Abstract

Let \( P \) and \( Q \) be finite point sets of the same cardinality in \( \mathbb{R}^2 \), each labelled from 1 to \( n \). Two noncrossing geometric graphs \( G_P \) and \( G_Q \) spanning \( P \) and \( Q \), respectively, are called compatible if for every face \( f \) in \( G_P \), there exists a corresponding face in \( G_Q \) with the same clockwise ordering of the vertices on its boundary as in \( f \). In particular, \( G_P \) and \( G_Q \) must be straight-line embeddings of the same connected \( n \)-vertex graph \( G \). No polynomial-time algorithm is known for deciding whether two labelled point sets admit compatible geometric graphs. The complexity of the problem is open, even when the graphs are constrained to be triangulations, trees, or simple paths.

We give polynomial-time algorithms to find compatible paths or report that none exist in three scenarios: \( O(n) \) time for points in convex position; \( O(n^2) \) time for two simple polygons, where the paths are restricted to remain inside the closed polygons; and \( O(n^3 \log n) \) time for points in general position if the paths are restricted to be monotone.

1 Introduction

Computing noncrossing geometric graphs on finite point sets that are in some sense ‘compatible’ is an active area of research in computational geometry. The study of compatible graphs is motivated by applications to shape animation and simultaneous graph drawing [4, 12].

Let \( P \) and \( Q \) be finite point sets, each containing \( n \) points in the plane labelled from 1 to \( n \). Let \( G_P \) and \( G_Q \) be two noncrossing geometric graphs spanning \( P \) and \( Q \), respectively. \( G_P \) and \( G_Q \) are called compatible, if for every face \( f \) in \( G_P \), there exists a corresponding face in \( G_Q \) with the same clockwise ordering of the vertices on its boundary as in \( f \). It is necessary, but not sufficient, that \( G_P \) and \( G_Q \) represent the same connected \( n \)-vertex graph \( G \). Given a pair of labelled point sets, it is natural to ask whether they have compatible graphs, and if so, to produce one such pair, \( G_P, G_Q \). The question can also be restricted to specific graph classes such as paths, trees, triangulations, and so on; previous work (described below) has concentrated on compatible triangulations. Compatible triangulations of polygons are also of interest, which motivated us to examining compatible paths inside simple polygons.

In this paper we examine the problem of computing compatible paths on labelled point sets. Equivalently, we seek a permutation of the labels 1, 2, \ldots, \( n \) that corresponds to a noncrossing (plane) path in \( P \) and in \( Q \). Figures 1(a)–(b) show a positive instance of this problem, and Figures 1(c)–(d) depict an affirmative answer.

Our results. We describe a quadratic-time dynamic programming algorithm that either finds compatible paths for two simple polygons, where the paths are restricted to remain inside the closed polygons, or reports that no such path exists. For the more limited case of two point sets in convex position, we give a linear time algorithm to find compatible paths (if they exist). For two general point sets, we give an \( O(n^2 \log n) \)-time algorithm to find compatible monotone paths (if they exist). Finding (unrestricted) compatible paths of point sets remains open.

1.1 Background

Saalfeld [11] first introduced compatible triangulations of labelled point sets, which he called “joint” triangulations. In Saalfeld’s problem, each point set is enclosed inside an axis-aligned rectangle, and the goal is to compute compatible triangulations (possibly using Steiner points). Although not every pair of labelled point sets admit compatible triangulations, Saalfeld showed that one can always construct compatible triangulations using (possibly an exponential number of) Steiner points.

Aronov et al. [2] proved that \( O(n^2) \) Steiner points are always sufficient and sometimes necessary to compatibly
triangulate two polygons when the vertices of the polygons are labelled 1, 2, ..., n in clockwise order. Babikov et al. [3] extended the $O(n^2)$ bound to polygonal regions (i.e., polygons with holes), where the holes are also labelled ‘compatibly’ (with the same clockwise ordering of labels). The holes may be single points, so this includes Saalfeld’s “joint triangulation” problem. Pach et al. [10] gave an $\Omega(n^2)$ lower bound on the number of Steiner points in such scenarios.

