Abstract: If the lightest CP-even Higgs boson in the MSSM is discovered at the LHC, two measurements could be made simultaneously: the Higgs mass $m_h$ and the event rate $B\sigma(gg \rightarrow h \rightarrow \gamma\gamma)$. We study to what extent the combination of these two measurements would allow us to extract parameters in the stop mass matrix, including the off-diagonal mixing term, with a focus on the MSSM golden region where the stops are light and the mixing is large. Even though both the production cross-section and the decay amplitude are not sensitive to supersymmetric parameters outside of the stop sector, the branching ratio depends on the total decay width, which is dominated by the Higgs decay to $b$ quarks and sensitive to both the pseudo-scalar mass $m_A$ and the supersymmetric Higgs mass $\mu$. In the end we find $m_A$ is an important input in extracting the stop mass parameters, while a fair estimate of the off-diagonal mixing term could be obtained without prior knowledge of $\mu$.

1 Introduction

Supersymmetry (SUSY) is widely considered as the leading proposal to address the hierarchy problem in the standard model. The simplest realization of SUSY, the minimal supersymmetric standard model (MSSM), is without a doubt the most popular extension of the standard model in the last three decades. Although a theoretically very appealing concept, SUSY has remained elusive in experimental searches despite tremendous amount of efforts. The non-discovery of any new particles or the Higgs boson to date introduces a certain amount of fine-tuning in the electroweak sector of MSSM \[1,2\] and creates a somewhat awkward situation given SUSY’s promise to solve the electroweak hierarchy problem.

There is, however, a particular region in the parameter space of MSSM where the fine-tuning in the Higgs mass is reduced. It is the region where the overall stop mass scale is light at several hundreds GeV and the mixing in the stop sector is maximized due to a large trilinear soft $A_t$ term, which implies two stop mass eigenstates below 1 TeV with a mass splitting in the order of a few hundreds GeV. Such a region is dubbed the “golden region” of MSSM by Perelstein and Spethmann in ref. [3] because it satisfies the experimental constraints, including the bound of 114 GeV on the Higgs mass, and minimizes the unnaturalness in the MSSM. Obviously implications of the MSSM golden region on the possible collider signatures at the Large Hadron Collider (LHC) deserve detailed studies if one wish to take the naturalness argument seriously. Previous works on the phenomenology of MSSM golden region can be found in refs. [3–9].

In this work we wish to study the implication of discovering the lightest CP-even Higgs in the MSSM golden region. Since the Higgs sector of the MSSM contains two Higgs doublets, after electroweak symmetry breaking there are five scalar Higgs bosons remaining: a pair of charged Higgs $H^\pm$, one CP-odd Higgs $A$, two CP-even Higgses $h$ and $H$ where $H$ is defined to be the heavier one. Moreover, it is found that, after including radiative corrections, there is an upper bound on the mass of the lightest CP-even Higgs at roughly $130 – 140$ GeV. (For a recent review, see ref. [10].) The importance of such a bound lies in
the observation that a Higgs boson in this mass range can be discovered at the LHC only through its decay into $\gamma\gamma$, which is a loop-induced process, because its mass is below the $W^+W^-$ and $ZZ$ thresholds; decays into $b\bar{b}$ pair are swamped by the background. On the other hand, the dominant production mechanism of the neutral Higgs boson at the LHC is the gluon fusion process\footnote{There are, nevertheless, ways to extract this cross section at the LHC with an uncertainty in the order of $30-40\%$\cite{14}, even though a recent study suggests a smaller uncertainty may be possible\cite{15}.}, also a loop induced process. Since both production and decay channels are loop induced, and hence very sensitive to effects of new physics if any, the process $gg \rightarrow h \rightarrow \gamma\gamma$ is the natural playground to look for deviations from standard model predictions.

