Abstract

**Background:** Suicide rates are up to four times greater in cancer compared to the general population, yet best practices for institutional suicide prevention are unknown. The objective of this study was to examine the association between suicide risk screening (SRS), clinician response, and suicide mortality at a comprehensive cancer treatment centre.

**Methods:** We conducted a naturalistic retrospective cohort study of patients attending the Princess Margaret Cancer Centre, where routine screening for suicidal intent (S-Int) within the Distress Assessment and Response Tool (DART-SRS) was implemented in 2010. Inverse probability of treatment weighting was used to evaluate the impact of DART-SRS completion on suicide mortality from 2005-2014. Chart audits were conducted for clinician response to suicidality and crude suicide rates over the study period were analyzed. All statistical tests were 2-sided.

**Results:** Amongst 78,650 cancer patients, 89 (0.1%) died by suicide, of whom only 4 (4.5%) had completed DART-SRS. Amongst DART-SRS completers (n=14,517), 69 (0.5%) reported S-Int, none of whom died by suicide. DART-SRS completion was associated with increased clinician response to suicidality (17.4% vs. 6.7%, p=0.04), more psychosocial service usage (30.5% vs. 18.3%, p<0.001), and lower suicide mortality (HR = 0.29; 95% CI = 0.28-0.31). Crude suicide rates at PM were lower in patients whose first contact year was after DART-SRS implementation.

**Conclusion:** DART-SRS completion is associated with lower suicide mortality and increased access to psychosocial care, but patients who did not complete DART-SRS were at highest
suicide risk. Further research is needed to identify mechanisms to ensure psychosocial and suicidality assessment in cancer patients who do not complete SRS.
Suicide is a leading cause of preventable death worldwide, with over 800,000 people dying from suicide-related deaths annually.\textsuperscript{1} The risk of suicide among individuals with cancer may be four times greater than that of the general population.\textsuperscript{2-4} However, there are currently no evidence-based standardized approaches to reduce suicide rates in patients with cancer.\textsuperscript{5}

National-level strategies to address suicide prevention have recommended suicide risk screening (SRS) in medical populations in some countries\textsuperscript{6-8}, but not others.\textsuperscript{9,10} The implementation of SRS remains rare in oncology and is not explicitly included as an accreditation requirement for cancer centers.\textsuperscript{11,12} This limited uptake of SRS may be related to the lack of consensus on appropriate suicide screening tools,\textsuperscript{7,13} concerns about medico-legal liabilities, and most importantly, the limited ability of SRS tools to predict suicides.\textsuperscript{14,15} Meta-analyses have shown that most patients at high risk for suicide will not die by suicide, and approximately half of all suicides will occur among people considered as low risk.\textsuperscript{16} There have been no studies demonstrating suicide reductions in response to SRS tools in routine care.

Strategies for effective “Zero Suicide” practices in health care settings has been identified as a research priority by the National Institute of Mental Health (NIMH) in the United States.\textsuperscript{17} However, there have been no naturalistic, ongoing implementation studies of the impact of suicide prevention practices on long-term patient outcomes in healthcare settings.\textsuperscript{17} A recent study of suicide risk assessment practices in the UK found that there was more emphasis on using SRS to identify those at risk of suicide than to trigger evidence-based mental health interventions to prevent this outcome.\textsuperscript{13} SRS, without a linked clinical response, does not reduce suicide attempts,\textsuperscript{18} although psychosocial assessment of patients presenting with self-harm has been associated with reduced risk of repeated self-harm.\textsuperscript{19}
In 2010, the Princess Margaret Cancer Centre (PM) developed the Distress Assessment and Response Tool (DART) to facilitate routine psychosocial assessment of patients with cancer. DART incorporates a SRS (DART-SRS) to alert clinicians about patients with suicidal intention (S-Int) who require urgent clinical intervention. However, the DART-SRS had not yet been validated for its predictive ability as a suicide risk screen, nor has the effectiveness of the DART-SRS process on suicide prevention been evaluated. The objective of this study was to characterize the association between patient completion of the DART-SRS, suicide mortality, and hospital-wide clinician response at PM.