Lubiw and Mondal [9] proved that finding the minimum number of Steiner points is NP-hard for the case of polygonal regions. The complexity status is open for the case of polygons, and also for point sets. Testing for compatible triangulations without Steiner points may be an easier problem. Aronov et al. [2] gave a polynomial-time dynamic programming algorithm to test whether two polygons admit compatible triangulations without Steiner points. But testing whether there are compatible triangulations without Steiner points is open for polygonal regions, as well as for point sets.

The compatible triangulation problem seems challenging even for unlabelled point sets (i.e., when a bijection between $P$ and $Q$ can be chosen arbitrarily). Aichholzer et al. [1] conjectured that every pair of unlabelled point sets (with the same number of points on the convex hull) admit compatible triangulations without Steiner points. So far, the conjecture has been verified only for point sets with at most three interior points.

Let $G_S$ be a complete geometric graph on a point set $S$. Let $H(S)$ be the intersection graph of the edges of $G_S$, i.e., each edge of $G_S$ corresponds to a vertex in $H(S)$, and two vertices are adjacent in $H(S)$ if and only if the corresponding edges in $G_S$ properly cross (i.e., the open line segments intersect). Every plane triangulation on $S$ has $3n-3-h$ edges, where $h$ is the number of points on the convex hull of $S$, and thus corresponds to a maximum independent set in $H(S)$. In fact, $H(S)$ belongs to the class of well-covered graphs. (A graph is well covered if every maximal independent set of the graph has the same cardinality). A rich body of research attempts to characterize well-covered graphs [6, 13]. Deciding whether two point sets, $P$ and $Q$, admit compatible triangulations is equivalent to testing whether $H(P)$ and $H(Q)$ have a common independent set of size $3n-3-h$.

2 Paths in Polygons and Convex Point Sets

In this section we describe algorithms to find compatible paths on simple polygons and convex point sets. By compatible paths on polygons, we mean: given two polygons, find two compatible paths on the vertices of the polygons that are constrained to be non-exterior to the polygons. (See Figures 2(a)–(b).) Note that convex point sets correspond to a special case, where the polygons are the convex hulls. Not every two convex point sets admit compatible paths, e.g., 5-point sets where the points are labelled (1,2,3,4,5) and (1,3,5,2,4), resp., in counterclockwise order (Appendix A).

We first give a quadratic-time dynamic programming algorithm for simple polygons, and then a linear time algorithm for convex point sets.

We begin with two properties of any noncrossing path that visits all vertices of a simple polygon. Let $P$ be a simple polygon with vertices $p_1, p_2, \ldots, p_n$ in some order (so the vertices have labels 1, 2, ..., n). Let $\sigma$ be a label sequence corresponding to a noncrossing path that lies inside $P$ and visits all vertices of $P$. Define an interval on $P$ to be a sequence of labels that appear consecutively around the boundary of $P$ (in clockwise or counterclockwise order). For example, in Figure 2(a), one interval is (2, 1, 7, 6). Define an interval set on $P$ to be the unordered set of elements of an interval.

Claim 1 The set of labels of every prefix of $\sigma$ is an interval set on $P$. Furthermore, if the prefix does not contain all the labels, then the last label of the prefix corresponds to an endpoint of the interval.

Proof. We proceed by induction on $t$, the length of the prefix, with the base case $t = 1$ being obvious. So assume the first $t - 1$ labels form an interval set corresponding to interval $I$. Let $\ell$ be the $t$-th element of $\sigma$. Suppose vertex $p_\ell$ is not contiguous with the interval $I$ on $P$. Let $u$ and $v$ be the two neighbors of $p_\ell$ around the polygon $P$. Then $u$ and $v$ do not belong to $I$, and so the path must visit both of them after $p_\ell$. But then the subpath between $u$ and $v$ crossing the edge of the path that arrives at $p_\ell$, contradicting the assumption that the path is noncrossing. Thus vertex $p_\ell$ must appear just...
before or after $I$, forming a longer interval with $p_t$ as an endpoint of the interval. □

**Claim 2** If $I$ is an interval on $P$ and $\sigma$ does not start or end in $I$, then the labels of $I$ appear in the same order in $\sigma$ and in $I$ (either clockwise or counterclockwise). Note that the labels need not appear consecutively in $\sigma$.