Within MSSM effects of supersymmetric particles in the production cross-section $\sigma(gg \rightarrow h)$ and the partial decay width $\Gamma(h \rightarrow \gamma\gamma)$ have been studied previously\cite{12,13}. It is found that for both amplitudes the leading corrections come from the stop sector and, to a lesser extent, charged SUSY particles such as the charginos. However, it is important to emphasize that, once the Higgs is discovered in the process $gg \rightarrow h \rightarrow \gamma\gamma$, two experimental measurements can be made at the same time: the event rate $\sigma(gg \rightarrow h) \times Br(h \rightarrow \gamma\gamma)$ and the Higgs mass $m_h$. One should therefore make use of the information from both measurements in trying to extract parameters of the MSSM. Indeed, ref.\cite{5} showed that it is possible to obtain a fairly good estimate on the trilinear soft $A_t$ term in the stop sector, which is otherwise difficult to measure, if one combines knowledge on the production cross section in the gluon fusion channel $\sigma(gg \rightarrow h)$ and $m_h$. One limitation of the proposal in\cite{5} is that the production cross section $\sigma(gg \rightarrow h)$ is not directly observable in collider experiments: only the product $\sigma(gg \rightarrow h) \times Br(h \rightarrow \gamma\gamma)$ is. Therefore, in this note we will study implications of combining two measurements, $\sigma \times Br$ and $m_h$, in $gg \rightarrow h \rightarrow \gamma\gamma$ with an emphasis on the golden region of the MSSM parameter space.

\section{Higgs couplings to $gg$ and $\gamma\gamma$ in the MSSM}

In this section we discuss the effects of superparticles on the Higgs coupling to two gluons and two photons. In particular, we will work in the so-called decoupling limit\cite{16} where the pseudo-scalar Higgs is much heavier than the $Z$ boson: $m_A \gg m_Z$. There are two reasons for considering the decoupling limit. The first is the lightest CP-even Higgs quickly reaches its maximal possible mass, which is phenomenologically desirable given the null result for Higgs searches at both LEP and Tevatron. The second reason is the tree-level couplings of $h$ in the MSSM to standard model fermions and gauge bosons approach the values for a standard model Higgs, and the two become almost indistinguishable. Therefore any deviations in the event rate from the standard model would come from effects of superparticles running in the loop. It is also worth mentioning that in this case all other Higgs bosons in the MSSM are roughly degenerate $m_A \approx m_H \approx m_{H^\pm}$. In practice, the decoupling limit is quickly reached for moderately large $m_A$ gets larger than the maximal possible value for $h$; the decoupling limit is reached when $m_A \gtrsim 300$ GeV. However, we will see later that Higgs couplings to vector bosons approach the decoupling limit much faster than Higgs couplings to fermions, which has important implications in the present study.
Analytic expressions for a CP-even scalar Higgs decaying into two gluons and two photons within the standard model were obtained long ago in refs. [17–19]. The loop induced amplitude $h \rightarrow gg$ is mediated by the top quark, which has the largest coupling to the Higgs among the fermions, whereas $h \rightarrow \gamma\gamma$ has the leading contribution from the $W$ boson loop with the top quark as the subleading contribution. In the MSSM expressions for effects of superpartners can be found in ref. [20]. In $h \rightarrow gg$ the top squark gives the dominant supersymmetric contribution, while all the charged superparticles, such as the sfermions, charged Higgs scalars, and the charginos, now contribute to $h \rightarrow \gamma\gamma$ as well. More explicitly,

$$
\Gamma(h \rightarrow gg) = \frac{G_F \alpha_s^2 m_h^3}{36\sqrt{2}\pi^3} \left| N_c Q_t^2 g_{hUt} A_t^h(\tau_t) + A^{gg} \right|^2,
$$

(2.1)

$$
\Gamma(h \rightarrow \gamma\gamma) = \frac{G_F \alpha_s^3 m_h^3}{128\sqrt{2}\pi} \left| N_c Q_t^2 g_{hWt} A_{1/2}(\tau_t) + g_{hWW} A^h(\tau_W) + A^{\gamma\gamma} \right|^2,
$$

(2.2)

where $g_{hUt}$ and $g_{hWt}$ are the coupling of $h$ to the top quark and the $W$ boson, respectively. Moreover $\tau_t = m_{\tilde{t}}/4m_t^2$ and the form factors are

$$
A^h_t(\tau) = \frac{2}{\tau^2} [\tau + (\tau - 1)f(\tau)],
$$

(2.3)

$$
A^h_0(\tau) = -\frac{1}{\tau^2} [\tau - f(\tau)],
$$

(2.4)

$$
A^h_1(\tau) = -\frac{1}{\tau^2} [2\tau^2 + 3\tau + 3(2\tau - 1)f(\tau)],
$$

(2.5)

$$
f(\tau) = \begin{cases} 
\arcsin^2 \sqrt{\tau} & \tau \leq 1 \\
-\frac{1}{4} \left( \log \frac{1 + \sqrt{1 - \tau^{-1}}}{1 - \sqrt{1 - \tau^{-1}}} - i\pi \right)^2 & \tau > 1.
\end{cases}
$$

(2.6)