Methods

Study design and setting

This study used a retrospective observational study design based on naturalistic clinical and sociodemographic administrative data available as of December 31st, 2014. Between DART implementation in 2010 and 2014, only 58 patients died by suicide. This sample size was underpowered for analyzing the predictive validity of DART-SRS on suicide mortality. The study therefore adopted a pre-post design to evaluate the impact of DART-SRS completion on suicide mortality in a cohort of patients with a diagnosis of malignant cancer who were first seen at PM in Ontario, Canada, between January 1st, 2005 to December 31st, 2013 (allowing for at least 1-year follow-up). Patients with in-situ tumors or tumors of uncertain behaviour were excluded from the analyses.

PM is the largest cancer care and research centre in Canada, providing care for over 17,000 patients annually. PM has a well-developed Psychosocial Oncology (PSO) program established since 2001, with a multi-disciplinary team of social workers, psychiatrists,
psychologists, and other health professionals providing treatment for cancer-related emotional distress. This study was approved by the University Health Network Research Ethics Board.

Data sources

Data linkages were conducted at Cancer Care Ontario, which houses provincial-level administrative health databases, for cause-of-death data available up until December 31st, 2014. Available data on sex, age, marital status, postal code, cancer type, cancer stage, number of malignancies, PSO psychiatry and psychology visits, and social work referrals were extracted from PM clinical databases. Patient postal codes were linked to Statistics Canada Postal Code Conversion File version (PCCF+ Version 6B) to obtain median household income as a proxy for socioeconomic status.22

The distress assessment and response tool (DART)

The DART program, an electronic symptom screening tool, became a routine standard of care at PM in 2010, with step-wise implementation across all ambulatory clinics. DART implementation gradually reached a target of >70% of all cancer patients screened at least once per month, by January 2013.20 DART is comprised of several validated patient-reported outcome measures, including the Edmonton Symptom Assessment System-revised (ESAS-r) for cancer-related symptoms,23 and the Patient Health Questionnaire (PHQ-9) for depression.24 Clinic receptionists direct patients to self-complete DART on iPads in the clinic waiting room before every appointment. A generated DART report (Supplementary Figure 1) is reviewed by the oncology team in clinic. Patients with low to moderate distress are provided with oncology
clinic-based support and self-management resources, while patients with high distress are flagged for clinicians to assess the need for a PSO referral.\textsuperscript{20}

**DART suicide risk screening (DART-SRS) algorithm**

The DART-SRS algorithm consists of three-steps, which is facilitated by intelligent software programming.\textsuperscript{21} The first step involves completing the depression item on ESAS-r, where patients who score $\geq 2$ are administered the PHQ-9. The second step involves completing the suicidal ideation item of the PHQ-9 (“thoughts that you would be better off dead or hurting yourself in some way”),\textsuperscript{21} where patients report the frequency of suicidal ideation within the past 2 weeks on a scale of 0 (“Not at all”) to 4 (“Nearly every day”). Endorsement of any suicidal ideation triggers the third step inquiry into suicidal intention (S-Int): “Is there a chance you would do something to end your life?”. S-Int is reported as a binary “yes” or “no”, although declining to answer is permitted after responding to a prompt to skip the question. Only patients who answer “yes” have their DART report flagged for clinicians to “Assess for Suicidal Concerns”.\textsuperscript{21}

**Chart audits**

A chart audit template (Supplementary Figure 2) was developed and conducted on all patients who reported S-Int on DART-SRS, and on patients who died by suicide, for evidence of clinic-based suicide assessment or intervention or offer of PSO referral. Audits were conducted on the same day that S-Int was endorsed on DART-SRS, or at any PM oncology appointment for those who died by suicide but never completed DART-SRS.
Outcome

The primary outcome was time to suicide. Death by suicide was defined by the following International Statistical Classification of Diseases and Related Health Problems, Tenth Edition (ICD-10) codes used in provincial-level mortality reports: X60-X84, Y87.0 (intentional self-harm), Y10-Y34, Y87.2, Y89.9 (event of undetermined intent), and X40-X49 (accidental poisoning and exposure to noxious substances). The inclusion of ICD-10 codes for events of undetermined intent and accidental poisonings (AP) in this study’s definition of suicide was done in order to capture all probable cases of suicide, as misclassification and underreporting of suicides is expected to be frequent at a national level.

