Abstract
The non-local game scenario provides a powerful framework to study the limitations of classical and quantum correlations, by studying the upper bounds of the winning probabilities those correlations offer in cooperation games where communication between players is prohibited. Building upon results presented in the seminal work of Cleve et al. (in: 19th IEEE annual conference on computational complexity, 2004), a straightforward construction to compute the Tsirelson bounds for simple two-player XOR games is presented. The construction is applied explicitly to some examples, including the Entanglement Assisted Orientation in Space (EAOS) game of Brukner et al. (Int J Quant Inf 4(2):365–370), proving for the first time that their proposed quantum strategy is in fact the optimal, as it reaches the Tsirelson bound.

Keywords Non-local game · XOR game · Tsirelson inequality · EAOS game

1 Introduction

Non-signaling games are cooperation multiplayer games where the players do not know all the information they could know in order to play the game in an ideal manner—they only know explicitly the information that was given to them by a neutral party, appropriately entitled as the Referee. This is usually imposed by a constraint called the No Signaling Condition, where communication either classical or quantum is not allowed between the players (physically one could think that the players are spacelike separated from one another). This type of game is called non-local when players using strategies that exploit the non-locality of quantum mechanics, i.e
quantum strategies, can reach higher probabilities to win than players restricted to using classical strategies. A short and concise overview on non-local games can be found in [3]. Such games always evolve according to the following stages:\(^1\)

- The Referee sends to each player a specific input, usually referred to as a question \((q)\);
- Each player only receives its own question and since they can’t communicate with one another they are ignorant of the others’. Then each player will produce an output i.e an answer \((a)\) based on a previously agreed common strategy and send them to the Referee;
- The Referee will check the players’ answers against the questions and see if they are “correct” i.e if they respect the winning condition specified in the rules of the game;

Also, depending on whether the questions and/or answers used in the game are classical or quantum information, we say the game is a classical non-local game or quantum non-local game, respectively. This work deals with classical non-local games, which means that the questions and answers are classical information - this does not imply, however, that the strategies should be exclusively classical. Quantum strategies which are strategies that exploit entangled quantum states can be used in the context of classical non-local games because the states are never explicitly communicated, they are just measured.

### 1.1 Notation and definitions

Since the questions and answers are classical, they are represented mathematically as elements of sets. Keeping the standard terminology of upper case for sets and lower case for elements of the set we say that \(Q_i\) and \(A_i\) are, respectively, the set of all questions and answers the \(i\)th player can receive. Similarly, \(q_i\) and \(a_i\) are the question and answer the \(i\)th player actually received in a run of the game. If we are dealing with a \(n\)-player \(\(n \geq 2\)\) non-local game, then

\[
Q = Q_1 \times \ldots \times Q_i \times \ldots \times Q_n; \quad A = A_1 \times \ldots \times A_i \times \ldots \times A_n;
\]

are, respectively, the set of all the possible questions the players can receive, and answers they can give. They are mathematically the Cartesian products of each players individual set of questions and answers. Accordingly we have that a general element of both of the previous sets, \((q_1 \ldots q_i \ldots q_n) \in Q\) and \((a_1 \ldots a_i \ldots a_n) \in A\), are the combination of questions the Referee gave and the answers he received in return from the \(n\) players.

Any given \(n\)-player \(\(n \geq 2\)\) non-local game is completely defined by.

---

\(^1\) These strictly speaking are the stages of just one round of a game and some games could have more than one round - since this work deals exclusively with one round games this description fully characterizes the evolution of such games.
- A probability distribution, which specifies how likely the Referee is to ask any given combination of questions to the players,

\[ p(q_1, \ldots, q_i, \ldots, q_n); \]

- The predicate, which is a Boolean function that outputs either 0 or 1 depending on its input. The input is some ending game configuration i.e a pair of the form \( \{(q_1, \ldots, q_i, \ldots, q_n), (a_1, \ldots, a_i, \ldots, a_n)\} \), and it evaluates to 1 if the configuration wins the game and to 0 if it loses. The predicate is usually written like,

\[ V(a_1, \ldots, a_i, \ldots, a_n|q_1, \ldots, q_i, \ldots, q_n). \]

in the spirit of a conditional probability, to illustrate that the validity of the answers is conditioned on the questions.

Now let us adopt the following short-hand notation, \( Q^x = (q_1 \ldots q_i \ldots q_n) \) if \((q_1 \ldots q_i \ldots q_n)\) is the \( x \)th element of set \( Q \) according to some specific order and \( A^y = (a_1 \ldots a_i \ldots a_n) \) if \((a_1 \ldots a_i \ldots a_n)\) is the \( y \)th element of set \( A \) according to the same type of order. There is nothing fundamental in this, it’s just for purposes of increased readability in the expressions. Now we have that some non-local game \( G \) is given by,

\[ p(Q^x) \text{ and } V(A^y|Q^x), \]

and to show explicitly that a non-local game \( G \) is defined by just these two things, it is usually written as \( G(V, p) \).

According to this notation the predicate is symbolically given by,

\[ V(A^y|Q^x) = \begin{cases} 1, & \text{if } \{Q^x, A^y\} \text{ is a winning configuration} \\ 0, & \text{otherwise} \end{cases} \]

1.2 Strategies for non-local games

A strategy \( S \) specifies the probability function \( p(A^y|Q^x) \), for every combination of \( x \) and \( y \). That is, the probability that the players will give a specific combination of answers upon being asked a specific combination of questions. It is not difficult to see that the probability to win some game \( G = (V, p) \) with strategy \( S \), is given by the expectation value of the probabilities to reach all possible configurations \( \{Q^x, A^y\} \) allowed by \( S \) and evaluated by the predicate \( V \). We write,

\[ W_S(G) = \sum_{x,y} p(Q^x) \ p(A^y|Q^x) \ V(A^y|Q^x), \]

(1)

\[ ^2 \text{Note that } Q^x \text{ does not mean the set of all possible questions for the } x \text{th player, like } Q_i \text{ meant for the } i \text{th player. It means the } x \text{th element of } Q, \text{ whatever it might be according to some arbitrary order. Likewise } A^y \text{ means the } y \text{th element of } A. \]
where $W_S(G)$ is to be read as “the probability to win game $G$ by using strategy $S$”. A good strategy $S$ is one which tries to maximize $W$. Obviously finding the best strategy would be trivial if communication was allowed, but in the context of non-local games, since that isn’t the case, players only know their own questions and the probability distribution $p(Q^i)$, so they are aware of how likely it is for the Referee to ask a specific combination of questions, but they do not know any other question aside their own when playing the game - this makes for a harder case.

