Horizontal gene transfer has had major impacts on the biology of a wide range of organisms from antibiotic resistance in bacteria to adaptations to herbivory in arthropods. A growing body of literature shows that horizontal gene transfer (HGT) between non-animals and animals is more commonplace than previously thought. In this study, we present a thorough investigation of HGT in the ctenophore *Mnemiopsis leidyi*. We applied tests of phylogenetic incongruence to identify nine genes that were likely transferred horizontally early in ctenophore evolution from bacteria and non-metazoan eukaryotes. All but one of these HGTs (an uncharacterized protein) are homologous to characterized enzymes, supporting previous observations that genes encoding enzymes are more likely to be retained after HGT events. We found that the majority of these nine horizontally transferred genes were expressed during development, suggesting that they are active and play a role in the biology of *M. leidyi*. This is the first report of HGT in ctenophores, and contributes to an ever-growing literature on the prevalence of genetic information flowing between non-animals and animals.

Abstract

Horizontal gene transfer has had major impacts on the biology of a wide range of organisms from antibiotic resistance in bacteria to adaptations to herbivory in arthropods. A growing body of literature shows that horizontal gene transfer (HGT) between non-animals and animals is more commonplace than previously thought. In this study, we present a thorough investigation of HGT in the ctenophore *Mnemiopsis leidyi*. We applied tests of phylogenetic incongruence to identify nine genes that were likely transferred horizontally early in ctenophore evolution from bacteria and non-metazoan eukaryotes. All but one of these HGTs (an uncharacterized protein) are homologous to characterized enzymes, supporting previous observations that genes encoding enzymes are more likely to be retained after HGT events. We found that the majority of these nine horizontally transferred genes were expressed during development, suggesting that they are active and play a role in the biology of *M. leidyi*. This is the first report of HGT in ctenophores, and contributes to an ever-growing literature on the prevalence of genetic information flowing between non-animals and animals.
Introduction

Evolution is commonly thought to occur by descent with modification from a single lineage. However, evidence has shown that genomes from bacteria, archaea, and eukaryotes are typically chimeric, resulting from horizontal (or lateral) gene transfers (Garcia-Vallvé et al. 2000; Katz 2002). As such, horizontal gene transfer (HGT) has likely impacted evolution more than originally thought by creating opportunities for rapid genetic diversification and contributing to speciation events. Moreover, HGT is a potential catalyst for organisms to acquire novel traits (Soucy et al. 2015) and creates opportunities for HGT receivers to exploit new ecological niches (Boto 2010). For example, HGTs have played an important role in herbivory in arthropods (Wybouw et al. 2016), venom recruitment in parasitoid wasps (Martinson et al. 2016), cellulose production in urochordates (Dehal et al. 2002) and plant parasitism in nematodes (Haegeman et al. 2011).

Although HGT is generally accepted as an important evolutionary mechanism in prokaryotes (Boto 2014), it remains controversial whether it occurs in animals, despite many convincing studies (Madhusoodanan 2015). Much of the skepticism has been fueled by high-profile reports of HGT (e.g., Lander et al. 2001; Boothby et al. 2015) that were later shown to be largely incorrect due to contamination or taxon sampling (Stanhope et al. 2001; Koutsovoulos et al. 2016). In addition, HGT in animals is hypothesized to be rare due to the origin of a sequestered germ line, which provides fewer opportunities for germ cells to be exposed to foreign DNA (Doolittle 1999; Andersson et al. 2001; Jensen et al. 2016). However, the presence and absence of germline sequestration is not well described across the animal tree of life, and
there are inconsistencies between studies regarding which animal groups have sequestered germlines (Buss, 1983; Radzvilavicius et al. 2016; Jensen et al. 2016).

The major challenges for HGT detection efforts have been taxon sampling and contamination. Many early reports of HGT in animals were overturned due to limited representation of taxa in public genomic databases (e.g., Salzberg et al. 2001). For example, a gene present in bacteria and humans, but absent from nematodes and drosophilids (the most highly represented taxa at the time) may have been considered the result of HGT, until discovering that the gene is present in many other animal genomes that were not available at the time of the initial claim. In these cases, the limited representation of taxa made it difficult to distinguish HGTs from differential gene loss (Andersson et al. 2006; Keeling & Palmer, 2008).

