First look at heavy-light mesons with a dressed quark-gluon vertex

Received: August 6, 2014

Abstract Following up on earlier work, we investigate possible effects of a dressed quark-gluon vertex in heavy-light mesons. In particular, we study corrections to the popular rainbow-ladder truncation of the Dyson-Schwinger–Bethe-Salpeter equation system. We adopt a simple interaction kernel which reduces the resulting set of coupled integral equations to a set of coupled algebraic equations, which are solved numerically. In this way, we extend previous studies to quark-antiquark systems with unequal current-quark masses, at first for the pseudoscalar case, and investigate the resulting set of problems and solutions. We attempt to find patterns in – as well as to quantify corrections to – the rainbow-ladder truncation. In addition, we open this approach to phenomenological predictions of the heavy quark symmetry.

Keywords Heavy-light mesons · Dyson-Schwinger Equations · Bethe-Salpeter Equation

1 Motivation

In modern studies of Quantum Chromodynamics (QCD) meson states made of one light and one heavy quark have attracted particular attention for a number of years. The reasons are manifold, e.g., the possibility to construct a theoretical bridge between effective field theories valid in opposite regimes like chiral perturbation theory as well as perturbative nonrelativistic QCD and heavy-quark effective theory, respectively. Another challenging reason is the need to understand a system determined by different scales of the order of $\Lambda_{\text{QCD}}$ on one hand and the bottom-quark mass on the other.

Among the most promising approaches that are able to deal with all of these requirements as well as able to provide a solid and modern theoretical framework for bound-state studies are lattice-regularized QCD studies and also methods of continuum quantum field theories. Our method of choice herein is the Dyson-Schwinger-Bethe-Salpeter-equation (DSBSE) approach, which has been applied to various problems of theoretical hadron physics in the past decades with increasing success and comprehension, see, e.g., [1, 2] and references therein.

Typically, sophisticated hadron studies in the DSBSE approach are numerical in nature and make use of a truncation of the infinite tower of coupled integral equations involved; see, e.g., [3–5] for the details of such a setup. A popular variant is the so-called rainbow-ladder (RL) truncation, where the dressed quark-gluon vertex [6] assumes a strongly simplified structure; it models the gluon-quark interaction and reduces the effort of solving relevant equations to the Dyson-Schwinger equation (DSE) of the quark propagator, and subsequently the quark-antiquark Bethe-Salpeter equation (BSE) with a suitable interaction kernel.
Despite its success, in particular for pseudoscalar mesons and their various properties \[7\]–\[11\], vector mesons \[12\]–\[15\], the heavy-quark domain \[14\]–\[15\], and an extension to a quark-diquark and later three-quark formulation for baryons \[16\]–\[20\], always see also references therein, this truncation has appeared limited in certain respects. Typically such limitations appear where the bare covariant (vector) structure left in the quark-gluon vertex in this truncation is expected to be insufficient for the treatment of certain states, such as those identified as orbital-angular-momentum excitations \[21\]–\[22\]. A situation similar to the latter case is presented by a heavy-light meson state, since one cannot expect the same simplicity as apparent in a pseudoscalar or vector meson ground state with equal-mass quarks. While heavy-light meson states have been investigated in the DSBSE approach, cf. \[23\] and references therein, the assumptions made there about the connection between the DSE and BSE kernels are different from the truncation scheme considered here and cannot easily be related to our present setup.

Herein, we investigate dressing effects in the quark-gluon vertex in a scheme developed earlier in the equal-mass-constituent case \[23\], \[25\] for a simple interaction model. This goes beyond an introduction of trivial dressing factors accompanying the bare structure in the quark-gluon vertex. For the sake of brevity, we merely sketch the formalism and rely on illustrations to highlight the problems and possibilities given by our study. We quantify dressing effects for select pseudoscalar states and present further directions of our work. The calculations are performed in Euclidean space.

\section{Setup and interaction model}

Meson studies in the DSBSE approach have a long-standing successful record. In the context of the present setup it is always instructive to note that first simplified attempts at meson spectroscopy analogous to the ones undertaken today were performed already several decades ago \[26\]. In fact, the present setup it is always instructive to note that first simplified attempts at meson spectroscopy were undertaken already several decades ago \[26\].

In order to study mesons, one needs to solve the BSE that contains two dressed quark propagators, obtained by solving Eq. (1), together with the quark-antiquark scattering kernel $K$ in the form

$$
\Gamma(p; P) = \int_q^A K(p; q; P) S(q_+)\Gamma(q; P)S(q_-),
$$

where $\Gamma$ is the Bethe-Salpeter amplitude (BSA) and $A$ a regularization scale. The (anti-)quark momenta are given by $q_+ = q + \eta P$ and $q_- = q - (1 - \eta)P$; the momentum partitioning parameter $\eta \in [0, 1]$ is an in principle free parameter, which accounts for the arbitrariness in the definition of the relative quark-antiquark momentum $q$. In the case of equal-mass quarks, the obvious (and most convenient) choice is $\eta = 1/2$, but in the present work we have to pay some attention to this particular parameter and its effects on the results, explained in detail below.