1.2.1 Classical strategies and Bell inequalities

A classical strategy $C$ could be either deterministic or non-deterministic. In a deterministic strategy, the answers are always given by a function of the form,

$$A^y = F(Q^i), \quad F(Q^i) \equiv f_1(q_1) \ldots f_n(q_n).$$

A non-deterministic strategy is just a probabilistic distribution over deterministic ones, so we have

$$A^y = F_i(Q^i), \quad \text{with probability } p_i,$$

where $i$ is the index spanning the set of the deterministic strategies under consideration. It is easy to see that a deterministic strategy is the special case of the non-deterministic one where $p_i = 1$ for some $i$. Perhaps not so immediate, but also true, is that you can find a deterministic strategy that behaves at least as good as the best non-deterministic one. This is because since a non-deterministic strategy is the probabilistic distribution over a set of deterministic strategies, we can just pick the best one out of that set\(^3\). Then, we shall assume without loss of generality that the strategy $C$ is deterministic, and as such we will substitute $A^y = F(Q^i)$ in (1) to get,

$$W_C(G) = \sum_x p(Q^x) p(F(Q^x)|Q^x) V(F(Q^x)|Q^x).$$

(2)

Since on input $Q^x$ the output will always be the one defined by $F(Q^x)$, it becomes evident that $p(F(Q^x)|Q^x) = 1$, so,

$$W_C(G) = \sum_x p(Q^x) V(F(Q^x)|Q^x).$$

(3)

The best classical strategy $C^*$ is the one that maximizes the winning probability in (3), then

$$W_{C^*}(G) \equiv \max_F \sum_x p(Q^x) V(F(Q^x)|Q^x),$$

(4)

\(^3\) This is equivalent to saying that the average over a set of positive numbers is never greater than the highest number of the set.
is the highest possible probability to win a given non-local game $G$, by means of a classical strategy, and is called the \textit{classical value} of the game. In the literature it is usually depicted as $\omega_c(G)$. The following inequality holds true for any non-local game $G$,

$$W_c(G) \leq \omega_c(G).$$

This is called a Bell inequality.

1.2.2 \textit{Quantum strategies} and Tsirelson inequalities

A \textit{quantum strategy} $Q$, in the context of non-local games, is usually assumed to be a strategy that adds an extra resource which players can use, namely, quantum entanglement. $Q$ is then defined by a finite dimensional entangled state $|\psi\rangle \in \mathcal{H} = \mathcal{H}_1 \otimes \ldots \otimes \mathcal{H}_n$ shared over all $n$ players, and a POVM for each $k$ player,

$$\hat{\Pi}_k \equiv \{ \forall q_k \in Q_k : \hat{\Pi}_{(q_k,a_k)} \}$$

This means that player $k$ has the POVM defined for every possible input $q_k$ in such a way, that the measurement outcome of this POVM on the state $|\psi\rangle$ will give him answer $a_k$ with some probability. Then, the collection of questions $Q^x = q_1 \ldots q_n$ will define

$$\hat{\Pi}_1 \otimes \ldots \otimes \hat{\Pi}_n \equiv \hat{\Pi}^x,$$

in such a way that the measurement outcome of $\hat{\Pi}^x$ will yield $A^x = a_1 \ldots a_n$ with probability $\langle \psi | (\hat{\Pi}^x)\dagger (\hat{\Pi}^x) | \psi \rangle$. Which is to say that

$$p(A^x|Q^x) = \langle \psi | (\hat{\Pi}^x)\dagger (\hat{\Pi}^x) | \psi \rangle.$$

Then for some quantum strategy $Q$, (1) becomes

$$W_Q(G) = \sum_x p(Q^x) \langle \psi | (\hat{\Pi}^x)\dagger (\hat{\Pi}^x) | \psi \rangle \ V(A^x|Q^x).$$

Similarly to the classical case, the best quantum strategy $Q^*$ is the one that maximizes (7). Then we have that

$$W_Q(G) \equiv \text{Max}_{\hat{\Pi}^x,|\psi\rangle} \sum_x p(Q^x) \langle \psi | (\hat{\Pi}^x)\dagger (\hat{\Pi}^x) | \psi \rangle \ V(A^x|Q^x),$$

is the highest possible probability to win a given non-local game $G$, by means of a quantum strategy, and is called the \textit{quantum value} of the game. It is usually depicted as $\omega_q(G)$. The following inequality holds true for any non-local game $G$,

$$W_Q(G) \leq \omega_q(G).$$

This is called a Tsirelson inequality.
1.2.3 Non-local and pseudo-telepathy games

In the context of non-local games, the Bell and Tsirelson inequalities define the upper bounds on the winning probabilities, achieved by classical and quantum strategies. The distinct characteristic of a non-local game \( G \) is then mathematically represented as

\[
\omega_c(G) < \omega_q(G),
\]

which is the mathematical representation of what was previously stated—a non-local game is a non-signaling game where the best quantum strategy always achieves a higher winning probability than the best classical strategy. This is not to say that quantum strategies are generally the optimal strategies in non-local games, a different type of strategies using another class of resources appropriately entitled non-local boxes, or PR boxes were engineered to be the best possible strategy for these types of games [4].

Interestingly, there is a special type of non-local game where the Tsirelson inequality is bounded by 1, which is to say that the best quantum strategy is the overall optimal strategy, since using the best quantum strategy will win the game with certainty i.e

\[
\omega_c(G) < 1 \land \omega_q(G) = 1.
\]

This type of non-local game is called a pseudo telepathy game [5]. The name was chosen to illustrate the fact that if the Referee was ignorant to the possibility of quantum strategies, that the only possible explanation for Alice and Bob being able to always win the game would be to assume that they would have to be connected by some sort of illicit telepathic channel, that worked around the No Signaling Condition. Some examples of this type of game are the Magic Square Game [6], the Kochen-Specker Game [1] and also the Simple Game [5].