The supersymmetric contributions $A^{gg}$ and $A^{\gamma\gamma}$ are

$$
A^{gg} = \sum_i N_c Q_t^2 g_{hUt,i} \frac{m_{\tilde{t}}^2}{m_t^2} A^h_0(\tau_t),
$$

(2.7)

$$
A^{\gamma\gamma} = g_{hH^+H^-} \frac{m_{\tilde{W}}^2}{m_{H^\pm}^2} A^h_0(\tau_{H^\pm}) + \sum_f N_c Q_f^2 g_{hQf} \frac{m_{\tilde{Q}}^2}{m_f^2} A^h_0(\tau_f) + \sum_i g_{hX_i} \frac{m_W}{m_{X_i}} A^h_0(\tau_{X_i}).
$$

(2.8)

Explicit forms for the couplings of $h$ to superparticles can be found in refs. [10, 20]. We will, however, write down $g_{h\tilde{t}\tilde{t}}$, since the stop contribution is the focus of present study. When normalizing to $2m_\tilde{t}^2(\sqrt{2}G_F)^{1/2}$,

$$
g_{h\tilde{t}_1\tilde{t}_1} = \cos 2\beta \left( \frac{1}{2} \cos^2 \theta_t - \frac{2}{3} s_w^2 \cos 2\theta_t \right) + \frac{m_{\tilde{t}}^2}{2m_{\tilde{t}}^2} - \frac{1}{2} \frac{m_{\tilde{t}}X_t}{m_{\tilde{t}}^2} \sin 2\theta_t,
$$

(2.9)

$$
g_{h\tilde{t}_2\tilde{t}_2} = \cos 2\beta \left( \frac{1}{2} \sin^2 \theta_t + \frac{2}{3} s_w^2 \cos 2\theta_t \right) + \frac{m_{\tilde{t}}^2}{2m_{\tilde{t}}^2} + \frac{1}{2} \frac{m_{\tilde{t}}X_t}{m_{\tilde{t}}^2} \sin 2\theta_t.
$$

(2.10)

In the above $s_w$ is the sine of Weinberg angle and $\theta_t$ is the mixing angle in the stop sector. The mixing parameter $X_t$ is the off-diagonal entry in the stop mass matrix

$$
M_{\tilde{t}}^2 = \begin{pmatrix}
\frac{m_{\tilde{t}_L}^2}{m_{\tilde{t}_L}} + m_{\tilde{t}}^2 + D_L^t & \frac{m_{\tilde{t}}X_t}{m_{\tilde{t}_L}} \\
\frac{m_{\tilde{t}}X_t}{m_{\tilde{t}_L}} & \frac{m_{\tilde{t}_R}^2}{m_{\tilde{t}_R}} + m_{\tilde{t}}^2 + D_R^t
\end{pmatrix},
$$

(2.11)
where

\[ D_L' = \left( \frac{1}{2} - \frac{2}{3} s_w^2 \right) m_Z^2 \cos 2\beta, \] (2.12)

\[ D_R' = \frac{2}{3} s_w^2 m_Z^2 \cos 2\beta, \] (2.13)

\[ X_t = A_t - \frac{\mu}{\tan \beta}. \] (2.14)

In the limit of heavy loops masses \( \tau_i \ll 1 \), the form factors approach the asymptotic values

\[ A_h^0 \to -\frac{1}{3}, \quad A_h^\frac{1}{2} \to -\frac{4}{3}, \quad A_1^h \to +7. \] (2.15)

Note that standard model contributions due to the top quark and \( W \) boson loops are finite in the asymptotic limit, whereas the supersymmetric contributions are suppressed by large loop masses. One exception is the stop contribution in the MSSM golden region when the stops are light and the mixing parameter \( X_t \) is large. In this case the stop mixing angle is maximal, \( |\sin 2\theta_t| \approx 1 \), and the \( g_{ht_1 t_1} \) coupling is strongly enhanced. Thus the stop correction in the Higgs production and decay amplitudes is the dominant one and very pronounced, despite being a loop effect. The particle giving the second largest effect is the chargino, not only because its effect decouples like \( 1/m_{\tilde{\chi}} \) when others decouple like \( 1/m^2 \), as can be seen in \( A^{\gamma\gamma} \), but also because of the larger asymptotic value of \( A_{1/2}^h \) than \( A_0^h \).