Statistical analyses

Descriptive statistics were calculated for the entire study cohort, stratified by patients who have completed DART at least once (DART-SRS completers) or not at all (DART-SRS non-completers) during the study period. Descriptive statistics were reported separately for all patients who died by suicide and for those who endorsed S-Int on DART-SRS. Differences in baseline characteristics and clinician response among the groups were compared with Wilcoxon or chi-square tests for continuous and categorical variables, respectively.

A cumulative incidence function was modeled to evaluate univariate associations between DART-SRS completion and suicide death, with the Gray’s test used to test statistically significant differences in suicide deaths between groups. The impact of DART-SRS completion on suicide mortality was evaluated using inverse probability treatment weighting (IPTW), with 95% confidence intervals (CIs) constructed from bootstrap resampling. To compute propensity scores for DART-SRS completion, we used a multivariable logistic regression model that
incorporated the following predictors based on previously published suicide risk factors that were available at the PM registry: age, sex, number of malignancies, cancer stage, cancer type, marital status, and household income estimates. First contact year at PM was also incorporated to account for the varying availability of DART at PM over the study period (Supplementary Table 1). Missing categorical data were imputed as an additional variable (i.e. ‘unknown’). Propensity scores were then incorporated into IPTW analyses to estimate the effect of DART-SRS completion on time to suicide, with DART-SRS completion status modelled as a time-varying covariate based on the date of the patient’s first DART-SRS survey. The proportional hazards assumption was tested by examination of Schoenfeld residuals. Estimation of treatment effects derived from propensity score models aim to mitigate bias inherent in observational, non-randomized data.$^{28}$

To assess the robustness of our main findings, we conducted multiple sensitivity analyses. To ensure that the effect of DART-SRS completion on suicide mortality was not substantially affected by the inclusion of suicide deaths defined by ICD-10 codes X40-X49 (accidental poisoning and exposure to noxious substances), we repeated our propensity score analyses excluding AP codes in our primary outcome. We also performed alternative statistical approaches accounting for the same covariates, including stratification on propensity scores, multivariable Cox-regression (unweighted) and Fine and Gray regression in dealing with competing risks in time-to-event analyses.$^{29}$ All statistical analyses were two-sided and conducted using R programming version 3.5.2.$^{30}$ A p-value of \( < 0.05 \) was considered statistically significant.

To assess temporal trends in suicide rates over the study period, we compared crude suicide rates in patients with first contact before (2005-2009) and after (2010-2013) DART
implementation and used Joinpoint regression for the PM study cohort and Ontario population (based on publicly available Statistics Canada mortality data) using the Joinpoint Regression Program, Version 4.5.0.1 (National Cancer Institute).

**Results**

**Study population**

Table 1 summarizes the demographic characteristics of our study population. In total, 78,650 adult patients with a confirmed malignant cancer diagnosis were seen at PM from 2005 to 2013. Of these patients, 14,517 (18.5%) patients completed DART-SRS at least once during the study period, with a majority (52.8%; 7,660 of 14,517) completing their first DART-SRS survey within the first year of their initial contact at PM. Almost 61% (39,081 of 64,133) of DART-SRS non-completers had a first contact year prior to DART implementation in 2010, although approximately 10% (4,312 of 43,393) of patients with a first contact year before 2010 still completed DART during ongoing care after 2010.

Patients who completed DART-SRS were more likely to be younger, female, have earlier stage disease, and to live in areas associated with higher household income than DART-SRS non-completers. Greater proportions of DART-SRS completers had visits to PSO (30.5% vs. 18.3%) compared to non-completers.

**Primary outcome and chart audit outcomes**

Table 2 summarizes and compares the characteristics of all patients who died by suicide, patients who died by non-suicide causes, and those who endorsed S-Int on DART-SRS. There were a total of 89 suicides, which comprised 0.26% of all deaths (n=34,561) and 0.1% of the
entire study cohort (n=78,650); 4 (4.5%) suicides were in the DART-SRS completer group and 85 (95.5%) suicides were in the DART-SRS non-completer group. Among the 4 patient suicides who completed DART-SRS, only one reported suicidal ideation, but denied S-Int. Suicides most often occurred in males (77.5%), in patients with head and neck cancer (27.0%), in patients who were not married (19.0%), had advanced disease (40.5%), and in patients who were younger compared to other non-suicide deaths (mean = 60.1 vs. 64.9 years, p<0.001). Approximately half of all suicides occurred within the first year of being treated at PM (49.5%).