With $S$ precomputed, a choice for $K$ is needed to proceed with the solution of the BSE. Such a choice is made possible via guiding restrictions by the axial-vector Ward-Takahashi identity (AVWTI), which guards the effects of chiral symmetry and its dynamical breaking in any model description of hadrons that implements a consistent set of interactions. While the simplest truncation of the DSBSE system to satisfy this constraint, the RL truncation, is well-known, steps beyond it have been sought and developed with the goal of a nonperturbative systematic scheme \[21\]–\[22\], \[24\]–\[25\] that would enable numerical studies of increasing sophistication, such as \[21\]–\[22\] \[24\]–\[25\] \[27\]–\[32\]. On a more general basis the AVWTI has been investigated to find construction principles for the meson-BSE kernel for a given type of quark-gluon vertex \[33\]–\[35\].

The setup employed here is a straight-forward adaptation of the one presented in \[25\], and we refer the reader to this reference for more details regarding the formalism and a comprehensive set of results.
for both the quark-propagator dressing functions as well as results for pseudoscalar and vector mesons with equal-mass quarks. Here we sketch only the most important ingredients of our study; more results and a detailed account of the involvement due to the unequal masses of the constituents in the BSE will be published elsewhere [36].

In order to understand and discuss the results presented herein, two more ingredients are necessary, namely the interaction model and the construction principle for the quark-gluon vertex. To define the interaction in this model, we follow [25, 26] in replacing the gluon propagator by

$$g^2 D_{\mu\nu}(k) := \left( \delta_{\mu\nu} - \frac{k_{\mu}k_{\nu}}{k^2} \right) \frac{(2\pi)^4}{G^2} \delta^4(k).$$

The parameter $G$ defines the (constant) interaction strength, sets a scale in the computations, and is determined a priori. All integrals collapse via the $\delta^4$-term and one is left with a coupled system of algebraic equations which are then solved numerically. Apart from this simplifying effect, one has to note as well that also in the BSA several structures (more precisely those involving factors of the relative momentum) become trivial, i.e., they vanish. As a result the manifest covariance of the BSA in this model is destroyed, which immediately impacts on the role of the momentum partitioning parameter $\eta$: meson masses and other results are no longer $\eta$-independent like in the case with all covariants taken into account.

In practice this means that the model assumptions oversimplify meson structure to the extent of partial loss of covariance and seem to have even more but indirect consequences such as: the lack of solutions for scalar and axial-vector meson states; the trivialization of the entire BSA for mesons with spin $J > 1$ [5, 37]; the lack of solutions for radially excited meson states; an unnatural connection of interaction strength and the resulting amount of dynamical chiral symmetry breaking, in particular at finite temperatures [38]. Nonetheless, the benefits outweigh these shortcomings in that one can probe dressing effects up to infinite order in any given scheme as well as more complicated approaches and new ideas with unparalleled ease as compared to studies using more realistic interactions.

As a first illustration we gauge the dependence on $\eta$ for the already-known case of equal-mass quarks in the case of the pion, as presented in Fig. 1; this serves as a guide for the heavy-light case in terms of a systematic error due to one particular choice for $\eta$. What we find is only a light variation of the order of a few percent of the pion’s mass for each stage in the recursive approach compared to the fully dressed quark-gluon vertex in our scheme (see below). The same needs to be done for the pseudoscalar quarkonia, presented in Fig. 2; there, while the effects look larger in the figure, their relative order of magnitude is still at the few-percent level, comparable with the pion case. Note also that not for all cases of $\eta$ a numerical solution can easily be found, in which cases the corresponding lines in the figure are missing. More precisely, the correction to RL $\sim 1.6\%$ for $\eta = 0.5$ in the charmonium case. The systematic error due to the model-artificial $\eta$-dependence can be quantified to be smaller than 6%. For pseudoscalar bottomonium, we obtain a correction to the RL result of $\sim 0.2\%$ for $\eta = 0.5$, where the systematic error due to the $\eta$-dependence is smaller than 1.5%.
The construction of the quark-gluon vertex follows a recursive pattern based on its DSE. Two correction terms to the bare vertex, the so-called abelian and non-abelian gluon corrections, are considered and combined effectively to a single term with unified form and variable dependence. The combination is weighted with an overall factor $C$, which, in turn, can be used to serve as a model parameter and adjusted to data; in the case of $[25]$ this was fit to data from lattice-regularized QCD on the propagator level. The effective equation to obtain the quark-gluon vertex reads

$$\Gamma_{\mu,n}(p) = \gamma_\mu - C \gamma_\rho S(p) \Gamma_{\mu,0}^C(p) S(p) \gamma_\rho ,$$

which illustrates the dependence on $C$. At the same time, it is clear that this equation can be approached with a recursive procedure and that the bare quark-gluon vertex serves as a starting value, $\Gamma_{\mu,0}(p) = \gamma_\mu$.