2 Two-player non-local games

From this section onward, we shall be dealing exclusively with classical two-player non-local games - the players are the archetypal Alice and Bob, and we adopt the conventional nomenclature where Alice is asked question \( s \in S \) and gives answer \( a \in A \), and Bob is asked question \( t \in T \) and gives answer \( b \in B \). The following table relates \( n \)-player to the two-player game nomenclature,

| \( n \)-player game | two-player game |
|---------------------|-----------------|
| \( Q^x = (q_1, \ldots, q_n) \) | \( Q^y = (s, t) \) |
| \( A^y = (a_1, \ldots, a_n) \) | \( A^y = (a, b) \) |
| \( p(Q^x) = p(q_1, \ldots, q_n) \) | \( p(Q^y) = p(s, t) \) |
| \( V(A^y|Q^x) \) | \( V(ab|st) \) |
| \( \hat{\Pi}^y = \hat{\Pi}_1 \otimes \ldots \otimes \hat{\Pi}_n \) | \( \hat{\Pi}^y = \hat{\Pi}_A \otimes \hat{\Pi}_B \) |
Figure 1 is an illustration of how the two-player game proceeds. The game goes as follows—the Referee selects according to a probability distribution \( p(s, t) \), question \( s \in S \) to send Alice and question \( t \in T \) to send Bob. Alice and Bob at that point know \( p(s, t) \) and their own respective questions, and choose their answers based on some preferred strategy, which is one that maximizes the winning probability\(^4\). If they are using a classical strategy, they have to pick a function \( F(s, t) \) that maximizes (3), on the other hand, if they are using a quantum strategy, they have to choose a state \( |\psi\rangle \) and two POVM’s \( \{\hat{I}_A, \hat{I}_B\} \) that maximize (7).

The graph in Fig. 1 is the DAG (Directed Acyclic Graph) that represents how the game unfolds throughout time. The DAG could just be thought as an abstract graph showing an interactive picture of the game, or could actually be interpreted as being embedded in a Minkowski spacetime, thus being promoted to the spacetime diagram of the game (where the time arrow points from left to right) in 1 + 1 dimensions i.e 1 of space plus 1 of time. If we think about the diagram in the latter terms, the edges become wordlines and the nodes become spacetime events - in that scenario the No Signaling Condition would not need to be stated explicitly, as it comes naturally from the geometry of the spacetime diagram, since there is no way for Alice and Bob to communicate without the message passing first through the Referee.

2.1 XOR games

XOR games are a particular interesting type of non-local games, as they represent one of the few classes of games for which general upper bounds are known - first

\(^4\) We make the implicit assumption that Alice and Bob always try to win the game with the highest possible probability.
introduced in [1], XOR games are a subset of yet a larger set of non-local games entitled binary games, in which the players only answer with bits to the Referee, even though the questions themselves need not be bits. A XOR game still restricts the set of binary games by specifying a special type of predicate - we then say that a given 2 player non-local game \( G \) is said to be a XOR game if the answers \( a \) and \( b \) are bits (i.e \( G \) is a binary game) and the predicate of the game is given by,

\[
V(ab|st)_{\text{XOR}} = \begin{cases} 
1, & \text{if } f(s, t) = a \oplus b \\
0, & \text{otherwise}
\end{cases}
\quad (12)
\]

This means that the winning condition of a XOR game does not depend explicitly on the outputs of the players but only on their parity, i.e whether the bits are the same or not. This is mathematically represented by the exclusive OR logical operation (which is just addition modulo 2) shortened as XOR. One example of a two-player XOR game is the famous CHSH\((V, p)\) game, in which the questions \( s, t \) are also bits. The game is defined by,

\[
V(ab|st)_{\text{CHSH}} = \begin{cases} 
1, & \text{if } s \cdot t = a \oplus b \\
0, & \text{otherwise}
\end{cases} \\
\forall_{s,t} \quad p(s, t) = \frac{1}{4};
\quad (13)
\]

It is a known result that \( \omega_c^{\text{CHSH}} = \frac{3}{4} \). One example of a deterministic strategy that maximizes \( W_c \) is given by

\[
F(s, t) \equiv \{ f(s), g(t) \} \quad \text{where},
\forall_{s,t} \quad f(s) = g(t) = 0,
\]

which means the players ignore the questions and always answer with 0. In the next section we see how to construct the Tsirelson bound for the CHSH game.

It is also worth mentioning that despite this work focusing mainly on simple two-player classical XOR games, there are very technically demanding generalizations in the literature regarding XOR games. For instance, in [7] XOR games with a large number of players are considered and their classical and quantum values are calculated, when under the restriction that the questions themselves are also bits. In [8] a specific class of \((n \geq 3)\)-player XOR games is described where no restriction is imposed over the set of questions, which is assumed to have a cardinality \( N^2 \) - for such games the authors prove that the ratio between the quantum and classical biases\(^5\) is of the order \( \sqrt{N} \). Another important generalization was introduced in [9] where the notion of quantum XOR games was proposed, in which the \textit{questions} and \textit{answers} are allowed to be quantum states.

\(^5\) The quantum/classical bias is the difference between the quantum/classical value and the winning probability offered by a trivial random answer - it is a standard way to measure the quantum over classical advantage in non-local games.
2.2 Best quantum strategies for two-player XOR games

In Cleve et al. [1], two powerful results were proven that we are going to use explicitly in the construction. These results specify some common features that the best quantum strategies for XOR games share. The results are not explicitly stated like so in the original paper, but they are equivalent to the following:

- If a non-local game is a XOR game, then the best strategy will be one where the POVMs are just projective measurements;
- For two-player XOR games of sufficiently small dimensions, the best strategy will be always realizable if Alice and Bob share an ebit of information;

Based on these results we are motivated to define a generic strategy for two-player XOR games, which abides in the most general way to the previous restrictions. As such, for any two-player XOR game of sufficiently small dimensions, we put forward the best strategy,

\[ |\psi\rangle \rightarrow |B_{xy}\rangle = \frac{1}{\sqrt{2}} \left( |0y\rangle + (-1)^x |1\bar{y}\rangle \right); \quad x, y \in \{0, 1\}; \]

\[ \hat{\Pi}_A \otimes \hat{\Pi}_B \rightarrow \hat{\Lambda} \otimes \hat{B}; \]