For the gluon fusion production, it has been shown that the stop could have an order unity effect when comparing with the standard model rate, especially in the region of light stops and large mixing \( X_t \) [5, 13], which is exactly the MSSM golden region. As for the Higgs decay into two photons, ref. [12] showed that the stop could have a sizable effect, in the order of 10% level, in the MSSM golden region. The effect is less dramatic than in the gluon fusion rate because the \( W \) boson loop is the dominant contribution in the decay into two photons, as can be seen from eq. (2.15), which shows \( A_1^h \) has the largest asymptotic value. Moreover, among all the charged superparticles only the chargino loop could have a significant effect again in the order of 10% when the chargino is as light as 100 GeV. For chargino masses above 250 GeV, the deviation is less than 8% through out the entire MSSM parameter space [12]. The direct search limit of charginos from LEP is at 103 GeV, which is quite robust and independent of model assumptions, whereas searches at Tevatron result in a lower bound of 145 GeV in a specific model choice [21]. In section IV we will demonstrate that throughout the MSSM golden region the chargino has a small effect, when considering the ratio of the event rate \( \sigma(gg \to h) \times Br(h \to \gamma\gamma) \) in the MSSM over the SM, once its mass is heavier than 200 GeV.

In addition to focusing on the region of MSSM parameter space where the stops are light and the mixing is large, we would follow ref. [5] and concentrate on the following choice of parameters:

- \( 10 \lesssim \tan \beta \lesssim m_t/m_b \),
- \( |m_b \mu \tan \beta| \lesssim m_{b_L}^2, m_{b_R}^2 \).

- 4 -
Figure 1. Plot of $R(B\sigma) = B\sigma(\text{MSSM})/B\sigma(\text{SM})$ as a function of $r$ for $m_{\tilde{t}} = 500\text{ GeV}$, $m_A = 400\text{ GeV}$, $\mu = 200\text{ GeV}$, and $M_{\text{SUSY}} = 1\text{ TeV}$. The (dark) solid and (red) dashed lines are for $\tan\beta = 10$ and $40$, respectively. The three sets of curves from top to bottom are for $X_t/m_{\tilde{t}} = 0, -1, \text{ and } -2$ respectively.

The main reason for doing so is to avoid the region where the sbottom contribution could be significant in the loop induced processes [13] as well as the Higgs mass [22]. Furthermore, the mass of the lightest CP-even Higgs is insensitive to $\tan\beta$ once $\tan\beta \gtrsim 10$. Since the bottom quark mass is very small $m_b \sim 5\text{ GeV}$, the above choice covers a very substantial region of MSSM parameter space.

Another important comment is related to the observation made in ref. [5] where it was shown that the gluon fusion production rate depends on only two out of the three parameters in the stop mass matrix in eq. (2.11). If we define the following parameters

$$m_{\tilde{t}}^2 = \frac{m_{\tilde{t}L}^2 + m_{\tilde{t}R}^2}{2}, \quad r = \frac{m_{\tilde{t}L}^2 - m_{\tilde{t}R}^2}{m_{\tilde{t}L}^2 + m_{\tilde{t}R}^2},$$

then the cross section $\sigma(gg \rightarrow h)$ only depends on $m_{\tilde{t}}^2$ and $X_t$ mostly; the dependence on $r$ is minimal when $|r| \lesssim 0.4$. In figure 1 we show that this is the case also in the ratio of the event rate $B\sigma(gg \rightarrow h \rightarrow \gamma\gamma)$ as well. From the figure we see that the variation in the ratio of $B\sigma(gg \rightarrow h \rightarrow \gamma\gamma)$ is less than 10% for large $X_t$ if $|r| \lesssim 0.5$. For $m_{\tilde{t}} = 500\text{ GeV}$ this translates into $m_{\tilde{t}L} \sim 600\text{ GeV}$ and $m_{\tilde{t}R} \sim 300\text{ GeV}$.

It turns out that, as pointed out in Ref. [5], the Higgs mass $m_h$ is also sensitive to the same two parameters in the stop mass matrix. Thus in the end two measurements in $m_h$ and $B\sigma$ could potentially yield useful information on two mass parameters, including $X_t$, in the stop sector of the MSSM.

3 The Higgs mass in the MSSM

In this section we very briefly discuss the mass of the lightest CP-even Higgs in the MSSM, as much of it has been studied extensively in the literature. The Higgs sector of the MSSM contains two Higgs doublets, $H_u$ and $H_d$, which couples to the up-type and down-type quarks separately due to constraints from the anomaly cancellation and the holomorphicity of the superpotential. After electroweak symmetry breaking five remaining physical
states are two CP-even neutral Higgs bosons, $h$ (the lighter one) and $H$ (the heavier one), one CP-odd neutral Higgs boson $A$, and the charged Higgses $H^\pm$. In the MSSM there are two free parameters in the Higgs sector, taken to be tan $\beta$ and $m_A$, and at tree level one can derive an upper bound on $m_h$ [10]:

$$m_h \leq m_Z |\cos 2\beta| \leq m_Z = 91.2 \text{ GeV},$$

which is well below the direct search limit of 114 GeV at LEP.