**Proof.** Consider three labels $i, j, k$ that appear in this order in $I$. Assume, for a contradiction, that these labels appear in a different order in $\sigma$ and suppose, without loss of generality, that they appear in the order $i, j, k$ in $\sigma$. Let $\ell$ be the last label of $\sigma$. Because $\ell$ does not lie in $I$, the order of vertices around $P$ is $p_i, p_j, p_k, p_t$. See, e.g., Figure 2(c) where $i, j, k = 7, 5, 3$. Then the subpath of $\sigma$ from $p_i$ to $p_k$ crosses the subpath from $p_k$ to $p_t$, a contradiction. □

### 2.1 An $O(n^2)$-time dynamic programming algorithm

Let $P, Q$ be two $n$-vertex simple polygons with labelled vertices. Let $p_i$ (resp., $q_i$) be the vertex of $P$ (resp., $Q$) with the label $i$.

Two vertices of a polygon are **visible** if the straight line segment connecting the vertices lies entirely inside the polygon. We precompute the visibility graph of each polygon in $O(n^2)$ time [8] such that later we can answer any visibility query in constant time.

Notation for our dynamic programming algorithm will be eased if we relabel so that polygon $P$ has labels 1, 2, …, $n$ in clockwise order. For each label $i = 1, \ldots, n$ and each length $t = 1, \ldots, n$ let $I_Q(i, t, cw)$ denote the interval on $Q$ of $t$ vertices that starts at $q_i$ and proceeds clockwise. Define $I_Q(i, t, ccw)$ similarly, but proceed counterclockwise from $q_i$. Define $I_P(i, t, cw)$ and $I_P(i, t, ccw)$ similarly. Note that $I_P(i, t, cw)$ goes from $p_i$ to $p_{i+t-1}$ (index addition modulo $n$).

We say that a path **traverses** interval $I_Q(i, t, d)$ (where $d = cw$ or $ccw$), if the path is noncrossing, lies inside $Q$, visits exactly the vertices of $I_Q(i, t, d)$ and ends at $q_i$. We make a similar definition for a path to traverse an interval $I_P(i, t, d)$.

Our algorithm will solve subproblems $A(i, t, d_P, d_Q)$ where $i$ is a label from 1 to $n$, $t$ is a length from 1 to $n$, and $d_P$ and $d_Q$ take on the values $cw$ or $ccw$. This subproblem records whether there is a path that traverses $I_Q(i, t, d_Q)$ and a path with the same sequence of labels that traverses $I_P(i, t, d_P)$. If this is the case, we say that the two intervals are **compatible**. Observe that $P$ and $Q$ have compatible paths if and only if $A(i, n, d_P, d_Q)$ is true for some $i, d_P, d_Q$.

We initialize by setting $A(i, 1, d_P, d_Q)$ to TRUE for all $i, d_P, d_Q$, and then solve subproblems in order of increasing $t$. In order for intervals $I_Q(i, t + 1, d_Q)$ and $I_P(i, t + 1, d_P)$ to be compatible, the intervals of length $t$ formed by deleting the last label, $i$, must also be compatible, with an appropriate choice of direction ($cw$ or $ccw$) on those intervals. There are two choices in $P$ and two in $Q$. We try all four combinations. For a particular combination to ‘work’ (i.e., yield compatible paths for the original length $t + 1$ intervals), we need the last labels of the length $t$ intervals to match, and we need appropriate visibility edges in the polygons for the last edge of the paths.