More recently, contamination has led to both overestimation and likely underestimation of HGT events. In several recent cases, contamination in newly generated datasets has been interpreted as HGT but later shown to be cross-contaminants present in genome sequences (Bhattacharya et al. 2013; Delmont & Eren 2016; Koutsovoulos et al. 2016). On the other hand, the presence of contaminants in public databases (e.g., a bacteria sequence labeled as an animal sequence) makes it difficult to identify *bona fide* HGTs, as “animal” sequences will appear among the top BLAST hits for a particular HGT, leading to false negatives. As such, contamination remains a major hurdle to contemporary studies of HGT.

Pairwise BLAST-based similarity scores (e.g., alien index (Gladyshev et al. 2008) and the HGT index (Boschetti et al. 2012)) are the most common criteria used to detect HGT in animals. However, these measures largely ignore phylogenetic information associated with
sequence data. While a positive BLAST-based result may be due to HGT, it may also result from
gene loss, selective evolutionary rates, convergent evolution, sequence contamination, and
species misassignment (Hall et al. 2005). Previous HGT studies have demonstrated that HGT
predictions need to be carefully considered and a combination of methods are required to rule out
false positives (Schönknecht et al. 2013). Hypothesis tests incorporating phylogenetic
incongruence are one such method that has been used to test HGT. While some studies in
animals have incorporated these techniques (e.g., Eliáš et al, 2016), they are more commonly
deployed in studies involving non-animals (e.g., Baptiste et al. 2003; Richards et al. 2006).

HGT has yet to be thoroughly explored in Ctenophora. Ctenophores (comb jellies) are
marine invertebrates that are morphologically characterized by eight rows of cilia used for
movement. They typically live in the water column, but the group includes benthic species as
well (Song & Hwang 2010; Alamaru et al. 2015; Glynn et al. 2017). Phylogenomic evidence
from studies including ctenophores has suggested that ctenophores are the sister group to all
other animals (Dunn et al. 2008; Hejnol et al. 2009; Ryan et al. 2013; Moroz et al. 2014;
Borowiec et al. 2015; Chang et al. 2015; Torruella et al. 2015; Whelan et al. 2015; Arcila et al.
2017; Shen et al. 2017; Whelan et al. 2017), but the position remains controversial with some
evidence supporting sponges as the sister group to the rest of animals (Philippe et al. 2009; Pick
et al. 2010; Pisani et al. 2015; Telford et al. 2015; Simion et al. 2017; Feuda et al. 2017). Thus,
investigating HGT in ctenophores is essential to understanding its implications on early animal
evolution.
Here, we apply a rigorous framework to identify and confirm HGTs in the ctenophore *Mnemiopsis leidyi*. Our process includes identification of HGT candidates by alien index and confirmation by phylogenetic hypothesis testing, providing statistical support in an evolutionary framework. Furthermore, we analyze gene expression profiles during development to obtain clues as to the function of these HGTs in *M. leidyi*.

**Material and Methods**

All command lines, parameters, and version numbers of programs are in the supplementary text.