With \( |B_{xy}\rangle \) representing any of the four Bell states,

\[ |B_{00}\rangle = \frac{1}{\sqrt{2}} \left( |00\rangle + |11\rangle \right) = |\phi^+\rangle, \]
\[ |B_{10}\rangle = \frac{1}{\sqrt{2}} \left( |00\rangle - |11\rangle \right) = |\phi^-\rangle, \]
\[ |B_{01}\rangle = \frac{1}{\sqrt{2}} \left( |01\rangle + |10\rangle \right) = |\psi^+\rangle, \]
\[ |B_{11}\rangle = \frac{1}{\sqrt{2}} \left( |01\rangle - |10\rangle \right) = |\psi^-\rangle, \]

and,

\[ \hat{\Lambda} \equiv \frac{1}{\sqrt{2}} \hat{P} \hat{R}(\alpha_s), \quad \hat{B} \equiv \frac{1}{\sqrt{2}} \hat{P} \hat{R}(\beta_t), \]

with \( \hat{P} = |0\rangle\langle 0| - |1\rangle\langle 1| \), the projection to the computational basis and \( \hat{R}(\alpha_s), \hat{R}(\beta_t) \) the rotation operations that Alice and Bob apply, respectively, which arguments
depend explicitly on the inputs they receive, \( s \) for Alice and \( t \) for Bob. The generic operator \( \hat{R}(\theta) \) acts like,

\[
\hat{R}(\theta)|y\rangle = \cos(\theta)|y\rangle + (-1)^y \sin(\theta)|\bar{y}\rangle, \ y \in \{0, 1\}
\]

From (6), we get that the general expression which gives the probabilities of Alice’s and Bob’s answers (\( a \) and \( b \)) is given by,

\[
\langle \psi| (\hat{N}_A \otimes \hat{N}_B) \dagger (\hat{N}_A \otimes \hat{N}_B)|\psi\rangle.
\]

which upon substitution from (14) yields,

\[
\langle B_{xy}| (\hat{A} \otimes \hat{B}) \dagger (\hat{A} \otimes \hat{B})|B_{xy}\rangle.
\]

The previous expression represents in closed form the best quantum strategy for a simple two-player XOR game. To understand why, let us substitute the operators \( \hat{A} \) and \( \hat{B} \) explicitly with (16), and work trough the algebra, to get to the equivalent expression,

\[
\frac{1}{2} \langle B_{xy}| (\hat{R}(\alpha_s) \otimes \hat{R}(\beta_t))^\dagger (\hat{P} \otimes \hat{P}) (\hat{R}(\alpha_s) \otimes \hat{R}(\beta_t)) |B_{xy}\rangle \tag{17}
\]

Now we proceed to show a useful expression—the most general state, after arbitrary rotations have been applied by Alice and Bob onto a shared Bell state,

\[
[\hat{R}(\alpha_s) \otimes \hat{R}(\beta_t)]|B_{xy}\rangle = \cos(\alpha_s + \beta_t \cdot (-1)^{a \oplus b}) |B_{xy}\rangle + (-1)^y \sin(\alpha_s + \beta_t \cdot (-1)^{a \oplus b}) |\bar{B}_{xy}\rangle. \tag{18}
\]

Let us also define a mapping, between the Hilbert space of dimension 4, spanned by the 4 Bell states, and a 2 dimensional Hilbert space spanned by parity base states, \( |a \oplus b = 0\rangle \) and \( |a \oplus b = 1\rangle \),

\[
\begin{align*}
|\phi^+\rangle & \quad \Longrightarrow \quad |a \oplus b = 0\rangle; \\
|\phi^-\rangle & \quad \Longrightarrow \quad |a \oplus b = 1\rangle;
\end{align*}
\]

Which can be represented more compactly as

\[
|B_{xy}\rangle \quad \Longrightarrow \quad |a \oplus b = y\rangle. \tag{19}
\]

This is obviously motivated by the fact that if either state, \( |\phi^+\rangle \) or \( |\phi^-\rangle \), is shared between Alice and Bob, when they both measure the same observable (e.g polarization) in the computational basis \( \{|0\rangle, |1\rangle\} \) they will get the same eigenvalues as a result of sharing those states; as such, if they convert the eigenvalues to bits, the parity of the outcome will be even. Likewise, if they share \( |\psi^+\rangle \) or \( |\psi^-\rangle \), a joint measurement in the computational basis of a given observable will always yield different eigenvalues, and hence the parity of the outcome will be odd.
We can take (18), and express according to mapping (19), what would the rotated state look like in the 2 dimensional Hilbert space spanned by \(|a \oplus b = 0\), \(|a \oplus b = 1\)|. We have,

\[
\hat{R}(\alpha_s) \otimes \hat{R}(\beta_t) |B_{xy}\rangle \mapsto \cos(\theta_{s,t}) |a \oplus b = 0\rangle + \sin(\theta_{s,t}) |a \oplus b = 1\rangle,
\]

which shows evidently that, regardless of what Bell state is shared between Alice and Bob and also which arbitrary rotations they perform, if we apply mapping (19), the outcome will generally be a state that in the space spanned by \(|a \oplus b = 0\), \(|a \oplus b = 1\)\rangle, is a superposition of the base states, \(|a \oplus b = 0\rangle\) and \(|a \oplus b = 1\rangle\). The amplitude coefficients of the superposition are trigonometric functions of an argument, \(s\), \(t\), which depends on the inputs \(s\) and \(t\), and also varies depending on the Bell state shared. This means that the information of which Bell state Alice and Bob share must be present in the coefficients.

Table 1 shows exactly what arguments are inside the functions for all four possible Bell states.