We give complete details for $A(i, t + 1, cw, cw)$. See Figure 2(d)-(e). (The other four possibilities are similar.) Deleting label $i$ from $I_P(i, t + 1, cw)$ gives $I_P(i + 1, t, cw)$ and $I_P(i + t, t, ccw)$. Let $q_j$ be the vertex following $q_i$ in clockwise order around $Q$ and let $q_k$ be the other endpoint of $I_Q(i, t + 1, cw)$ (in practice, for efficiency, we would store $k$ with the subproblem). Deleting label $i$ from $I_Q(i, t + 1, cw)$ gives $I_Q(j, t, cw)$ and $I_Q(k, t, ccw)$. The two possibilities for $P$ and $Q$ are shown by blue dash-dotted and red dotted lines in Figures 2(d) and (e), respectively. We set $A(i, t + 1, cw, cw)$ TRUE if any of the following four sets of conditions hold:

1. Conditions for $I_P(i + 1, t, cw)$ and $I_Q(j, t, cw): i + 1 = j$ and $A(i + 1, t, cw, cw)$.
2. Conditions for $I_P(i + 1, t, cw)$ and $I_Q(k, t, ccw): i + 1 = k$ and $q_k$ sees $q_i$ in $Q$ and $A(i + 1, t, cw, ccw)$. Note that the last edge of the path in $Q$ must be $(q_k, q_i)$ which is why we impose the visibility condition.
3. Conditions for $I_P(i + t, t, ccw)$ and $I_Q(j, t, cw): i + t = j$ and $p_{i+t}$ sees $p_i$ in $P$ and $A(i + t, t, ccw, cw)$. 

![Figure 2](image_url)
4. Conditions for $I_P(i+t, t, ccw)$ and $I_Q(k, t, ccw)$: $i + t = k$ and $p_{i+t}$ sees $p_i$ in $P$ and $q_k$ sees $q_i$ in $Q$ and $A(i + t, t, ccw, ccw)$.

Since there are a quadratic number of subproblems, each taking constant time to solve, this algorithm runs in time $O(n^2)$, which proves:

**Theorem 1** Given two $n$-vertex polygons, each with points labelled from 1 to $n$ in some order, one can find a pair of compatible paths or determine that none exist in $O(n^2)$ time.

### 2.2 A linear-time algorithm for convex point sets

In this section we assume that the input is a pair of convex point sets $P, Q$, along with their convex hulls.

Given a label $x$, we first define a greedy construction to compute compatible paths starting at $x$. The output of the construction is an ordered sequence $\sigma_x$ of labels. Using Claim 1 we keep track of the intervals in $P$ and $Q$ corresponding to $\sigma_x$. Initially $\sigma_x$ contains the label $x$. Each subsequent step attempts to add a new label to $\sigma_x$, maintaining intervals in $P$ and $Q$. Suppose the intervals corresponding to the current $\sigma_x$ are $I_P$ and $I_Q$ in $P$ and $Q$ respectively. Let $a$ and $b$ be the labels of the vertices just before and just after interval $I_P$ on the boundary of $P$. Similarly, let $c$ and $d$ be the labels of the vertices just before and just after interval $I_Q$ on the boundary of $Q$. If $\{a, b\} = \{c, d\}$, then we add $a$ and $b$ to $\sigma_x$ in arbitrary order. Otherwise, if there is one label in common between the two sets, we add that label to $\sigma_x$. Finally, if there are no common labels, then the construction ends. Let $\sigma_x$ be a maximal sequence constructed as above.

**Lemma 2** $P$ and $Q$ have compatible paths starting at label $x$ if and only if $\sigma_x$ includes all $n$ labels.

**Proof.** If $P$ and $Q$ have compatible paths with label sequence $s_y$ starting at a label $y$ in $\sigma_x$, then $z$ be the first label that appears in $s_y$ but not in $\sigma_x$. Let $I_P$ and $I_Q$ be the intervals corresponding to $\sigma_x$ in $P$ and $Q$ respectively. By Claim 1 the prefix of $s_y$ before $z$ corresponds to intervals, say $I_P'$ and $I_Q'$ on $P$ and $Q$, respectively. Then $I_P' \subseteq I_P$ and $I_Q' \subseteq I_Q$ (by our assumption that $z$ is the first label of $s_y$ not in $\sigma_x$). Since the vertex with label $z$ must be adjacent to $I_P'$ on the boundary of $P$ and to $I_Q'$ on the boundary of $Q$, and $z$ does not appear in $\sigma_x$, therefore the vertex with label $z$ must be adjacent to $I_P$ on the boundary of $P$ and to $I_Q$ on the boundary of $Q$. But then our construction would add label $z$ to $\sigma_x$. □

We will use Lemma 3 to show that we can eliminate some labels entirely when $\sigma_x$ is found to have length less than $n$. Suppose $\sigma_x$ does not include all labels. Let $I_P$ and $I_Q$ be the intervals on $P$ and $Q$, respectively, corresponding to the set of labels of $\sigma_x$. Let $a$ and $b$ be the labels that appear at the endpoints of $I_P$.

