(De)Localization in the Prime Schrödinger Operator

César R. de Oliveira and Giancarlo Q. Pellegrino

Abstract

It is reported a combined numerical approach to study the localization properties of the one-dimensional tight-binding model with potential modulated along the prime numbers. A localization-delocalization transition was found as function of the potential intensity; it is also argued that there are delocalized states for any value of the potential intensity.

PACS numbers: 03.65.-w, 72.20.Ee, 72.10.Bg
Problems related to the distribution of prime numbers are usually interesting and difficult. Maybe, the most challenging open problem in mathematics is the so-called Riemann’s hypothesis on the distribution of the (nontrivial) zeros of his zeta function, a problem directly related to the distribution of prime numbers and other mathematical issues. Also, the interplay between number theory, with the set of prime numbers playing a major role, and physics has been fruitful; see the short note by Wolf [1] and references therein for recent discussions.

In the last years there has been a large interest in spectral properties of discrete Schrödinger operators on $l^2(\mathbb{Z})$

$$(HV)u = u_{n+1} + u_{n-1} + \lambda V_n u_n,$$

with nonrandom finite valued potentials $V = \{V_n\}$ (see [2] [3] [4] [5] [6] [7] and references therein); $\lambda > 0$ is the potential intensity. Such one-dimensional models with potentials along almost periodic sequences taking a finite number of values $\{\mathbb{Z}, \mathbb{Z}, \mathbb{Z}\}$, like substitution and circle sequences, have been dominated by singular continuous spectra. Recall, however, that for the cases of periodic and random potentials $V$ it is well known that the Hamiltonian $HV$ has absolutely continuous and point spectra, respectively [8]; these are mathematical characterizations of delocalized and localized (insulator) behaviours, respectively.

There has also been recent work on Schrödinger operators with sparse potentials [9] [10] [11] [12] [13]. A characteristic defining a sparse potential is the constancy of its values in a sequence of increasing intervals. In this case one can have point, absolutely continuous and singular continuous spectra, depending on the growing speed of the gaps and how the intensity of the bumps behaves at infinity. There is, in fact, some competition among different properties of the potential, resulting in rich spectral possibilities.

The prime numbers are straight related to both kind of potentials discussed above, namely nonrandom and sparse. It is well known that the set of prime numbers is not finite and that there are arbitrarily large gaps between consecutive primes, a property characterizing sparseness. By defining a potential $V_0 = 0$, $V_n = 1$ if $n + 1$ is a prime number and $V_n = 0$ if not, and extending symmetrically to negative values of $n$, i.e., $V_{-n} = V_n$, one gets an instance of finite valued sparse potential. The nonnegative values of the potential $V$ are 01101010001010001 \ldots.

The main aim of this Letter is to discuss numerically the spectral properties of the corresponding discrete Schrödinger operator, which will be shortly referred to as “the prime Schrödinger operator.” The rigorous analytical study of this system, although desirable, seems to be subtle and far from
trivial. Since in this Letter we consider this problem from just a numerical point of view, we find more appropriate to avoid the mathematical spectral terms, and instead shall try to use the physical ones localization (insulator) and delocalization to characterize our results.

By exploring dynamical as well as geometrical quantities related to the spectral properties of the model, we find a (rather smooth) transition from predominantly delocalized states to localized ones, as the potential intensity is increased. Nevertheless, some delocalized states always remain, no matter how large is the potential. Also, the combined use of geometrical and dynamical tools, supportive and to some extent complementary to each other, seems to be applicable to other cases with coexisting spectral components.

Here two different sets of numerical tools are used in such investigations. The dynamical tools are the average probability for the system to return to its initial state $u_0 = \delta_{n,n_0}$, concentrated on the site $n_0$,

$$C(t) = \frac{1}{t} \int_0^t |\langle u(s)|u_0 \rangle|^2 ds,$$

and the second moment

$$d_2(t) = \sum_n (n-n_0)^2 |u_n(t)|^2,$$

$u = (u_n)_{n \in \mathbb{Z}}$. Recall that for large values of $t$ it is expected that $C(t) \sim t^{-D_2}$ and $d_2(t) \sim t^{2\beta}$, with $D_2$ being the correlation dimension of the spectral measure associated with the initial state [14, 15, 16]. Continuous spectra are usually numerically characterized by $0 < D_2, \beta$; although it is possible to have exceptional systems with point spectrum and with any value $0 \leq \beta < 1$ [17].

Due to the rather irregular distribution of prime numbers [1] we suspect the quantum dynamics generated by $H_V$ can strongly depend on the initial wave function, at least for small times; therefore, the initial condition was always concentrated on $n_0 = 0$. These dynamical tools were restricted to $0.5 \leq \lambda$, since for small $\lambda$ it is not possible to neglect logarithmic corrections to the algebraic behaviours of $C(t)$ and $d_2(t)$ [4].