Now we can also show that the joint projection can be written in terms of the Bell states,

\[
\hat{P} \otimes \hat{P} = (|0\rangle \langle 0| - |1\rangle \langle 1|) \otimes (|0\rangle \langle 0| - |1\rangle \langle 1|)
\]

\[
= (|\phi^+\rangle \langle \phi^+| + |\phi^-\rangle \langle \phi^-|) - (|\psi^+\rangle \langle \psi^+| + |\psi^-\rangle \langle \psi^-|)
\]

\[
= \sum_{x,y} (-1)^y |B_{xy}\rangle \langle B_{xy}| \tag{21}
\]

and according to (19) it follows that in the subspace spanned by the parity base states the projection operator is mapped to,

\[
\hat{P} \otimes \hat{P} \mapsto \sum_y (-1)^y 2 |a \oplus b = y\rangle \langle a \oplus b = y|
\]

\[
= 2(|a \oplus b = 0\rangle \langle a \oplus b = 0| - |a \oplus b = 1\rangle \langle a \oplus b = 1|). \tag{22}
\]

Taking (20) and its conjugate, along with the operator mapping (22), we are now able to see that expression (17), which is an expression in the 4-dimensional Hilbert space, is mapped to the following expression in the two-dimensional Hilbert space spanned by the parity base states,

\[
\left( \langle E| \cos(\theta_{s,t}) + \langle O| \sin(\theta_{s,t}) \right) \left( |E\rangle \langle E| - |O\rangle \langle O| \right) \left( \cos(\theta_{s,t}) |E\rangle + \sin(\theta_{s,t}) |O\rangle \right),
\]

where \(|E\rangle\) is a short notation for the even parity state, \(|a \oplus b = 0\rangle\), and likewise \(|O\rangle\) for the odd state, \(|a \oplus b = 1\rangle\).

Expression (23) represents a measurement of an observable which eigenvalues determine the parity of the individual measurement outcomes that Alice and Bob get. Since the state is in a superposition of the even and odd base states, it means that when Alice and Bob jointly measure the state they will get,
Operationally speaking then, the strategy boils down to Alice and Bob choosing angles $\theta_s$ and $\theta_t$, for every possible input they can receive $s$ and $t$, such that the argument $\theta_s$ maximizes the probability to measure the Bell state in the most convenient base state, of either even or odd parity, depending on the specific input. It is clear why this approach is the ideal strategy for XOR games, since in these kind of games the individual outputs do not matter, only their parity does. We can represent symbolically the expression that gives the probability to win any XOR game, according to this generic recipe as

$$W_Q(XOR) = \sum_{s,t} p(s,t) [\cos^2(\theta_s) V_{\text{XOR}}^e(s,t) + \sin^2(\theta_s) V_{\text{XOR}}^o(s,t)],$$  \hspace{1cm} (24)$$

where,

$$V_{\text{XOR}}^e(s,t) = \begin{cases} 1, & \text{if } f(s,t) = 0, \\ 0, & \text{otherwise} \end{cases}$$

$$V_{\text{XOR}}^o(s,t) = \begin{cases} 1, & \text{if } f(s,t) = 1, \\ 0, & \text{otherwise} \end{cases}$$

such that,

$$\omega_q^{\text{XOR}} \equiv \text{Max} \{W_Q(XOR)\},$$  \hspace{1cm} (25)$$

which means that finding the quantum value for a two-player XOR game can be reduced to solving the maximum value problem (26).

### 3 Simple two-player XOR games

The word *simple* has been used throughout the paper, but exactly in what way are these two-player XOR games simple? What is meant by *simple* is that the number of possible game configurations is small enough such that we can either analytically or numerically solve the maximum value problem (26), for some XOR game with a general winning probability given by expression (24). Since the answers in XOR games are necessarily bits, this means that this restriction on configurations is translated to a restriction on the set of questions, in other words, a simple two-player XOR game is a two-player XOR game for which the cardinality of the set of questions allowed is not so big as to render the solution of (26) impossible. Now we will compute the quantum value for some examples of such simple two-player XOR games by employing the previously showed construction, i.e., using (24) to write the winning probability for said games, and solving their respective maximum value problems (26).
3.1 Quantum value for the CHSH game

We write the predicate of the game (13) once again,

\[ V(ab|st)_{\text{CHSH}} = \begin{cases} 1, & \text{if } s \cdot t = a \oplus b \\ 0, & \text{otherwise} \end{cases} \]

\[ \forall s,t \quad p(s, t) = \frac{1}{4}, \quad (27) \]

and now we shall write the probability of winning the game explicitly for all possible game configurations, using expression (24),

\[ W_Q(\text{CHSH}) = \frac{1}{4} \cos^2(\theta_{0,0}) + \frac{1}{4} \cos^2(\theta_{0,1}) + \frac{1}{4} \cos^2(\theta_{1,0}) + \frac{1}{4} \sin^2(\theta_{1,1}). \quad (28) \]

The expression states that Alice and Bob need even outcomes for the first 3 terms, which correspond to questions (0, 0), (0, 1), (1, 0), respectively, and they need odd outcomes for the last term which corresponds to question (1, 1). Then we should find a \( \theta_{s,t} \) that maximizes (28).

The first thing we need to do is to commit to an actual Bell state. Say, without loss of generality, that Alice and Bob share the state \( |\phi^-\rangle \), which means according to Table 1 that,

\[ \theta_{s,t} = \alpha_s + \beta_t, \]

thus we have,

\[ W^\text{CHSH}_Q(\alpha_0, \beta_0, \alpha_1, \beta_1) = \frac{1}{4} \cos^2(\alpha_0 + \beta_0) + \frac{1}{4} \cos^2(\alpha_0 + \beta_1) \]

\[ + \frac{1}{4} \cos^2(\alpha_1 + \beta_0) + \frac{1}{4} \sin^2(\alpha_1 + \beta_1). \quad (29) \]

If we solve (26) for this case, for instance numerically in Mathematica, we get that,

\[ \text{Max}\{ W^\text{CHSH}_Q(\alpha_0, \beta_0, \alpha_1, \beta_1) \} \approx 0.853553... = \cos^2 \frac{\pi}{8} \equiv \omega_{q}^{\text{CHSH}} \quad (30) \]