The recursion relation is

$$\Gamma_{\mu,n}(p) = -C \gamma_\rho S(p) \Gamma_{\mu,n-1}(p) S(p) \gamma_\rho$$

and the final result for the quark-gluon vertex is obtained by $\Gamma_{\mu}^C(p) = \sum_{n=0}^{\infty} \Gamma_{\mu,n}(p)$.

In view of these relations, additional information for the interpretation of Figs. 1 and 2 is at hand. The value of $C = 0.51$ was chosen in $[25]$ and is adopted here without change together with the value $\mathcal{G} = 0.69$ GeV; this value enables a reasonable phenomenological description of the equal-mass pseudoscalar and vector states and is thus an ideal choice for our study, where a quantification of systematics beyond RL truncation is sought. Also, we can now interpret $n$ as the number of times the recursion in Eq. (5) has been applied to the bare-vertex RL case in the quark DSE and the consistent BSE: $n = 0$ corresponds to the RL truncation itself and is thus completely insensitive to the parameter $C$. $n = \infty$ is obtained by an exact summation of all terms in the series construction of $\Gamma_{\mu}^C(p)$ and offers a unique perspective that reaches beyond a set of results obtained using any finite number of terms.

3 Results and Discussion

After the necessary details have been laid out and checks for the equal-mass cases have been presented, we now focus on the goal of our study, namely, to obtain information about the importance of dressings of the quark-gluon vertex such as the one sketched above in heavy-light mesons. This is particularly interesting, since an immediate and comprehensive phenomenologically successful sophisticated RL-study of heavy-light mesons is still missing in the repertoire of the DSBSE approach; see $[39]$ for a recent account of efforts and status of current research in this direction.

As a first proving ground for our approach we investigated the kaon which is the prototype of the unequal-mass constituent meson in every DSBSE study. The results shown in Fig. 3 are completely analogous to the ones shown for the pion in Fig. 1. In our setup we find a correction to RL of $\sim 7\%$ for $\eta = 0.5$. The systematic error due to the $\eta$-dependence can be quantified to be smaller than 10%.

The symmetry with regard to $\eta \leftrightarrow (1 - \eta)$ apparent for the pion in the right panel of Fig. 1 is clearly broken in the kaon case due to the unequal masses of the quarks. We also note here that for the kaon
there are no intersections of curves in the right panel of Fig. 3 for each value of $\eta$ the convergence pattern from $n = 0$ towards $n = \infty$ is the same. While not shown here for the sake of brevity, we note that this behavior is not guaranteed by any particular aspect of our setup and that the curves for the different $n$ can indeed intersect in other cases.

The two heavy-light meson masses investigated here are those of the $D$ and $B$ mesons, for which we show our results in the left and right panels of Fig. 4 respectively. In terms of quantitative information we extract the following numbers: For the $D$ meson we find a correction to RL truncation of $\sim 5\%$ for a choice of $\eta = 0.75$. The corresponding systematic error due to the model-artificial $\eta$-dependence can only be weakly constrained to be less than 15%, which somewhat blurs possible conclusions from the differences among results for different $n$, but is still a valuable guide for sophisticated studies analogous to the present. The result for the $D$ meson mass in the fully dressed case in our scheme underestimates the experimental value by about 10%, which is still reasonable, given the considerations above.

For the $B$ meson we obtain a correction to RL truncation of $\sim 2\%$ for $\eta = 0.95$. The error due to the $\eta$-dependence is somewhat smaller than for the $D$, namely below 12%. Our result for the $B$ mass in the fully-dressed case again underestimates the experimental value, by about 4%, but yet again lies within a reasonable range given the $\eta$-variations quoted above. Regarding the values chosen for $\eta$ we note that they are typical values chosen in a DSBSE meson calculation. For example, in the original treatment of the present interaction model in its RL setup in [26], the values chosen for $\eta$ in the $D$ and $B$ meson cases were 0.8 and 0.92, respectively. We also note that the authors in [26] find mass-variations with $\eta$ of similar size to our own; they quote that such variations are smaller than 15\%.

4 Conclusions

Based on previous works we investigated the $K$, $D$, and $B$ meson masses in a systematic truncation scheme of the DSBSE system with a simplifying but far-reaching model-interaction setup. After an estimate of systematic model-inherent errors we proceed to quantify corrections to the popular RL truncation. In particular, a comparison of the dressing effects for the equal-mass and heavy-light cases
could suggest that a simultaneous phenomenological description of both kinds of pseudoscalars in an RL treatment can in fact be successful, which is an important piece of outlook for future sophisticated hadron studies in this approach [40]. Next steps for the work presented here are the inclusion of vector mesons and a direct check of heavy-quark symmetry predictions like they have been performed recently in a similar setup in relativistic Hamiltonian dynamics [41].
