt{s_{NN}} = 200$ and 193 GeV, respectively. We observe the ratio $v_4/v_2^2$ of $\phi$ meson is constant for U+U and Au+Au collisions. We found that the ratio has higher values for central collisions compared to peripheral collisions in both U+U and Au+Au collisions. We also found that the ratio $v_4/v_2^2$ has higher values than expected from a hydrodynamic model [13].

4. Summary

$\phi$ meson azimuthal anisotropy coefficients $v_n$ ($n = 2-5$) has been measured in U+U and Au+Au collisions at $\sqrt{s_{NN}} = 193$ GeV and 200 GeV, respectively. The $v_n$ results were compared as a function of the transverse momentum for minimum bias (0-80%) events and in the centrality ranges 0-10%, 10-40% and 40-80%. A strong centrality dependence is observed for elliptic flow ($v_2$), but no clear centrality dependence is observed for $v_3$, $v_4$ and $v_5$ for both the Au+Au and U+U systems. The ratios of flow coefficients has been measured as function of the transverse momentum. The ratio $v_3/v_2$ for $p_T > 1.5$ GeV/c is found to be constant for both the U+U and Au+Au systems, and is consistent with the expectations from a hydrodynamic model [13]. The ratio $v_4/v_2^2$ is found to be higher than expected from the hydrodynamic model [13].