This value is achieved by Alice and Bob, when they choose the following functions over the inputs they receive,

\[ \alpha_s \equiv \alpha(s) = \frac{4\pi}{16}s - \frac{\pi}{16} \]

\[ \beta_t \equiv \beta(t) = \frac{4\pi}{16}t - \frac{\pi}{16}, \quad (31) \]

obviously that these functions would be different if for instance they had shared another Bell state.
3.2 Quantum value for the odd cycle (OC) game

Another game used as example in the Cleve et. al paper was the Odd Cycle game, in which the players’ objective is to try and convince the Referee that an odd \( n \)-cycle graph, \( C_n \) \((n > 2)\) is two-colorable i.e vertices belonging to the same edge should have different colors, which obviously can’t be the case since the graph has an odd number of vertices. The game proceeds as follows - the Referee will ask Alice and Bob, \( s \) and \( t \), respectively, which correspond to the vertices of the graph, from 1 to \( n \), which color he would like to know, and Alice and Bob will answer back \( a \) and \( b \), which correspond to the colors appropriately chosen, according to some strategy. The answers will be obviously bits, which correspond to the coding of any two distinct colors they so choose, e.g., \( 0 = \text{black} \) and \( 1 = \text{white} \). There exists another particularity in this game, which is that the questions are not entirely arbitrary, i.e., the Referee can’t ask any two given vertices of the graph to the players; the questions must obey the following rule:

- The vertices asked are either the same, or they share an edge and the vertex asked to Bob is clockwise after Alice’s;\(^6\)

Since Alice and Bob want to convince the Referee that the odd \( n \)-cycle graph is two-colorable, they will have to answer with the same color if the vertices asked are the same, and with different colors if they are different. Thus the winning condition is formalized in the following predicate,

\[
V(ab|st)_{OC} = \begin{cases} 
1, & \text{if } [s \oplus 1 = t \pmod{n}] = a \oplus b \\
0, & \text{otherwise}
\end{cases}
\]

(32)

\[
p(s, s = t) = \frac{1}{2}; \quad p(s, s \oplus 1 = t) = \frac{1}{2};
\]

[\( s \oplus 1 = t \pmod{n} \)] is the truth value of the proposition \( s \oplus 1 = t \pmod{n} \). If the proposition is false it evaluates to 0 and it means that \( s = t \) is true, which is the

---

\(^6\) It is this exact rule that makes this a simple two-player XOR game. If there would be no restrictions on the questions, then (26) would be ever harder to solve for increasing values of \( n \).
only other option according to the rules of the game, on the other hand if indeed \( s \oplus 1 = t \) is true then it evaluates to 1.

Assuming that \( s \oplus 1 = t \) is false, which means that \( s = t \) is true, the Referee asks the same vertices to both Alice and Bob, so in order for them to win they must output the same color, which is precisely to what the condition in the predicate reduces to, \( a \oplus b = 0 \). If \( s \oplus 1 = t \) is true, then the Referee is asking vertices that share an edge, so Alice and Bob must output different colors, i.e \( a \oplus b = 1 \).

The best classical strategy that Alice and Bob can conceive is actually to agree upon a possible color configuration that maximizes their winning probability, by choosing just two vertices with a common edge to be the same color, and then stick to it. Obviously they will fail if the Referee asks for the color of such two vertices, but in general that will only happen \( \frac{1}{2n} \) of the times for a \( C_n \) graph, which means that

\[
\omega_{c}^{n-\text{Odd Cycle}} = 1 - \frac{1}{2n}.
\]

For instance, in the special case of a 3-cycle graph,

\[
\omega_{c}^{3-\text{Odd Cycle}} = \frac{5}{6}.
\]

Figure 2 shows a specific example of a possible coloring scheme that Alice and Bob could agree upon, in the case for a \( C_3 \) graph, that reaches the classical value.

Let us see how the quantum strategy goes. Alice and Bob need to answer bits whose parity is even when \( s = t \) and odd when \( s \oplus 1 = t \). From (24) we have that the best quantum strategy is

\[
\mathcal{W}_{\text{Q}}(\text{OC}) = \frac{1}{2} \cos^2(\theta_{s,t=s}) + \frac{1}{2} \sin^2(\theta_{s,t=s \oplus 1}).
\]

If Alice and Bob share \( |\phi^+\rangle \) then according to Table 1, (35) becomes

\[
\mathcal{W}_{\text{Q}}^{\text{OC}}(\alpha_s, \beta_t) = \frac{1}{2} \cos^2(\alpha_s - \beta_t) + \frac{1}{2} \sin^2(\alpha_s - \beta_t \oplus 1).
\]

Now we want to solve the maximum value problem (26), for the previous expression (36). We will do this analytically. First, without loss of generality, assume that \( \beta_{s \oplus 1} = \beta_s - \phi_n \), where \( \phi_n \) is the angle that Bob offsets \( \beta_s \) (the ideal measurement orientation in the case when they receive equal inputs). To clarify - if \( \beta_s \) is the optimal orientation in which Bob performs the measurement in the situation where him and Alice receive the same input, then \( \beta_{s \oplus 1} \) is the optimal orientation in which Bob does a measurement when him and Alice receive different inputs. This last orientation \( \beta_{s \oplus 1} \) will now be written in terms of the other orientation and some offset angle \( \phi_n \), which we make no assumption on at this point, aside from the fact that it must be something which depends on the dimension of the game. Under such considerations the probability now becomes

\[
\mathcal{W}_{\text{Q}}^{\text{OC}}(\alpha_s, \beta_s, \phi_n) = \frac{1}{2} \cos^2(\alpha_s - \beta_s) + \frac{1}{2} \sin^2(\alpha_s - \beta_s + \phi_n).
\]
Since we want to maximize the previous expression, a straightforward approach in doing so is to relate the trigonometric arguments in the following way,

\[ (\alpha_s - \beta_s) = \frac{\pi}{2} - (\alpha_s - \beta_s + \phi_n) \]

or equivalently,

\[ (\alpha_s - \beta_s) = \frac{\pi}{4} - \frac{\phi_n}{2}. \]

Then we have that the maximum probability is

\[ \max\{W_{OC}(\alpha_s, \beta_s, \phi_n)\} = \frac{1}{2} \cos^2\left(\frac{\pi}{4} - \frac{\phi_n}{2}\right) + \frac{1}{2} \sin^2\left(\frac{\pi}{4} + \frac{\phi_n}{2}\right) = \frac{1}{2} \left(1 + \sin(\phi_n)\right) \equiv \omega_q(\phi_n). \] (38)