**Identification of HGT candidates by alien_index**

As part of this project, we developed the program alien_index and complimentary metazoan/non-metazoan sequence databases to automate the generation of alien index (Gladyshev et al. 2008) and HGT index scores (Boschetti et al. 2012). We BLASTed the entire set of *M. leidyi* gene models (ML2.2) against a database of animal and non-animal sequences (alien_index_db version 0.01) and then calculated alien index values as the logarithmic difference between the best BLASTP E-values for animal and non-animal hits (as outlined in Gladyshev et al. 2008) (Fig. 1A). In more simple terminology, the alien index reflects the difference between the E-value of the best non-animal BLAST hit and that of the best animal hit. The database used includes translated gene models from curated genomes that include bacteria (5), archaea (2), non-animal eukaryotes (5), and animals (12). See Table S1 or http://ryanlab.whitney.ufl.edu/downloads/alien_index/ for the entire list of taxa. HGT index
117 values were computed by the difference in the highest non-metazoan and metazoan bit scores
118 generated from the alien_index database. The alien_index program is available at:
119 https://github.com/josephryan/alien_index
120
121 **Confirmation of HGTs**
122
123 We applied a phylogenetic approach to confirm putative HGTs. HGT candidates from
124 alien_index were used as queries for BLASTP against NCBI’s RefSeq database (O'Leary et al.
125 2016) using the NCBI BLAST interface. We collected the top ten sequences each from bacteria,
126 eukaryotes, fungi, and animals with an E-value cutoff of 0.1. We included only the first sequence
127 if there were hits to sequences from species in the same genus (Fig. 1B). We also added the top
128 BLAST hit (E-value $\leq 0.1$) from each of the following fully sequenced animals *Amphimedon*
129 *queenslandica*, *Trichoplax adhaerens*, *Nematostella vectensis*, *Capitella teleta*, *Drosophila*
130 *melanogaster*, and *Homo sapiens* from version 0.01 of the alien_index database. Sequences were
131 aligned against the corresponding putative HGT using MAFFT (Katoh et al. 2002; Katoh &
132 Standley 2013) and trimmed with Gblockswrapper (Castresana 2000) (Fig. 1C). There were six
133 genes (ML012034a, ML06718a, ML03277a, ML02232a, ML18354a, ML219316a) with
134 BLASTP hits to non-animals but not to animals (E-value $\leq 0.1$), preventing us from performing
135 additional phylogenetic analyses on these sequences. We considered the lack of animal BLASTP
136 hits below our cutoff as sufficient evidence that these six were clearly HGTs. ML018031a and
137 ML00882a only had two BLASTP hits to animal sequences. Since it was unclear if this resulted
138 from contamination, we were unable to test these genes using phylogenetic approaches, so they
139 were removed from contention as HGTs.
We performed maximum-likelihood analyses on the remaining 29 alignments using RAxML version 8.1.21 (Stamatakis 2014) (Fig. 1C). Since the RefSeq database has many instances of contamination (Pible et al. 2014), we allowed a maximum of two non-ctenophore animal sequences to fall outside of the main animal clade. To implement this, we pruned putative contaminants if the removal of two taxa resulted in a monophyletic animal clade (Fig. S1). We discarded any HGT candidates with more than two taxa disrupting animal monophyly.

We explicitly tested topologies in opposition to HGT (i.e., animal monophyly) with the SOWH test using SOWHAT (Church et al. 2015) and the AU test using CONSEL (Shimodaira and Hasegawa 2001) (Fig. 1C). The SOWH and AU test evaluate statistical support for phylogenetic incongruence by comparing the likelihood values between trees to a distribution of trees generated by parametric sampling in the SOWH test and non-parametric sampling in the AU test. We required that these two different approaches to hypothesis testing agreed to ensure that our criteria confirming *bona fide* HGTs was stringent. To address any potential problems of selection bias in the AU test (causing the likelihood value to bias upwards for the maximum likelihood best tree when included in the dataset), we performed multiple AU analyses using bootstrap trees as suboptimal trees (similar to Eliáš et al. 2016). We generated 100 bootstrap trees using RAxML rapid bootstrap analyses, and verified there were no duplicate trees in our 100 bootstrap set using the ape package in R (Paradis et al. 2004). RAxML was used to generate per-site log likelihoods for the best maximum-likelihood tree, the tree constraining the putative HGT to metazoans (i.e., metazoan-constraint tree), and suboptimal trees, to perform the AU test implemented through CONSEL. To test the effectiveness of comparing to bootstrap trees, we
manually created a set of suboptimal trees for each candidate HGT by shuffling clades of three
(Fig. S2) and running the same analyses. We evaluated the tree space covered by suboptimal
trees in the AU test (i.e., bootstrap and manually generated trees) by visualizing the data using
violin plots. We calculated likelihood proportions for each tree by dividing individual likelihood
scores by the average likelihood score of suboptimal trees. This was done to make the data
comparable for visualization since the likelihood scores differ between sets of gene trees. The
trees and scripts used to automate these phylogenetic analyses are available in the accompanying
GitHub site.