Based on patients’ first DART-SRS completion, 5003 of 14,517 (34.5%) reported ESAS-r depression ≥2 and 613 of 14,517 (4.2%) reported suicidal ideation. While none of these patients died by suicide, 69 of 613 (11.3%; 0.5% of all DART-SRS completers) reported S-Int, 369 of 613 (60.2%) denied S-Int, and 175 of 613 (28.5%) declined to answer. No differences in sociodemographic and medical characteristics were observed between patients who died by suicide (n=89) and those who endorsed S-Int on DART (n=69), with the exception of cancer type (p<0.05 (Table 2). Suicide discussions (17.4% vs. 6.7%, p=0.04 and PSO visits (30.5% vs. 18.3%, p<0.001) occurred more frequently in patients who reported S-Int on DART-SRS compared to patients who died by suicide (Table 3). Overall rates of suicide discussions and supportive care interventions for DART-SRS-reported S-Int were low, at only 17.4% and 13.0%, respectively (Table 3).

Survival analyses

Figure 1 illustrates the cumulative incidence curve for suicide for DART-SRS completers and non-completers. The median and range of the follow-up times for DART completers and non-completers was 3 (range = 0-10) years and 1.5 (range = 0-10) years,
respectively. Cumulative incidence of suicide was statistically significantly lower in DART-SRS completers than in non-completers (Gray’s test, p<0.001). DART-SRS completers were at a statistically significant lower risk of suicide compared to non-completers, yielding an IPTW hazard ratio (HR) of 0.29 (95% CI = 0.28-0.31) (Table 4).

Sensitivity analyses

In our sensitivity analyses, exclusion of ICD-10 codes for accidental poisoning and exposure to noxious substance from our definition of suicide did not alter our findings substantially (IPTW HR = 0.27; 95% CI = 0.25-0.29). Alternative statistical analyses yielded consistent results, which included stratification on propensity score (HR = 0.34; 95% CI = 0.31-0.37), multivariable Cox proportional hazards model (HR = 0.12; 95% CI = 0.05-0.34) and the multivariable Fine-Gray model (HR = 0.16; 95% CI = 0.06-0.44) (Table 4).

Trends in crude suicide rates

Crude suicide rates decreased by a statistically significant 50.88 suicides per 100,000 patients (95% CI = 4.72-97.04) in patients who made first contact after DART implementation (2010-2013) compared to those who made first contact before DART implementation (2005-2009) (Table 5). Joinpoint analyses showed a statistically significant increase in crude suicide rates in Ontario over the study period (annual percent change (APC) = 1.19, p =0.04, while there was no statistically significant change at PM (APC = -3.88, p =0.52) based on final selected models of 0-Joinpoints (Supplementary Figure 3, A and B). Using 1-Joinpoint models demonstrated a statistically significant increase in Ontario suicide rates beginning in 2008 (APC = 2.02, p=0.01 ), while a decreasing trend at PM was observed beginning in 2012 (APC = -19.36,
p=0.77), coincident with the time DART implementation approached saturation in all oncology clinics\textsuperscript{20} \textit{(Supplementary Figure 3, C and D)}.

**Discussion**

This single-institution retrospective cohort study of 78,650 patients with cancer confirmed that completion of a SRS is associated with more access to psychosocial care and a lower risk of suicide death. However, the report of S-Int on DART-SRS only infrequently resulted in a direct clinician response and patients with cancer who ultimately died by suicide tended not to complete DART-SRS. Patients who died by suicide tended to be of the male sex and to have advanced stage disease, to have head and neck cancer, to be unmarried, and to be within the first year of diagnosis.\textsuperscript{2, 3, 31}

