Abstract. We show that simple Two Higgs Doublet models might still provide a viable explanation for the matter-antimatter asymmetry of the Universe via electroweak baryogenesis, even after taking into account the recent order-of-magnitude improvement on the electron-EDM experimental bound by the ACME Collaboration. Moreover we show that, in the region of parameter space where baryogenesis may be possible, the gravitational wave spectrum generated at the end of the electroweak phase transition is within the sensitivity reach of the future space-based interferometer LISA.

1 Introduction

The origin of the baryon asymmetry of the Universe (BAU) remains one of the most important unsolved puzzles in high energy physics and cosmology. Current observations [1, 2] lead to a ratio of the net baryon number per entropy density in the Universe of

$$\eta_{\text{obs}} \equiv \frac{n_B}{s} \simeq 8.7 \times 10^{-11},$$

meaning an excess of roughly one baryon for every one billion matter-antimatter annihilation events taking place in the early Universe. The three necessary ingredients for generating such an asymmetry dynamically [3] are in principle present within the Standard Model (SM): (i) baryon number violation due to the chiral anomaly and non-perturbative sphaleron transitions [4–6]; (ii) violation of charge (C) and charge-parity (CP) symmetries from the electroweak interactions and quark mixings; (iii) displacement from equilibrium coming from the Hubble expansion of the Universe and possibly from the electroweak phase transition (EWPT) [7–9]. A closer analysis indicates, however, that the sphalerons and the CP violating diffusion processes are never simultaneously out of equilibrium with respect to the Hubble expansion [10], so a BAU can only be generated if the process of electroweak symmetry breaking proceeds via a first order phase transition. Kinetic equilibrium would then be broken by the expansion of bubbles of the true vacuum, with a sufficiently large vacuum expectation value (VEV) inside the bubble required in order to avoid washout of the generated asymmetry in the broken phase (see [11] for a recent review on electroweak baryogenesis). As it turns out, this latter condition is not satisfied in the SM, since the would-be phase transition is actually a smooth crossover [12, 13]. Furthermore, a second and unrelated problem is the far too small amount of CP violation coming from the CKM matrix, which is suppressed by the Jarlskog invariant [14, 15] as well as by the tiny quark
Yukawa couplings, hence leading to a prediction for the BAU which is at best ten orders of magnitude below the observed value [16–18].

The BAU is therefore an observable which asks for an extension of the SM with additional sources of CP violation and extra particles coupling to the Higgs sector. However, the presence of the former has an impact on electric dipole moments (EDMs), which are tightly constrained experimentally. In particular, there has recently been an update on the electron EDM (eEDM) by the ACME collaboration improving the bound by one order of magnitude with respect to the previous experimental limit [19], thus casting doubts on whether certain models would still be viable candidates for successful electroweak baryogenesis, and, if so, which regions of their parameter space would still be allowed. In this work we investigate the current status of baryogenesis in simple Two Higgs Doublet Models (2HDMs).\footnote{A recent work has tackled this issue in the context of 2HDM scenarios with an additional inert singlet. The presence of an extra singlet tends to strengthen the phase transition and therefore decouples the source of a strong EWPT (mainly from the extra singlet) to that of CP violation (which comes from the two doublets), thus alleviating the impact of experimental bounds [20].}

Previous studies on this problem have already established the \textit{a priori} viability of obtaining the BAU in this framework [21–28], but only one of them takes the ACME eEDM constraint into account [27], albeit with a parameter set that is now excluded by flavor observables. Furthermore, most of these studies assumed a very particular and simplified parameter choice for the study of the EWPT (except for [26, 28]). A more recent analysis of the EWPT in 2HDM scenarios indicates a significantly wider range of parameters allowing for a strong first order transition [29, 30], in particular pointing to regions of the parameter space with a rather exotic phenomenology so far largely unexplored by collider searches [30, 31]. On the other hand, recent analyses on the CP violation front show that the ACME eEDM bound places tight constraints on the CP violating mixing angle among the scalars [32–34]. Whether the amount of allowed CP violation is still sufficient to generate the observed BAU in 2HDMs is a key question we aim to answer in this work.

A first order cosmological phase transition would generate yet another important relic from the early Universe, namely a stochastic gravitational wave (GW) background sourced by the dynamics of scalar field bubbles which generates acoustic waves and possibly turbulence in the plasma at the very end of the transition. For such a source, active at the electroweak scale, the red-shifted spectrum is expected to peak at frequencies $\mathcal{O}(0.1−10\text{ mHz})$ [35], within the range of detectability of the near-future space-based GW interferometer LISA [36]. The importance of observing such a signal cannot be underestimated: it would not only provide us with a first image of the early Universe beyond the recombination epoch, but would also constitute an alternative, cosmology-based method for probing beyond the SM (BSM) particle physics which is complementary to collider experiments. The recent measurement of GW from binary black hole mergers by LIGO [37, 38] has already demonstrated our capability to reliably and accurately detect these waves, and has therefore paved the way for using this brand new source of information as a probe of physics from cosmological down to microscopic scales.