We verified that HGT candidates were not the result of bacterial contaminants by using
the *M. leidyi* genome browser (Moreland et al. 2014) to examine the intron/exon structure of
each HGT candidate, as well as the origin of their neighboring genes. We examined each intron
to determine whether they are actively handled by spliceosomes (which are only found in
eukaryotes), since bacteria, archaea, and viruses contain Group I and II introns. U2 spliceosomal
introns were identified by conserved GT dinucleotides at the 5’ end and conserved AG
dinucleotides at the 3’ end of introns. We also conducted reciprocal best BLASTP searches for
each HGT candidate (identified from the genome and gene models from an *M. leidyi* individual
collected in Woods Hole, MA) against the transcriptome of an *M. leidyi* individual collected
from St. Augustine, Florida, as well as seven other ctenophore transcriptomes reported in Moroz
et al. (2014): *Bolinopsis infundibulum, Beroe abyssicola, Dryodora glandiformis, Pleurobrachia
bachei, Vallicula multiformis, Coeloplana astericola, Euplokamis dunlapae*. For these searches
we used default parameters and an E-value cutoff of 0.1.

**HGT developmental expression profiles**
An extensive transcriptomic developmental timecourse of *M. leidyi* was recently generated from single-embryos over the first 20 hours of embryogenesis (Levin et al. 2016). To examine whether HGTs might play a role in development we used these data (GSE70185), as well as additional time points for *M. leidyi* generated after this publication (GSE111748).

The Levin et al. (2016) data was produced by using three replicate timecourses that each consisted of 20 isolated embryos from fertilization to 20 hours. Embryos were flash frozen and RNA was extracted with TRIzol and sequenced using Illumina sequencing according to the CEL-Seq protocol (Hashimshony et al. 2012). The reads were mapped to *M. leidyi* gene models (ML2.2) using bowtie2 version 2.2.3 (Langmead & Salzberg 2012) with default settings and counted using htseq-count (Anders et al. 2015). Since the CEL-Seq protocol considers only the 3’ end of transcripts, the results occur in transcripts per million (tpm) without normalized transcript lengths.

Since the publication of Levin et al. (2016), six additional time points (four replicates each) for hours 14-19 (not included in the original study) have been sequenced and submitted to the Gene Expression Omnibus (GSE111748). These additional data were produced by the same researchers (i.e., Itai Yanai and Mark Martindale) from the original study using the same methods and facilities. To create a baseline for what is considered adequate expression during development, we summed median transcript-per-million values along the 25 time points for each of our 9 confirmed HGTs. HGTs that had summed median read counts of 100 or greater were classified as being expressed sufficiently to have roles in development. We chose a value that
was 10 times stricter than the minimum criteria in Levin et al. (2016) (i.e., 10 transcripts) to err on the side of caution.

**HGT origins and functions**

To uncover the functional roles of HGTs, we used the BLAST interface provided by UniProt and the UniProtKB database (Pundir et al. 2017) to identify homologous sequences to characterize genes. Annotations of the top hits (E-value ≤0.1) were assigned to HGT candidates. We also associated HGTs with Pfam-A domains using the MGP Portal under the *Mnemiopsis* Gene Wiki (Moreland et al. 2014). In all cases, the annotations based on BLAST and Pfam-A analyses were consistent with the results from our phylogenetic analyses.

**Results**

*Mnemiopsis leidyi* HGTs

Figure 1 shows our pipeline and results for each method during this analysis. We calculated an alien index for every *M. leidyi* gene model using a database of 12 animals and 12 non-animals (Table S1). We identified 37 genes with alien indices greater than 45 and designated these as HGT candidates (Fig. 1A; Table S2). In addition to the alien_index database, we BLASTed the RefSeq database at NCBI restricting hits to bacteria, then to animals, and then to non-animal eukaryotes (Fig. 1B). All but six HGT candidates had BLAST hits to animals with E-
values ≤ 0.1. We classified these six (ML012034a, ML06718a, ML03277a, ML02232a, ML18354a, ML219316a) as absent from all other animals. We analyze these six further below.