Therefore, large radiative corrections from superparticles with significant couplings to $h$ are required to raise $m_h$ above the LEP bound. Among the new particles in MSSM the stops have the largest coupling to the lightest CP-even Higgs due to the top Yukawa couplings. (We are avoiding the region of very large tan $\beta$ and large $\mu$ where the sbottom couplings could also be significant, as mentioned in the previous section.) If we assume for simplicity $m_{\tilde{t}_R} \simeq m_{\tilde{t}_L} = m_t$, the one-loop correction to $m_h$ is approximately given as [10, 23]

$$\Delta m_h^2 \simeq \frac{3G_F}{\sqrt{2}\pi^2} m_t^4 \left\{ \log \frac{m_t^2}{m_{\tilde{t}}^2} + \frac{X_t^2}{m_t^2} \left( 1 - \frac{X_t^2}{12m_t^2} \right) \right\},$$

which grows only logarithmically with the stop mass $m_{\tilde{t}}$. Therefore to lift $m_h$ from $m_Z$ to be above 114 GeV requires very heavy stops if there is no large mixing. Typically for $m_{\tilde{t}_R} \simeq m_{\tilde{t}_L}$ the stop masses need to be very large, $\mathcal{O}(1 \text{ TeV})$, to evade the LEP bound. On the other hand, the up-type Higgs mass-squared increases quadratically with $m_{\tilde{t}}$,

$$\Delta m_{H_u}^2 \simeq -\frac{3}{8\pi^2} m_{\tilde{t}}^2 \log \frac{\Lambda^2}{m_{\tilde{t}}^2}.$$ (3.3)

Thus heavy stop masses at around 1 TeV would lead to large ($\mathcal{O}(m_Z^2/m_t^2) \lesssim 1\%$) fine-tuning in electroweak symmetry breaking. However, the fine-tuning can be reduced if the stop masses could be significantly below 1 TeV while at the same time keeping $m_h \gtrsim 114$ GeV. This is possible only if there is large mixing in the stop sector, in which case the fine tuning can be reduced to the level of 5%. The Higgs mass is maximized for $|X_t/m_t| \sim 2$ and with this mixing light stops, $m_{\tilde{t}_R} \simeq m_{\tilde{t}_L} \simeq 300$ GeV, are sufficient to raise the Higgs mass above the LEP limit.

4 Results

We use the program FeynHiggs-2.6.4 [24, 25] in our numerical analysis with the following relevant parameters: $m_t = 172.6$ GeV, $m_b = 4.2$ GeV, and the pseudo-scalar Higgs mass $m_A = 400$ GeV (unless otherwise noted.) It is perhaps worth emphasizing that FeynHiggs employs various approximation schemes in computing the MSSM Higgs production and decay rates, which are extrapolated from the SM predictions. In this work we use the program mainly to study the dependence on other SUSY parameters and demonstrate the feasibility of our proposal. Higher-order QCD corrections could be important and should be included if a full-fledged analysis were performed, which is beyond the scope of the current work. In the following the main observable we consider is the ratio of the event
Figure 2. Contour plot of $m_{\chi_1}$ and $R(B\sigma)$ in the $\mu - M_2$ plane. In this plot $\tan \beta = 30$, $M_{\text{SUSY}} = 1000 \text{ GeV}$, $m_{\tilde{t}_L} = m_{\tilde{t}_R} = 500 \text{ GeV}$, and $X_t = -700 \text{ GeV}$. The (dark) solid lines correspond to the $R(B\sigma)$ contours, whereas the (red) dashed lines are for the $m_{\chi_1}$ contours. This set of parameters would result in a Higgs mass slightly above the LEP bound of $114 \text{ GeV}$.

rates in the MSSM over the standard model: $R(B\sigma) = B\sigma(\text{MSSM})/B\sigma(\text{SM})$. (When we speak of the event rate, we would always have in mind the ratio of the event rates!)