The other kind of tools, geometrical tools, are the direct inspection of eigenfunctions and the Lyapunov exponent (LE) $\gamma$, also called inverse localization length, calculated for each eigenfunction of the finite basis approximation. The typical basis size used here is $10^4$; the robustness of the numerical calculations with respect to the basis size was verified in each case. Localization, i.e., point spectrum, is characterized by nonvanishing $\gamma$.

From the Thouless formula [3, 8], in particular from its proof, one sees
that the LE at energy $E$ can be estimated as

$$\gamma(E) \approx \frac{1}{N} \sum_{j=1}^{N} \ln |E - E_j|,$$

with $E_j$ running over all eigenvalues (distinct from $E$) of the finite basis approximation of size $N$.

In Fig. 1 it is shown the Lyapunov exponent $\gamma$ as function of the energy for some values of the potential intensity $\lambda$. For $\lambda = 0.5$ the vanishing of the LE for most energies $E$ indicates the predominancy of delocalized states; by increasing the potential intensity the LE becomes different from zero, except in a left neighborhood of $E = 0$. This phenomenon was verified for all values of potential intensity considered (up to $\lambda = 40.0$), i.e., the LE vanishes just below $E = 0$. This strongly indicates a transition from delocalization to localization with a remaining set of delocalized states near $E = 0$.

The above conclusions were also supported by numerical solutions of the Schrödinger equation and computation of dynamical quantities (also with lattice size up to $10^4$). In Fig. 2 it is shown $d_2(t)$ for two values of $\lambda$; $d_2(t)$ saturates for $\lambda = 6.0$ (as well as $C(t)$; not shown), indicating the presence of localized states; while for $\lambda = 0.5$ the values of $d_2(t)$ increase until a critical probability density value is reached at the basis border ($|u|^2 < 10^{-6}$ was used), indicating the presence of delocalized states. Notice that, due to the presence of both localized and delocalized states for the prime Schrödinger operator, it can be difficult to retrieve information on its spectral type only from dynamical quantities. This justifies the choices of potential intensity values in Fig. 2, used to exemplify the spectral transition: for $\lambda = 0.5$ most states are delocalized, while for $\lambda = 6.0$ the energy band corresponding to delocalized states is very narrow.

Of course a numerical vanishing LE is not exactly zero. The LE $\gamma_p$ for a periodic case was computed with the above method; since it should be zero in the spectrum of the corresponding Schrödinger operator, any $\gamma \leq \gamma_p$ was in practice considered to indicate the presence of delocalized states for the prime case. This was used to estimate the length of the interval $[-b(\lambda), 0]$ of the “delocalized band” as function of $\lambda$. As another check for such transition, the dynamical quantities $d_2(t)$ and $C(t)$ were computed for short times taking into account two different sets of eigenvectors: those whose eigenvalues were in the delocalized band $[-b(\lambda), 0]$, and those in intervals with positive LE. The distinctions in their qualitative behaviours are evident. For example, in Fig. 3 the value $\lambda = 1.0$ was fixed and $d_2$ was computed by restricting the dynamics to eigenvalues in the range $[-0.6, 0.0]$ (a subset of $[-b(1), 0]$) and also to eigenvalues in the range $[1.6, 2.0]$ (corresponding to positive LE). In
the former case $d_2(t)$ grows with time, while in the latter case it is clearly bounded; such results also support the presence of mobility edges in the spectrum of the prime Schrödinger operator.

Fig. 4 shows some values of $b(\lambda)$; the best fitting line is also shown and its slope is equal to $-1$. Therefore, it is numerically found that $b(\lambda) \sim \lambda^{-1}$, at least for large $\lambda$, so that it does not vanish and the spectrum of the prime Schrödinger operator should have a set of delocalized states for any potential intensity. Notice that the eigenfunctions corresponding to eigenvalues in the range $[-b(\lambda), 0]$ are extended over the finite bases, while they are exponentially localized if the corresponding LE is greater than zero (not shown here).

In summary, a delocalization-localization transition, with mobility edges, was found numerically for the one-dimensional prime Schrödinger operator, a transition as the intensity of the potential is increased; however, there remains a band of delocalized states whose length scales as $\sim \lambda^{-1}$, assuring the presence of delocalized states for any value of $\lambda$. These results, and the calculations presented, suggest that the same approach could be applied to cases with other aperiodic potentials, for which one suspects to have simultaneously continuous and point spectral components.

Acknowledgments

We thank CAPES-DAAD for supporting our visit (PROBRAL Project) to Prof. M. Schreiber’s group at Technische Universität Chemnitz, where part of this work was done. We also thank Prof. W. F. Wreszinski for his patient cooperation. GQP was supported by FAPESP and CRO was partially supported by CNPq.