For the remaining 29 candidates, we conducted detailed phylogenetic analyses using the top 10 hits of unique non-animal and animal taxa from each of the RefSeq searches along with sequences from *Amphimedon queenslandica*, *Trichoplax adhaerens*, *Nematostella vectensis*, *Capitella teleta*, *Drosophila melanogaster*, and *Homo sapiens* that were top hits from our initial BLASTs of the alien_index database (Fig. 1C). HGT candidates that formed a clade with all other animals were ruled out as potential HGTs and candidates that disrupted animal monophyly were tested further. We discarded 14 candidates with more than 2 non-ctenophore animal sequences disrupting animal monophyly; in cases of 2 or less sequences, the disrupting sequences were considered potential contaminants and pruned (e.g., Fig. S1). We discarded three more candidates after pruning because the trees continued to result in a non-monophyletic clade of animals. We then applied the SOWH and AU tests to the remaining 12 candidates to compare the maximum-likelihood topology to the alternative hypothesis that candidate HGTs were more closely related to animals (Fig. 2). This involved comparing likelihood values of optimal trees to those that were constrained to produce a monophyletic Animalia. Our results showed that the AU test was more conservative in confirming HGTs than the SOWH test (Table 1). For perspective on how optimal trees compared to constrained trees, we ran AU tests comparing optimal and constrained trees to bootstrap trees (Fig. 3). The likelihood scores of the constrained trees from our confirmed HGTs in the AU test tend to fall outside or on the tails of the distribution of likelihood scores of suboptimal trees, whereas the likelihood scores of constrained trees for unconfirmed HGTs were all closer to the most likely tree than the bootstrap trees (Fig. 3). We
confirmed seven HGTs in which gene trees significantly differed (p < 0.05) from the metazoan constraint trees in both the SOWH and AU analyses (Table 1).

We then analyzed the BLAST results of the seven HGT candidates confirmed by phylogenetic analyses and the six genes which were absent in other animals (ML012034a, ML06718a, ML03277a, ML02232a, ML18354a, ML219316a). We removed four of these genes from contention (ML092610a, ML06718a, ML03277a, ML02232a) because the top hits from BLAST against RefSeq were either Choanoflagellatea or Ichthyosporea (the two non-animal lineages most closely related to animals) (E-value ≤ 0.1). If ctenophores are the sister group to the rest of animals, vertical inheritance remains a possibility for these cases. As such, these tests support a total of nine HGTs.

We used the *M. leidyi* genome browser to examine the intron/exon structure of each of these nine HGTs, as well as the origin of their neighboring genes for evidence of bacterial contamination (lack of introns would indicate bacterial contamination). Eight HGTs were found on scaffolds with intron-containing genes and eight HGTs contained introns (Table 2). The only HGT not found on a scaffold with other intron-containing genes was ML49231a (itself containing 6 introns). All intron-containing genes had U2 spliceosomal introns (except ML219315a, a gene on the same scaffold as an HGT). These data suggest that our HGT candidates were not bacterial contaminants.

To further test that these nine genes were not contaminants, we confirmed using BLAST that these genes were also present in a transcriptome from an *M. leidyi* individual collected from
St. Augustine, FL (M. leidyi genome and gene models were from individuals collected in Woods Hole, MA). We also performed reciprocal best BLASTP searches for each of the nine HGTs against seven of the ctenophore transcriptomes published in Moroz et al. (2014): Bolinopsis infundibulum, Beroe abyssicola, Dryodora glandiformis, Pleurobrachia bachei, Vallicula multiformis, Coeloplana astericola, Euplokamis dunlapae. Each HGT was present in the transcriptome of at least one other ctenophore species and in the Florida M. leidyi transcriptome (Fig. 4). Because it is unlikely that the same species contaminated each of these datasets, these comparisons provide additional evidence against HGT sequences resulting from contamination. Here, we have included as much evidence as possible to carefully confirm nine HGTs in M. leidyi.