Suppose $P$ and $Q$ have compatible paths (of length $n$) with label sequence $\sigma$. Then by Lemma 2 the initial and final label of $\sigma$ lie outside of $\sigma_x$. Furthermore, by Claim 2, the set of labels of $\sigma_x$ must appear consecutively and in the same order around $P$ and around $Q$ (either clockwise or counterclockwise). Our algorithm checks whether $I_P$ and $I_Q$ have the same ordered lists of labels. If not, then there are no compatible paths.

So suppose that $I_P$ and $I_Q$ have the same ordered lists of labels. Then the endpoints of $I_Q$ must have labels $a$ and $b$. We will now reduce to a smaller problem by discarding all internal vertices of $I_P$ and $I_Q$. Let $P'$ and $Q'$ be the point sets formed from $P$ and $Q$, respectively, by deleting the vertices with labels in $\sigma_x - \{a, b\}$.

**Lemma 4** Suppose $z$ is a label appearing in $P', P$ and $Q$ have compatible paths with initial label $z$ if and only if $P'$ and $Q'$ have compatible paths with initial label $z$.

**Proof.** If $P$ and $Q$ have compatible paths (of length $n$) with initial label $z$, then we claim that deleting from those paths the vertices with labels in $\sigma_x - \{a, b\}$ yields compatible paths of $P'$ and $Q'$ with initial label $z$. It suffices to show that if we delete one vertex from a non-crossing path on points in convex position then the resulting path is still noncrossing. The two edges incident to the point to be deleted form a triangle, and the new path will use the third side of the triangle. Since the points are in convex position, the triangle is empty of
other points, and so the new edge does not cross any other edge of the path.

For the other direction, suppose that \( \sigma' \) is a label sequence of compatible paths of \( P' \) and \( Q' \) with initial label \( z \). Suppose without loss of generality that label \( a \) comes before label \( b \) in \( \sigma' \). Construct a sequence \( \sigma \) by adding the labels of \( \sigma_x = \{a, b\} \) after \( a \) in \( \sigma' \) in the order that they appear in \( I_P \). It remains to show that the corresponding paths in \( P \) and \( Q \) are noncrossing. This follows from the fact that in both \( P \) and \( Q \) the added points appear consecutively around the convex hull following the point with label \( a \).

We can now prove the main result of this section.

**Theorem 5** Given two sets of \( n \) points in convex position (along with their convex hulls) each with points labelled from 1 to \( n \), one can find a pair of compatible paths or determine that none exist in linear time.

**Proof.** The algorithm is as described above. At each stage we try some label \( x \) to be the initial label of compatible paths, by computing \( \sigma_x \) using the greedy construction. If \( \sigma_x \) has length \( n \) we are done. Otherwise if \( \sigma_x \) has length 1 or 2, then we have ruled out the labels in \( \sigma_x \) as initial labels. Finally, if \( \sigma_x \) has length less than \( n \) and at least 3 then we test whether the intervals corresponding to \( \sigma_x \) in \( P \) and \( Q \) have the same ordering, and if they do, then we apply the reduction described above and recurse on the smaller instance as justified by Lemma 4.

The running time of the algorithm is determined by the length of all the \( \sigma \)-sequences we compute. Define a \( \sigma \)-sequence to be ‘long’ or ‘short’ depending on whether it contains at least three labels or not. Every long sequence of length \( \ell \) reduces the number of points by \((\ell - 2)\) and requires \( O(\ell) \) time. Thus, long sequences take \( O(n) \) time in total. Computing any short sequence takes \( O(1) \) time. Since for each label, we compute \( \sigma \) at most once, the short sequences also take \( O(n) \) time in total. \( \square \)

3 Monotone Paths in General Point Sets

In this section we examine arbitrary point sets in general position, but we restrict the type of path.