It is interesting to note that the baryon asymmetry and the stochastic GW spectrum resulting from the EWPT behave oppositely as a function of the expansion velocity of the scalar field bubbles. Baryogenesis is optimal for relatively slow subsonic bubble walls, allowing enough time for the CP violating diffusion processes to generate an excess of handedness in front of the bubble, later to be converted into a BAU by the sphalerons. On the other hand, a detectable stochastic GW spectrum requires a rather strong phase transition, releasing a
large amount of free-energy which can then be converted into bulk motion of the plasma and kinetic energy of the bubbles, thus typically resulting in faster supersonic walls. In particular, when the GW source was modelled as rapidly expanding shells of kinetic energy, after the bubble sphericity has been broken by their collision (the so-called “envelope approximation”), then a sizeable spectrum was usually predicated on ultra-relativistic walls, in which case electroweak baryogenesis is impossible. However, recent developments in the field have significantly improved our understanding of GW generation via acoustic waves [39, 40], which remain active long after bubble collisions end and are therefore a much more efficient source also in the case of deflagrating bubbles.\(^2\) Moreover, it has been noted that the prospective sensitivity of LISA to power-law like spectra can be greatly enhanced by integrating over the frequency of such broadband signals, leading to an improvement of a factor \(\sim O(10^3)\) with respect to an estimate based only on the raw sensitivity of the apparatus [42]. Using these new developments, we show that the EWPT from 2HDMs could actually lead to both an observable BAU and detectable GWs by LISA, as a result of yielding rather strong phase transitions with relatively slow moving bubbles.

The paper is organized as follows. In section 2 we briefly review the two-Higgs-doublet model and summarize the theoretical and experimental constraints that ought to be taken into account for the present purpose. In section 3 we introduce the hierarchical benchmark scenario on which we focus, with a large mass splitting between the new scalars which favours a strongly first order phase transition [29, 30]. We then show that the bubble walls can be expected to be subsonic even for very strong transitions, a key feature in allowing for the simultaneous generation of the correct BAU and an observable stochastic GW spectrum. The baryogenesis computation is detailed in section 4. In the semiclassical approximation, the final asymmetry is expected to depend on the EWPT strength \(v_n/T_n\), the bubble wall width \(L_w\), and the total shift \(\Delta \Theta_t\) of the top-quark CP violating phase along the wall according to

\[ \eta \sim (v_n/T_n)^4 L_w^{-1} \Delta \Theta_t. \]  

(1.2)

One then notices that an increase in the phase transition strength can compensate for a diminishing CP violating phase, allowing for the generation of the correct BAU while evading the tight eEDM bounds. The price to pay is that a stronger transition typically involves larger couplings, potentially jeopardizing the validity of the 1-loop expansion used in our results. Such perturbativity issues are discussed in appendix A. Section 5 is devoted to the computation of the GW spectrum. Our concluding remarks are left for section 6.

## 2 Two-Higgs-Doublet Models

Two Higgs doublet models are among the most minimalistic extensions of the SM, differing from it only by the addition of an extra scalar SU(2)\(_L\) doublet to its field content. In the most general setup the presence of two or more doublets coupling to fermions leads to tree-level flavor changing neutral currents, which require some suppression mechanism for agreement with the highly sensitive experimental data. We impose here a \(Z_2\) symmetry, forcing each type of fermion to couple to one doublet only [43] (see refs. [44–49] for a few alternatives). Our focus will be on models of Type II, where leptons and down-type quarks couple to \(\Phi_1\) while up-type quarks couple to \(\Phi_2\) [50, 51]. If the \(Z_2\)-symmetry is exact, however, the

\(^2\)The impact of turbulence is not yet fully understood, especially the dynamics of its generation from the acoustic waves and the efficiency in converting turbulent movement into GWs. Nevertheless, it is known that turbulence can also remain active long after the phase transition has completed [41].
scalar sector does not break CP, neither explicitly nor spontaneously [52]. We therefore allow for soft breaking of $Z_2$, in which case the most general renormalizable and gauge-invariant potential for two doublets can be written as

$$V_{\text{tree}}(\Phi_1, \Phi_2) = -\mu_1^2\Phi_1^\dagger\Phi_1 - \mu_2^2\Phi_2^\dagger\Phi_2 - \frac{1}{2}\left(\mu^2\Phi_1^\dagger\Phi_2 + \text{H.c.}\right)$$

$$+ \frac{\lambda_1}{2}\left(\Phi_1^\dagger\Phi_1\right)^2 + \frac{\lambda_2}{2}\left(\Phi_2^\dagger\Phi_2\right)^2 + \lambda_3\left(\Phi_1^\dagger\Phi_1\right)\left(\Phi_2^\dagger\Phi_2\right) + \frac{1}{2}\left[\lambda_5\left(\Phi_1^\dagger\Phi_2\right)^2 + \text{H.c.}\right].$$