We first consider the effect of the chargino mass on $R(B\sigma)$. In MSSM the chargino mass is determined by the gaugino mass parameter $M_2$ and the supersymmetric Higgs mass parameter $\mu$. In figure 2 we present a contour plot of $R(B\sigma)$ and the lightest chargino mass $m_{\chi_1}$ in the $\mu - M_2$ plane, in which $m_{\chi_1}$ varies from 200 to 900 GeV. We see that contours of constant $R(B\sigma)$ runs somewhat parallel to the $M_2$ axis, which implies $R(B\sigma)$ is sensitive to $\mu$ only. Therefore $R(B\sigma)$ depends on the chargino mass only through its dependence on the $\mu$ parameter. For example, let’s choose $\mu = 900 \text{ GeV}$ and change $M_2$ from 200 to 1000 GeV, which results a modification in $m_{\chi_1}$ from 200 to 900 GeV. The corresponding $R(B\sigma)$ remains roughly constant at 0.99, as can be seen from figure 2, in spite of a large variation in $m_{\chi_1}$. On the other hand, one could vary $\mu$ while keeping $m_{\chi_1}$ constant, and $R(B\sigma)$ would change significantly according to $\mu$. It has been previously observed that the chargino has a small effect in the partial width $\Gamma(h \to \gamma \gamma)$ [12]. Here we see what is important is the value of the $\mu$ parameter, instead of the chargino mass itself. If $\mu$ is not too large, then the effect of the chargino is small not only in the partial width of $h \to \gamma \gamma$, but also in the ratio of the event rate $B\sigma(gg \to h \to \gamma \gamma) = \sigma(gg \to h) \times Br(h \to \gamma \gamma)$.

On the other hand, we observe in figure 2 that $R(B\sigma)$ does have a strong dependence in the supersymmetric Higgs mass parameter $\mu$. From the discussion above we know this dependence cannot come from the charginos. It turns out the $\mu$ dependence does not arise from effects of supersymmetric particles in either the production cross-section $\sigma(gg \to h)$ or the partial decay width $\Gamma(h \to \gamma \gamma)$. Somewhat surprisingly, the strong $\mu$ dependence resides in the radiative corrections of supersymmetric particles to the bottom Yukawa coupling. The bottom Yukawa coupling controls the decay amplitude of $h \to b \bar{b}$, which partial width dominates the total decay width of the lightest CP-even Higgs in MSSM.
Figure 3. Dependence on $\mu$ in the event rate $R(B\sigma)$. In these plots $\tan\beta = 30$, $M_{\text{SUSY}} = 500$ (solid lines) and 1000 (dashed lines) GeV, $m_{\tilde{t}_L} = m_{\tilde{t}_R} = 300$ GeV, and $X_t = \pm 500$ and $\pm 600$ GeV. The two choices of $X_t$ correspond a Higgs mass of 116 and 119 GeV, respectively. The left plot is for $m_A = 400$ GeV and the right for $m_A = 1000$ GeV. In the plots we have also set the gaugino mass parameter $M_2 = M_{\text{SUSY}}$.

Since the branching ratio is given as

$$Br(h \rightarrow \gamma\gamma) = \frac{\Gamma(h \rightarrow \gamma\gamma)}{\Gamma_{\text{tot}}} \approx \frac{\Gamma(h \rightarrow \gamma\gamma)}{\Gamma(h \rightarrow bb)},$$

(4.1)

the event rate $B\sigma$ is very sensitive to supersymmetric corrections to $h \rightarrow bb$.

More specifically, at one-loop the running $b$-quark mass receives contributions from sbottom-gluino loops and stop-charged Higgsino loops,\footnote{There is also a sbottom-wino loop whose contribution is suppressed by the smallness of the electroweak gauge coupling.} which depends on the gluino mass, the stop and sbottom eigenmasses, the supersymmetric Higgs mass $\mu$ as well as the stop mixing parameter $X_t$. Such corrections become more important when $\tan\beta$ becomes larger, which is the regime we are interested in. However, since we are avoiding regions where the sbottoms are light, we find the sbottom-gaugino loop is numerically unimportant. In figure 3 we single out the $\mu$ dependence of $R(B\sigma)$ for $\tan\beta = 30$ and some choices of stop masses and $X_t$. The reason that the variation is asymmetric in $X_t \rightarrow -X_t$ is because the contribution from stop-chargino loop is linear in $X_t$ at leading order. So for one sign it adds to the tree-level result while for the opposite sign it subtracts. Nevertheless, the important observation is that as the mixing parameter $X_t$ becomes larger, the variation becomes smaller. In this case, one of the stop mass eigenstates is heavy and suppresses the loop contributions. Therefore if we are only interested in the MSSM golden region, where $X_t$ is large and $|X_t/m_{\tilde{t}}| \sim 2$, the $\mu$ dependence is reduced.