Let \( P \) be a point set in general position. An ordering \( \sigma \) of the points of \( P \) is called monotone if there exists some line \( \ell \) such that the orthogonal projection of the points on \( \ell \) yields the order \( \sigma \). A monotone path is a path that corresponds to a monotone ordering. Note that every monotone path is noncrossing.

Two points sets \( P \) and \( Q \) each labelled 1, 2, \ldots, \( n \) have compatible monotone paths if there is an ordering of the labels that corresponds to a monotone path in \( P \) and a monotone path in \( Q \). To decide whether compatible monotone paths exist, we can enumerate all the monotone orderings of \( P \), and for each of them check in linear time whether it determines a monotone path in \( Q \).

A method for enumerating all the monotone orderings of a point set \( P \) was developed by Goodman and Pollack:

**Theorem 6 (Goodman and Pollack [7])** Let \( \ell_0 \) be a line not orthogonal to any line determined by two points of \( P \). Starting with \( \ell = \ell_0 \), rotate the line \( \ell \) through 360° counter-clockwise about a fixed point. Project the points onto \( \ell \) as it rotates giving all the possible monotone orderings of \( P \). There are \( 2^{\binom{n}{2}} = n(n-1) \) orderings, and each successive ordering differs from the previous one by a swap of two elements adjacent in the ordering.

Furthermore, the sequence of swaps that change each ordering to the next one can be found in \( O(n^2 \log n) \) time by sorting the \( O(n^2) \) lines (determined by all pairs of points) by their slopes.

This gives a straight-forward \( O(n^3) \) time algorithm to find compatible monotone paths, since we can generate the \( O(n^2) \) monotone orderings of \( P \) in constant time per ordering, and check each one for monotonicity in \( Q \) in linear time.

We now present a more efficient \( O(n^2 \log n) \) time algorithm. For ease of notation, relabel the points so that the order of points \( P \) along \( \ell_0 \) is 1, 2, \ldots, \( n \). As the line \( \ell \) rotates, let \( L^P_0, L^P_1, \ldots, L^P_{t-1} \), where \( t = n(n-1) \), be the monotone orderings of \( P \), and let \( S^P \) be the corresponding swap sequence. Similarly, let \( L^Q_0, L^Q_1, \ldots, L^Q_{t-1} \) be the monotone orderings of \( Q \) and let \( S^Q \) be the corresponding swap sequence (Figure 4). We need to find whether there exist some \( i \) and \( j \) such that \( L^P_i = L^Q_j \).
As noted above, $S_P$ and $S_Q$ have size $O(n^2)$ and can be computed in time $O(n^2 \log n)$.

Recall that the inversion number, $I(L)$ of a permutation $L$ is the number of pairs that are out of order. It is easy to see that the inversion numbers of the $L_j^P$’s progress from 0 to $\binom{n}{2}$ and back again. In particular, $I(L_j^P) = i$ for $0 \leq i \leq \binom{n}{2}$. Our algorithm will compute the inversion numbers of the $L_j^Q$’s, which also have some structure. Let $I_j$ be the inversion number of $L_j^Q$. Note that we can compute $I_j$ in $O(n \log n)$ time—sorting algorithms can be modified to do this [5].

Claim 3 For all $j$, $1 \leq j \leq n(n-1)$, $I_j$ differs from $I_{j-1}$ by $\pm 1$, and can be computed from $I_{j-1}$ in constant time.

Proof. $L_j^Q$ is formed by swapping one pair of adjacent elements in $L_{j-1}^Q$. If this swap moves a smaller element after a larger one then $I_j = I_{j-1} + 1$. Otherwise, it is $I_j = I_{j-1} - 1$. \hfill \Box

The main idea of our algorithm is as follows. If $L_j^Q = L_i^P$, then they must have the same inversion number, $I_j$. There is one value of $i$ in the range $0 \leq i < \binom{n}{2}$ that gives this inversion number, namely $i = I_j$. There is also one value of $i$ in the second half of the range that gives this inversion number, but we can ignore the second half of the range of $i$.