HGTs are expressed in development

We summed transcript-per-million values (medians for each set of expression values at 25 time points) from single-embryo RNA-Seq analyses over 20 hours for each of the nine confirmed HGTs to identify those HGTs that were expressed during development. Six of the nine HGTs had sums greater than 100 (Fig. 5), suggesting that these had some role in development. ML00955a was expressed maternally (0 hours post fertilization (hpf)) and throughout early cleavage stages (1-3 hpf) with reduced expression later in development. Three genes (ML005129a, ML18354a, ML012034a) were expressed later in development with spikes during tentacle morphogenesis (9-12 hpf). ML02771a and ML219316a displayed cyclic expression throughout development suggesting a potential role in cell cycle.
HGTs are enzymes originating from non-animal eukaryotes and bacteria

We used phylogenetic evidence to determine the origin of the nine HGTs. Four HGTs originated from bacteria and five from non-animal eukaryotes (Table 3). We found no evidence of HGTs that were transferred from Archaea. The five HGT events that originated from non-animal eukaryotes appear to be transferred from Stramenopiles, Viriplantae, Rhodophyta or Amoebozoa. To characterize gene function, we BLASTed the nine confirmed HGTs against the UniProt database. All HGTs except one uncharacterized protein (ML219316a) were homologous to known characterized enzymes (Table 3).

Discussion

HGTs in ctenophores and their implications

It had been previously speculated that ctenophores had HGTs since initial profiling revealed that many ‘bacteria-like’ genes in ctenophores contained introns and were on chromosomes with vertically inherited (i.e., non-HGT) genes (Artamonova et al. 2015). We confirmed that all HGTs except ML012034a had spliceosomal introns and were on scaffolds with other spliceosomal intron-containing genes (Table 2). This provided evidence that these candidates were not the result of extrinsic contamination. We provided additional evidence that candidates were not contaminants by showing that all HGTs were found in both Massachusetts and Florida M. leidyi individuals, as well as in many other ctenophore species (Fig. 4). Six HGTs were present in the E. dunlapae transcriptome suggesting that the majority of these HGT events
occurred very early in ctenophore evolution (Fig. 4). This deep evolutionary history suggests that these HGTs may have had important impacts on the biology of ctenophores.

**Mechanisms driving HGT in ctenophores**

While we are uncertain about the mechanisms driving HGT, we speculate that some of these may have resulted from symbiotic relationships with bacteria and non-animal eukaryotes. *Gammaproteobacteria* and *Bacteroidetes* have been identified as two of the most abundant groups of bacteria associated with ctenophores (Daniels & Breitbart 2012). These groups were identified as the likely donors of three HGTs (i.e., ML00955a, ML02771a, ML18354a) in the *M. leidyi* genome and confirmed in almost all other ctenophores transcriptomes. Other possible donors could have been gymnamoebae symbionts that have been described living on the surface of comb plates and on the ectoderm of ctenophores (Moss et al. 2001). However, studies investigating symbiotic relationships with ctenophores are limited. Further studies are needed to improve our understanding of the impacts of symbiotic relationships on HGT, as well as to potentially understand the mechanisms that drive HGT between organisms.

*Mnemiopsis leidyi* HGTs are expressed during development and encode enzymes

Many HGTs are likely to be deleterious and lost, but some HGTs will be neutral or provide a selective advantage and spread throughout a population (Thomas & Nielsen 2005). HGT integration is thought to mainly occur in neutral genes with low levels of expression (Park & Zhang 2012). Once integrated, neutral HGTs may become a source of novel genetic variation.
upon which selection can act (Soucy et al. 2015). HGTs may then become more highly expressed after recruitment of transcription factors and regulators from the host genome (Lercher & Pál 2008). Six of the nine HGTs we identified showed high expression during the first 20 hours of development, suggesting potentially important developmental roles (Fig. 5). ML02771a is expressed during development and encodes penicillin acylase or amidase, which catalyzes the hydrolysis of benzylpenicillin. This reaction creates key intermediates for penicillin synthesis and may be important to defend against microbial infection or colonization.