The fact that the total decay width $\Gamma_{\text{tot}} \approx \Gamma(h \rightarrow bb)$ enters into $Br(gg \rightarrow h \rightarrow \gamma\gamma)$ introduces additional sensitivity on the mass of the pseudo-scalar Higgs $m_A$, which is absent in either the cross-section $\sigma(gg \rightarrow h)$ or the partial decay width $\Gamma(h \rightarrow \gamma\gamma)$, because the Higgs coupling to bottom quarks depends on $m_A$ in a complicated fashion. When normal-
Figure 4. Dependence of $R(B\sigma)$ on $m_A$. In this plot $\tan \beta = 30$, $M_{\text{SUSY}} = 1000 \text{ GeV}$, $m_{\tilde{t}_L} = m_{\tilde{t}_R} = 300 \text{ GeV}$, and $X_t = \pm 500$ and $\pm 600 \text{ GeV}$. These two choices of $X_t$ correspond a Higgs mass of 116 and 119 GeV, respectively. In the plot we have set $\mu = M_2 = M_{\text{SUSY}}$.

When going to $im_b/v$, the tree-level Higgs coupling to bottom quarks in MSSM can be written as

$$g_{hbb} = \frac{\sin \alpha}{\cos \beta}, \quad \alpha = \frac{1}{2} \arctan \left( \tan 2\beta \frac{m_A^2 + m_Z^2}{m_A^2 - m_Z^2} \right),$$

where $\alpha$ is the mixing angle in the CP-even Higgs sector and $-\pi/2 \leq \alpha \leq 0$. The usual decoupling regime of MSSM, where the lightest CP-even Higgs has standard model-like couplings, is obtained in the limit of large $\tan \beta$ and $m_A \gg m_Z$. In this limit the Higgs coupling to the standard model gauge bosons, $g_{hVV} \propto \sin(\beta - \alpha) \to 1$, approaches that of a standard model Higgs boson. This limit happens quite fast for moderately heavy $m_A$ and one sometimes define the decoupling regime as the region where $\sin^2(\beta - \alpha) \geq 0.95$ [10]. However, because the Higgs coupling to bottom quarks is proportional to $-\sin \alpha/\cos \beta$, instead of $\sin(\beta - \alpha)$, $g_{hbb}$ approaches its standard model value much slower than the $g_{hVV}$ couplings. For example, at $\tan \beta = 30$ and $m_A = 400 \text{ GeV}$, we have $\sin^2(\beta - \alpha) = 0.99999$ whereas $g_{hbb}^2$ is only 0.81, still quite far from the standard model value at unity. In figure 4 we plot the $m_A$ dependence of the event rate $R(B\sigma)$ and one sees that the sensitivity is quite strong in varying $m_A$ from 400 to 1000 GeV, especially for a light Higgs mass $m_h \approx 116 \text{ GeV}$.

The slow approach to the decoupling limit of the tree-level coupling in $g_{hbb}$ is indicative of the strong $m_A$ dependence in $\Gamma(h \to b\bar{b})$, and hence $\Gamma_{\text{tot}}$. However, the sensitivity in figure 4 cannot be explained by the change in the tree-level coupling alone, and higher-order corrections play an important role here. Since $m_A$ is taken as one of the input parameters in the Higgs sector of MSSM, it is clear that $m_A$ enters into the higher-order corrections in a complicated way and its effect cannot be disentangled easily. For example, in addition to the supersymmetric loop corrections to the bottom Yukawa couplings mentioned previously, there are also higher-order corrections to the off-diagonal matrix element of the CP-even Higgs mass matrix [29, 30]. We would perhaps only comment that all these higher-order corrections have been incorporated in the numerical code FeynHiggs [31], which is employed in this study. It is also worth observing that the dependence of $R(B\sigma)$ on $\mu$ becomes weaker for large pseudo-scalar mass $m_A$, as can be seen in figure 3.
Given the strong $m_A$ dependence and, to a less extent, the $\mu$ dependence in $R(B\sigma)$, it is desirable to have knowledge of these two input parameters before one can use both $m_h$ and $B\sigma$ to extract $m_{\tilde{t}}$ and $X_t$ in the stop sector. This is contrary to the case of utilizing the the Higgs production rate in the gluon fusion channel in conjunction with $m_h$, as suggested in [5], where the sensitivity to SUSY parameters other than $m_{\tilde{t}}$ and $X_t$ are very weak. In figure 5 we present contours of $R(B\sigma)$ and $m_h$ in the $m_{\tilde{t}} - X_t/m_{\tilde{t}}$ plane for $m_A = 1000$ GeV. In the plot we have included the $\mu$ dependence by varying $\mu$ from 200 to 1000 GeV and using the shaded region to represent the corresponding change in $R(B\sigma)$. We see that in the region where $X_t$ is small and the MSSM fine-tuned, the $R(B\sigma)$ contour runs somewhat parallel to the $m_h$ contours and no useful information on $m_{\tilde{t}}$ and $X_t$ could be extracted. On the other hand, in the less fine-tuned MSSM golden region where the stops are light and $X_t$ is large, the two contours run almost perpendicular to each other and one could potentially get a fair estimate on the magnitudes of $m_{\tilde{t}}$ and $X_t$. Moreover, in this region of particular interests, $R(B\sigma)$ deviates substantially from unity in that the event rate in the MSSM is much smaller than in the standard model, which implies it may take longer time and more statistics to observe the Higgs at the LHC if indeed the MSSM is realized in nature in a less fine-tuned region of parameter space. In addition, the variation due to $\mu$ in $R(B\sigma)$ is also smaller in this particular region.