Expression (38) shows in closed form, the quantum value for an n-Odd Cycle game still explicitly dependent on the generic offset angle \( \phi_n \). What should \( \phi_n \) be? We know that the players can’t win with certainty, because the only way to do so would be to actually have a 2 color configuration of an odd cycle graph, which we know to be impossible. Bearing this in mind the following inequality comes naturally,

\[ \sin(\phi_n) < 1 \iff \phi_n < \frac{\pi}{2}. \]

Also the probability to win the game should approach 1 for ever increasing values of \( n \), which translates to

\[ \sin(\omega_n \rightarrow \infty) = 1 \iff \omega_n \rightarrow \infty = \frac{\pi}{2}. \]

Then, the simplest expression for \( \phi_n \) is,

\[ \phi_n = \frac{\pi}{2} \left(1 - \frac{1}{n}\right), \] (39)
which in turn means that (38) becomes

\[
\text{Max}\{W^{OC}_Q(\alpha_s, \beta_s, \phi_n)\} = \frac{1}{2}[1 + \sin\left(\frac{\pi}{2}(1 - \frac{1}{n})\right)] = \cos^2\left(\frac{\pi}{4n}\right) \equiv \alpha_q^{n}\text{-Odd Cycle}.
\]

This result is obtained when,

\[
(\alpha_s - \beta_t) = \frac{\pi}{2}(1 - \frac{1}{n})(s - t) + \frac{\pi}{4n},
\]

which means that if, \(s = t\),

\[
(\alpha_s - \beta_s) = \frac{\pi}{4n},
\]

and if, \(s \neq t\),

\[
(\alpha_s - \beta_{s\oplus 1}) = \frac{\pi}{2} - \frac{\pi}{4n}.
\]

The previous arguments appear in the trigonometric functions if Alice and Bob choose the following measurements orientations,

\[
\alpha_s \equiv \alpha(s) = \frac{\pi}{2}(1 - \frac{1}{n})s + \frac{\pi}{4n};
\]

\[
\beta_t \equiv \beta(t) = \frac{\pi}{2}(1 - \frac{1}{n})t.
\]

### 3.3 Quantum value for the entanglement assisted orientation in space (EAOS) game

The EAOS game [2] was originated by conjuring an hypothetical physical scenario to demonstrate the advantage of using quantum strategies in the “real world”. The scenario is as follows—Alice and Bob are in the poles (e.g Alice is in the South Pole and Bob is in the North Pole) and can’t communicate, but they want to meet in the equator line in such a way that either they arrive at the same point, or they arrive at points which are apart by no more than 60° along the Earth’s surface, the argument being that if aided by some magnification apparatus they could still see each other in this case.

Now, let us assume that there are 6 possible destinations to which they can arrive to, originated by setting three equally separated possible paths (1, 2, 3), 120° apart, and two ways (0, 1) to go along each path. Due to the geometry of the situation, Alice and Bob win if they choose to walk along the same way for equal paths (in which case they arrive at the same destination), or walk along opposite ways for different paths (in which case they arrive at the neighboring destinations 60° apart); see Fig. 3.

Obviously that if both Alice and Bob had known beforehand that they would be in this scenario they could agree on a meeting point, trivializing the problem, so in order to elevate this scenario to that of a non-local game, we should assume that
Alice and Bob do not have agency to pick their paths, only the ways to walk along each path, which in turn is chosen and communicated to them by a third party, i.e., the Referee. Then the paths are the questions, and the ways are the answers of the EAOS game. Under such circumstances it is not terribly difficult to see that this game is an XOR game, since the winning probability depends only on the parity of the answers—Alice and Bob win the game if they happen to walk along the same way for equal paths, and opposite ways for different paths, regardless of what individual way is chosen. Actually, the EAOS game bears a striking resemblance to the $n = 3$ Odd Cycle game - if instead of vertices we have paths, and instead of 2 possible colors which to paint the vertices with, we have 2 ways to go along each path, then it seems that, terminology aside, the set up is the same. In fact, the winning condition also seems to hold under the change of terminology—if the paths/vertices are the same, then the game is won if the parity of the ways/colors is even. On the other hand, if the paths/vertices are different the ways/colors should have odd parity—so we could assume that the games are equivalent, and in doing so we would be wrong. The error is in ignoring a subtle distinction in the predicates of both games. If we recall, the Odd Cycle game had an extra restriction on the way that the Referee asked the questions,
– The vertices asked are either the same, or they share an edge and the vertex asked to Bob is clockwise after Alice’s;

and there is no corresponding restriction in the EAOS game. Obviously that in the EAOS game, if the paths are different, they will necessarily be adjacent to one another, but there is nothing that specifies an order between the paths each player received. If we lift this restriction from the predicate of the Odd Cycle game (32), and write it for the special case of \( n = 3 \), we get exactly the predicate for the EAOS game,

\[
V(ab|st)_{EAOS} = \begin{cases} 
1, & \text{if } \left[ s \oplus 1 = t \pmod{3} \right] + \left[ s \ominus 1 = t \pmod{3} \right] = a \oplus b \\
0, & \text{otherwise}
\end{cases}
\]

(42)

So, in this scenario we evaluate the truth value of Bob’s path being after \( \left[ s \oplus 1 = t \pmod{3} \right] \) or before \( \left[ s \ominus 1 = t \pmod{3} \right] \) Alice’s, and since those are the only two possibilities when the paths are different, due to the dimensions of the game, that amounts to saying we evaluate the truth value of the paths being different, regardless of the order. Although writing the predicate in the form of (42) is useful because it illustrates the difference to the regular Odd Cycle predicate (32), we can rewrite it in a more user friendly manner,

\[
V(ab|st)_{EAOS} = \begin{cases} 
1, & \text{if } 1 - \delta_{st} = a \oplus b \\
0, & \text{otherwise}
\end{cases}
\]

(43)

where \( \delta_{st} \) is the Kronecker delta defined as,

\[
\delta_{st} = \begin{cases} 
1, & \text{if } s = t \\
0, & \text{if } s \neq t
\end{cases}
\]

To completely define the EAOS game we assume that the probability distribution over the set of the questions is as follows,

\[
p(s, s = t) = p(s, s \oplus 1 = t) = p(s, s \ominus 1 = t) = \frac{1}{3},
\]

i.e., the Referee is equally likely to demand that each player walks on any given path. At this point we have EAOS\((V, p)\) completely defined.