Observations of HGT patterns in prokaryotes have also suggested that there is a preference to retain operational genes (e.g., metabolic enzymes) rather than informational genes (Lawrence & Roth 1996; Jain et al. 1999; Garcia-Vallvé et al. 2000). Informational genes, such as those involved in DNA replication, transcription, and translation are seldom found in sets of HGTs (Thomas & Nielsen 2005). This propensity for operational genes is thought to occur because informational genes are involved in larger and complex systems (Jain et al. 1999). Recently, this pattern has also been observed in animal HGTs (Boto, 2014) (e.g., Zhu et al. 2011; Boschetti et al. 2012; Sun et al. 2013; Eyres et al. 2015; Conaco et al. 2016). These reports suggest that operational genes are preferentially transferred and/or retained in both prokaryotes and eukaryotes. Our data support this idea since all of the characterizable genes in our HGT set encode enzymes.

Commonly used BLAST-based methods for identifying HGTs in animals are insufficient
Identifying HGTs can be challenging due to bacterial associations with hosts (Artamonova & Mushegian 2013; Chapman et al. 2010; Fraune & Bosch 2007), DNA extraction kits and reagents that have led to contamination (Naccache et al. 2013; Salter et al. 2014), and/or laboratory conditions that can contaminate preparations during DNA extraction (Laurence et al. 2014; Strong et al. 2014). These challenges associated with sequencing and assembly have resulted in contamination in public databases (Longo et al. 2011; Merchant et al. 2014) and make HGT predictions difficult. Moreover, while BLAST-based approaches (i.e., alien index and the HGT index) are useful for identification of HGT candidates, they are difficult to implement, lack an evolutionary perspective, and do not address problems associated with contamination.

To overcome some of these challenges, we developed alien_index to automate the generation of alien index and HGT index scores for rapid identification of HGT candidates. We confirmed HGTs by using rigorous phylogenetic approaches to address the problems associated with the lack of evolutionary perspective from BLAST methods. Our phylogenetic tests of incongruence provided clear metrics from which to judge the level of certainty applied to each HGT candidate. Our study showed that many of the predictions based on BLAST did not stand up to hypothesis testing, and suggest that the similarity between sequences that cause high alien indices do not necessarily provide true phylogenetic signal. Consequently, incorporation of phylogenetic likelihood-based methods are necessary when performing HGT analyses in animals.

Conclusion
The importance of HGT as an evolutionary mechanism in prokaryotes and eukaryotes has been underestimated. While studies of HGT in animals are gradually becoming more accepted, many challenges remain to quantify the extent of HGT and its impacts. To mitigate some of these challenges, rigorous approaches that employ both BLAST- and phylogenetic likelihood-based methods should be applied to future HGT studies in animals. Here we provided evidence of nine cases of HGT in ctenophores by applying these rigorous methods (among others), and found similar patterns of transfer between prokaryotes and eukaryotes with preference for operational genes. It should be noted that we implemented an extremely conservative approach and there are likely to be more HGTs in *M. leidyi*. However, many more studies will be necessary to gain a comprehensive overview of HGT and the mechanisms by which HGT occurs in animals.
Acknowledgements

We would like to thank Melissa DeBiasse for constructive comments on earlier versions of our manuscript.

Pipeline and outputs to identify and confirm HGTs.

(A) alien_index was used to identify 37 HGT candidates. (B) These candidates were then BLASTed against RefSeq; two candidates were removed because they only had two significant animals hits and six were set aside for future testing because they lacked animal hits. (C) The remaining 29 candidates were tested by phylogenetic analyses and hypothesis testing (SOWH and AU test). The 6 candidates that lacked animal hits and those that passed hypothesis testing (7 candidates) were screened for significant hits to Choanoflagellates.