In figure 6 we focus in the region where $300$ GeV $\leq m_{\tilde{t}} \leq 600$ GeV and $-2.25 \leq X_t/m_{\tilde{t}} \leq -1.0$ for two different values of $m_A$ at 400 and 1000 GeV. We have chosen the minus sign for $X_t$ since constraints from rare $B$ decays seem to favor negative $X_t$ [32]. As commented previously, the variation due to $\mu$ is larger for smaller value of $m_A$. We see that it is important to know the mass of the pseudo-scalar Higgs $m_A$. But once $m_A$ is known, one could get a fair estimate of $m_{\tilde{t}}$ and $X_t$ even without prior knowledge of the supersymmetric Higgs mass $\mu$, especially in the region where $R(B\sigma) \lesssim 0.8$. 

Figure 5. Contours of $R(B\sigma)$ and $m_h$ in the $m_{\tilde{t}} - X_t/m_{\tilde{t}}$ plane. This plot is for $\tan \beta = 30$, $M_{\text{SUSY}} = 1000$ GeV, and $m_A =$1000 GeV. The shaded regions correspond to the variation in $R(B\sigma)$ when changing $\mu$ from 200 to 1000 GeV.
Figure 6. Contours of $R(B\sigma)$ and $m_h$ in the MSSM golden region. In these plots $\tan \beta = 30$ and $M_{\text{SUSY}} = 1000 \text{ GeV}$. In the top plot $m_A = 400 \text{ GeV}$ and in the bottom plot $m_A = 1000 \text{ GeV}$. The shaded regions have the same meaning as in figure 5.

5 Conclusion

In this work we studied implications of discovering the lightest CP-even Higgs boson in the MSSM golden region, when measurements on the Higgs mass $m_h$ and the event rate $B\sigma(gg \to h \to \gamma\gamma)$ are made at the same time. Previously it was suggested that $m_h$ and the Higgs production cross-section in the gluon fusion channel could be used to extract two parameters, $m_{\tilde{t}}$ and $X_t$, in the stop sectors, which are important to understand the degree of fine-tuning in the MSSM. We find that in the case of the event rate there are additional sensitivities on the pseudo-scalar mass $m_A$ and the supersymmetric Higgs mass $\mu$. It turns out that both sensitivities result from the Higgs coupling to bottom quarks, which partial decay width dominates the total decay width of the lightest CP-even Higgs boson in the MSSM. The fact that the branching ratio $Br(h \to \gamma\gamma)$ depends on the total width introduces sizable dependence of $B\sigma$ on $m_A$ and $\mu$, even though neither the production cross-section $\sigma(gg \to h)$ nor the partial decay width $\Gamma(h \to \gamma\gamma)$ is sensitive to these two parameters. We also find that, in the MSSM golden region where the stops are light and the mixing is large, the most important input parameter is $m_A$, whereas ignorance of $\mu$ could still allow for a fair estimate of $m_{\tilde{t}}$ and $X_t$ in the stop sector. Moreover, we find that throughout the MSSM golden region the event rate $B\sigma$ is significantly smaller than the standard model rate, which implies it may take more time to make the discovery. Given that there is no known method to directly measure the stop mixing parameter $X_t$, it will be important to combine the study presented here with the proposal in ref. [5] to get indirect measurements on $m_{\tilde{t}}$ and $X_t$.