Remark 1 If there exist $i$, $j$ such that $L_j^P = L_i^Q$, then there is such a pair with $i$ in the first half of the index range, i.e., $0 \leq i < \binom{n}{2}$.\hfill \Box

Proof. The second half of each list of orderings contains the reversals of the orderings in the first half [7]. Thus if there is a match $L_j^P = L_i^Q$ then the reversals of the two orderings also provide a match, say $L_{i'}^P = L_j^Q$, and either $i$ or $i'$ is in the first half of the index range.

Our plan is to iterate through the orderings $L_j^Q$ for $0 \leq j < n(n-1)$. Since each ordering differs from the previous one by a single swap, we can update from one to the next in constant time. For each $j$, we will check if $L_j^Q$ is equal to $L_j^P$, i.e., for each $j$, $0 \leq j < n(n-1)$ we will compute the following four things:

- $L_j^Q$, $I_j$, $L_j^P$, and
- $H_j$, which is the Hamming distance—i.e., the number of mismatches—between $L_j^Q$ and $L_j^P$.

If we find a $j$ with $H_j = 0$ then we output $L_j^Q$ and $L_j^P$ as compatible monotone paths. Otherwise, we declare that no compatible monotone paths exist. Correctness of this algorithm follows from Remark 1 and the discussion above:

Claim 4 $P$ and $Q$ have compatible monotone paths if and only if $H_j = 0$ for some $j$, $0 \leq j < n(n-1)$.

We now give the details of how to perform the above computations. For $j = 0$ we will compute everything directly, and for each successive $j$, we will show how to update efficiently. We initialize the algorithm at $j = 0$ by computing $L_j^Q$ and $I_j$ in $O(n \log n)$ time, $L_j^P$ in $O(n^2)$ time, and $H_j$ in linear time.

Now consider an update from $j-1$ to $j$. As already mentioned, $L_j^Q$ differs from $L_{j-1}^Q$ by one swap of adjacent elements, so we can update in constant time. By Lemma 3, $I_j$ differs from $I_{j-1}$ by $\pm 1$ and we can compute it in constant time. This also means that $L_j^P$ differs from $L_{j-1}^P$ by one swap of adjacent elements, so we can update it in constant time.

Finally, we can update the Hamming distance in a two-step process as the two orderings change. When we update from $L_{j-1}^Q$ to $L_j^Q$, two positions in the list change, and we can compare them to the same positions in $L_{j-1}^P$ to update from $H_{j-1}$ to $H_j$ to obtain the number of mismatches between $L_j^Q$ and $L_j^P$. When we update to $L_j^P$, two positions in this list change, and we can compare them to the same positions in $L_j^Q$ to update to $H_j$. This two-step process takes constant time.

In total, we spend $O(n^2)$ time on initialization and constant time on each of $O(n^2)$ updates, for a total of $O(n^2)$ time. We thus obtain the following theorem:

Theorem 7 Given two point sets, each containing $n$ points labelled from 1 to $n$, one can find a pair of compatible monotone paths or determine that none exist in $O(n^2 \log n)$ time.

Appendix A

In this section we show that for every $n \geq 5$, there exist two convex labelled point sets, each containing $n$ points, that do not admit compatible trees. Note that this also rules out the existence of compatible paths.

Claim 5 Let $P$ and $Q$ be point sets in convex position, each containing $n \geq 2$ points labelled by $\{1, 2, \ldots, n\}$. If they admit a compatible tree that is not a star, then there exists a partition $\{1, 2, \ldots, n\} = A \cup B$ such that $2 \leq |A| \leq |B| \leq n - 2$ such that $A$ and $B$ are interval sets for both $P$ and $Q$.

Proof. Suppose that $P$ and $Q$ admit a compatible tree $T$, which is not a star. Then $T$ has an edge $e$ between two vertices of degree two or higher. The deletion of $e$ decomposes $T$ into two subtrees, say $T_1$ and $T_2$, each with at least two vertices. The vertex sets of $T_1$ and $T_2$, resp., correspond to an interval set in $P$ and $Q$. \hfill $\Box$