**9 Confirmed HGTs**
Maximum-likelihood best tree and metazoan-constraint tree compared in the SOWH and AU tests.

Gene IDs (in black) denote the putative HGTs. (A), (C), and (E) are examples of RAxML best trees for HGT candidates validated by phylogenetic analyses and hypothesis testing. (B), (D), and (F) are examples of trees where putative HGTs have been constrained to produce monophyletic Animalia and have been optimized in RAxML. Taxa that are prefixed “META_” are from our alien_index database version 0.01 (i.e., META_NVEC (*Nematostella vectensis*), META_TADH (*Trichoplax adhaerens*), META_HSAP (*Homo sapiens*), META_CTEL (*Capitella teleta*), META_DMEL (*Drosophila melanogaster*), META_AQUE (*Amphimedon queenslandica*). MET=Metazoa; BAC=Bacteria; EUK=Eukaryota; FUN=Fungi; More details for each taxon are specified in Table S3. The asterisk indicates a gene that is later removed from contention.
Figure 3 (on next page)

A comparison of likelihood proportions between the best tree, metazoan-constrained tree, and bootstrap trees for HGT candidates with BLAST hits to Metazoa.

Likelihood proportions are individual likelihood values divided by the average likelihood value for suboptimal trees (i.e., bootstrap trees). Red points indicate likelihood proportions of the best tree (i.e., tree indicating HGT). Blue points indicate likelihood proportions of the metazoan constrained tree (i.e., tree contradicting HGT). The violin plot shows the distribution of likelihood proportions of 100 bootstrap trees for each HGT candidate. The side in teal shows HGT candidates validated by phylogenetic analyses and hypothesis testing. The asterisk indicates a gene that is later removed from contention.
Comparisons of confirmed HGTs identified in the *M. leidyi* genome to other ctenophore species’ transcriptomes.

Purple boxes indicate the specified HGT is present in the species’ transcriptome confirmed by reciprocal best BLAST hits; white boxes indicate the gene is absent in the species’ transcriptome. Tree was inferred by Moroz et al. (2014). Percent identity among genes are described in Table S4.
Coeloplana astericola
Vallicula multiformis
Pleurobrachia bachei
Dryodora glandiformis
Beroe abyssicola
Bolinopsis infundibulum
Mnemiopsis leidyi (FL)
Mnemiopsis leidyi (MA)
Figure 5 (on next page)

Expression profiles of the nine HGTs identified in this study.

Single-embryo RNA-Seq analyses were performed over 20 hours. (A-F) Confirmed HGTs with transcript-per-million values (medians for each set of time-point replicates) greater than or equal to 100 over 20 hours (25 time points) are shown. (G-I) Confirmed HGTs with transcript-per-million values less than 100 over 20 hours. (J) Ctenophore stages of development over the timecourse. Early cleavage stages occur at 1-3 hpf. Gastrulation occurs at 4-6 hpf. Tentacle morphogenesis occurs at 9-12 hpf. N refers to the number of replicates.
Number of Mapped Reads (Transcripts-per-million)

Hours post fertilization
Hypothesis testing on HGT candidates that were confirmed by phylogenetic analyses. P-values indicate the level of support for HGTs in comparison to the metazoan constraint tree for the SOWH test and suboptimal trees (bootstrap and manually generated) in the AU test. Candidates in blue have significant values in all three tests (p ≤ 0.05) likely HGTs. The asterisk indicates a gene that is later removed from contention.

1
Table 3

Summary of confirmed HGT origins and functions.

HGT functions were determined by BLAST against the UniProt database and associated Pfam-A domains were searched on the *Mnemiopsis* Genome Portal. The origin column shows the domains of life from which these genes are predicted to have been transferred (Bac = Bacteria; Euk = Eukaryota). The RefSeq column shows a more detailed classification for the origin of HGTs. All rows highlighted in orange indicate genes that show developmental expression.
| Genes     | Function                                                                 | Domains                                                                 | Origin       | RefSeq           |
|-----------|---------------------------------------------------------------------------|-------------------------------------------------------------------------|--------------|------------------|