This study cannot determine whether DART-SRS is effective in predicting or preventing suicides due to gaps in screening implementation. While more than half of those who did not complete DART-SRS had a first contact year prior to 2010 and therefore had less opportunity to access DART, other reasons for DART non-completion included barriers of language, literacy, discomfort with technology or feeling too unwell, all factors associated with higher suicide risk. The low rates of direct suicide assessment and intervention by clinicians for reported S-Int is concerning in terms of missed opportunities for suicide prevention, although the protective effects of SRS have been more strongly linked to improving access to psychosocial assessment than to suicide-specific intervention.\textsuperscript{19}

The finding that DART-SRS completion was associated with a lower risk for suicide, even when it was infrequently followed by a clinical assessment or intervention, deserves consideration. This may be a case of confounding by indication, where attributes of those who
complete DART-SRS (i.e. younger, more affluent, female, earlier stage disease) are also associated with a lower risk of suicide, although our propensity score analyses attempted to control for these variables. However, consistent with studies showing a protective effect of psychosocial assessment by any clinician, it may be that the increased access to specialized PSO services among DART-SRS completers lowers their risk for suicide (Table 1). The suicide and DART-SRS S-Int groups have similar suicide risk factors, except that only 19% (17 of 89) of the suicide group had a PSO visit compared to 70% (48 of 69) in the DART-SRS S-Int group, none of whom ultimately died by suicide (Table 3).

Implementing a standardized operating procedure to link SRS with psychosocial assessment may be necessary to reduce institutional risk for suicides. The reduction in crude suicide rates at PM over the study period, despite sharply increasing crude suicide rates in the province during this time (Supplementary Figure 3), could be related to systemic changes in both cancer care and supportive care at PM, including the implementation of DART. This includes more proactive symptom control through greater access to psychosocial and palliative care and the development of specialized clinics for older adults. The reduction in suicide rates reported here contrasts with recent evidence that suicide risk in cancer patients have doubled over the past decade.

This is the first study to evaluate the impact of SRS on suicide outcomes in a “real-world” clinical oncology or medical setting and to identify mechanisms that may diminish suicide risk, which are key research priorities of the NIMH. Strengths of the current study include the large sample size within a single institution, and the study of a well-established standardized electronic SRS protocol in a comprehensive cancer treatment centre. The inclusion
of chart audits for clinician response to suicidality is also unique and has the potential to elucidate mechanisms that increase suicide risk.

A study limitation is the absence of data related to other medical and social determinants of health, such as living situation, pre-existing psychiatric or neurocognitive disorders, which could affect the ability or willingness to complete DART-SRS and suicide outcomes. Also, chart audits that were used as a proxy for clinical encounters may underestimate the true frequency and quality of clinician response to suicidality due to differences in documentation practices.

The present study demonstrates that the completion of SRS by patients with cancer is associated with a lower risk of suicide. Those who complete such screening may be more likely to access psychosocial services and less likely to die by suicide, while those who ultimately die by suicide tend not to complete screening measures or to access psychosocial care. Institutional efforts should continue to prioritize physical and emotional symptom screening, timely management, and referral to supportive care services, but should also pay particular attention to patients who do not complete screening, who may be at the highest risk of suicide.

\(^a\) AP = accidental poisonings and exposure to noxious substances; CI = confidence interval; HR = hazard ratio; IPTW = inverse probability of treatment weighting; PM = Princess Margaret Cancer Centre.
| Cohort by first contact date | Total No. in cohort | No. of suicides | Suicide rate per 100,000 | Difference in suicide rate (95% CI) |
|-----------------------------|---------------------|-----------------|-------------------------|-----------------------------------|
| 2005-2009                   | 43393               | 59              | 136.0                   | 50.88 (4.72 to 97.04)             |
| 2010-2013                   | 35257               | 30              | 85.0                    |                                   |

*CI = confidence interval*
Figure Legend

Figure 1: Cumulative incidence for suicide deaths. Univariate comparisons between cumulative suicide mortality and DART-SRS completion status (completer vs. non-completer group) were made using Gray’s test of a two-sided hypothesis. The cumulative incidence functions were modelled accounting for non-suicide deaths as a competing risk.
Figure 1

Filled DART

- Yes
- No

Gray's test p-value <0.001

Number of events and numbers at risk:

- Yes: 14517, 9936, 5223, 2317, 801, 0
- No: 64133, 27257, 15522, 7580, 2806, 0