The best classical strategy for the EAOS game, which was shown in [2], is for Alice and Bob to agree on a deterministic mapping of the ways they go depending on the paths received and allow them to share the same mapping, like in the Odd Cycle game. Say that \( f(s) = g(s) \) (i.e they share the same mapping) such that \( F(s, t) \equiv f(s) \cdot g(t) \) is given by \( F(s, t) \equiv f(s) \cdot f(t) \). The predicate now becomes

\[
V(ab|st)_{EAOS} = \begin{cases} 
1, & \text{if } 1 - \delta_{st} = f(s) \oplus f(t) \\
0, & \text{otherwise}
\end{cases}
\]

Then a possible mapping that gives the \textit{classical value} of the EAOS game is give by
Table 2 shows the winning condition evaluated for every possible combination of the outputs that the deterministic strategy offers to Alice and Bob. There are two impossible conditions $l = 0$, and thus, it is easy to see this strategy wins the game with a probability

$$\frac{7}{9} \equiv \omega_c(EAOS).$$

Now let us proceed to the quantum strategy. Alice and Bob need even parity outcomes when $s = t$ and odd parity outcomes when $s \oplus l = t$ and $s \ominus l = t$. Then according to (24),

$$W_Q(EAOS) = \frac{1}{3} \cos^2(\theta_{s,t=\bar{s}}) + \frac{1}{3} \sin^2(\theta_{s,t=\bar{s} \oplus 1}) + \frac{1}{3} \sin^2(\theta_{s,t=\bar{s} \ominus 1}),$$

and if the shared Bell state is $|\phi^+\rangle$,

$$W_Q(EAOS) = \frac{1}{3} \cos^2(\alpha_s - \beta_{l=\bar{s}}) + \frac{1}{3} \sin^2(\alpha_s - \beta_{l=\bar{s} \oplus 1}) + \frac{1}{3} \sin^2(\alpha_s - \beta_{l=\bar{s} \ominus 1}).$$

Following the same line of reasoning as in the Odd Cycle game, we rewrite the expression such that Bob’s orientations in the odd parity terms ($\beta_{l=\bar{s} \oplus 1}$, $\beta_{l=\bar{s} \ominus 1}$), are given as functions of an “offset angle”, $\phi_3$, from his orientation in the even parity case ($\beta_{l=\bar{s}}$). Due to the symmetry of the situation, we assume that the way that Bob offsets his ideal measurement orientation, in the case where the Alice’s path is after Bob’s, i.e $\beta_{l=\bar{s} \oplus 1}$, will be the negative of the case when Alice’s path is before Bob’s, $\beta_{l=\bar{s} \ominus 1}$. Thus we have

$$W^{EAOS}_{Q}(\alpha_s, \beta_s) = \frac{1}{3} \cos^2(\alpha_s - \beta_s) + \frac{1}{3} \sin^2(\alpha_s - \beta_s + \phi_3) + \frac{1}{3} \sin^2(\alpha_s - \beta_s - \phi_3),$$

where $\phi_3$ is computed from (39) and we get

$$\phi_3 = \frac{\pi}{2}(1 - \frac{1}{3}) = \frac{\pi}{3}.$$

This in turn gives
If we define $\alpha_s - \beta_s \equiv x$ we have the probability given as a function of $x$,

$$W^E_{\text{Q}}(x) = \frac{1}{3} \cos^2(x) + \frac{1}{3} \sin^2(x - \frac{\pi}{3}) + \frac{1}{3} \sin^2(x + \frac{\pi}{3})$$  \hspace{1cm} (48)$$

and we can compute the derivative and calculate the global maximum of the function. We get that

$$\text{Max} \{ W^E_{\text{Q}}(x) \} = \frac{1}{3} \cos^2(0) + \frac{1}{3} \sin^2(-\frac{\pi}{3}) + \frac{1}{3} \sin^2(\frac{\pi}{3}) = \frac{5}{6} \equiv \omega_q(\text{EAOS})$$  \hspace{1cm} (49)$$

This is the exact value that was achieved by the strategy presented in the original paper [2], proving that the strategy is in fact the optimal quantum strategy. The strategy is achieved by setting the following measurements orientations,

$$\alpha_s \equiv \alpha(s) = \frac{\pi}{3}s - \frac{\pi}{3}$$  \hspace{1cm} (50)$$

$$\beta_t \equiv \beta(t) = \frac{\pi}{3}t - \frac{\pi}{3}$$

## 4 Conclusions

Based on two theorems proved in [1], we have seen a constructive approach to compute the Tsirelson bounds for a set of two-player XOR games, which we called simple two-player XOR games, for which finding the bound reduces to solving a maximum value problem (26). The adjective *simple* is a lose characterization, which means that the analytic or numerical solution of the maximum value problem that comes out of the strategy is solvable. The number of possible game configurations will, in principle, dictate the difficulty of finding the solution of (26), and since in XOR games the set of answers is restricted to bits, that means a given XOR game could be *simple* or not depending on the size of the set of questions. We used the strategy explicitly in the calculation of the Tsirelson bound for two well known examples of such simple two-player XOR games - the CHSH (30) and the $n$-Odd Cycle (40) bounds. Additionally, we also computed the Tsirelson bound for the EAOS game, which was calculated by hinging on the fact that its predicate (42) could be retrieved by relaxing the predicate of the 3-Odd Cycle game and, as such, was also a simple two-player XOR game where our constructive strategy was valid. Solving the maximum value problem (26) for the winning probability (48) we got the EAOS bound (49), which was calculated for the first time since the game was introduced in [2]. Furthermore, we can also conclude that since the value of the EAOS bound (49) is achieved by the strategy presented in the original paper, there is no better quantum strategy to win the EAOS game.