Note that $\mu^2$ and $\lambda_5$ can be complex, allowing for explicit CP violation in the scalar sector. In this case the VEV of the doublets will also be complex in general, of the form $\langle \Phi \rangle = \mu + i\lambda$. For soft breaking of $Z_2$, the scalar potential for two doublets can be written as [34]

$$\langle \Phi_1 \rangle = \frac{1}{\sqrt{2}}\begin{pmatrix} 0 \\ v \cos \beta \end{pmatrix}, \quad \langle \Phi_2 \rangle = \frac{1}{\sqrt{2}}\begin{pmatrix} 0 \\ v \sin \beta e^{i\theta} \end{pmatrix},$$

with $v \approx 246.22$ GeV. However, only two of these three complex phases are a priori independent [33, 54], since a field redefinition can always be used to set one of them to zero. The two field-redefinition-invariant phases can be written as [34]

$$\delta_1 = \text{Arg}(\mu^2 5^4), \quad \delta_2 = \text{Arg}(v_1 v_2^2 \mu^2 5^5).$$

Moreover, imposing that $V_{\text{tree}}$ have a minimum as in eq. (2.2) yields three equations, two of which enable us to trade $\mu_1^2$ and $\mu_2^2$ for $v$ and $\tan \beta$, and a third constraining $\delta_1$ and $\delta_2$,

$$|\mu|^2 \sin(\delta_1 - \delta_2) = v^2 \sin \beta \cos \beta |\lambda_5| \sin(\delta_1 - 2\delta_2),$$

so that there is ultimately only one free CP violating parameter. Because the CP violating mixing angle between the three neutral scalars must be small due to EDM constraints, it makes sense to speak of two mostly CP-even mass eigenstates, $h^0$ and $H^0$ (with $m_{H^0} \geq m_{h^0}$), and a mostly CP-odd state $A^0$ (see e.g. [33]). A pair of charged scalars $H^\pm$ then completes the scalar spectrum.

We set $m_{h^0} = 125$ GeV, identifying the lightest $h^0$ with the Higgs boson observed at the LHC [55, 56]. A further mixing angle, $\beta - \alpha$, regulates how the properties of $h^0$ relate to those of the SM Higgs $h_{\text{SM}}$: in the CP conserving case, $\beta - \alpha = \pi/2$ corresponds to $h^0 = h_{\text{SM}}$, the so-called alignment limit [57]. When CP is violated, this equality can never hold exactly since $h^0$ is not a pure CP-even state. But because the allowed CP violating mixings are small, it is still legitimate to speak of alignment, at least to a good approximation.

2.1 Brief summary of experimental constraints

Due to the presence of new scalars mediating loop diagrams, oblique corrections to electroweak precision observables in 2HDMs [58, 59] (see also [60]) can be quite sizeable, particularly affecting the $\rho \equiv m_W^2/m_Z^2 \cos^2 \theta_W$ parameter. Enforcing $\rho \approx 1$ leads to an approximate degeneracy between $H^\pm$ and one of the additional neutral scalars, $H^0$ or $A^0$, this being related to the limit when custodial symmetry is approximately recovered [61, 62]. Moreover, flavor observables whose leading-order contribution in the SM comes from 1-loop diagrams are also highly sensitive to the presence of new scalars. In the $Z_2$-symmetric 2HDM the most
important of these are $\bar{B}_d - B_d$ mixing and $\bar{B} \rightarrow X_s \gamma$ transitions \cite{63, 64}. For the latter we use the recent NNLO QCD results from \cite{65, 66}. Remarkably, for Type II this yields the stringent bound $m_{H^\pm} \geq 480$ GeV at 95% C.L.

CP violating phases are tightly constrained by upper bounds on the neutron and electron EDMs. The relevant effective operators are given by \cite{67}

\begin{equation}
\mathcal{L} \supset - \sum \frac{d_f}{2} (i f \sigma_{\mu\nu} \gamma_5 F^{\mu\nu}) - \sum \frac{\tilde{d}_f}{2} (ig_s f \sigma_{\mu\nu} \gamma_5 T^a G^{\mu\nu}) + \frac{d_W}{6} f_{abc} \epsilon^{\mu\nu\rho\sigma} G^{\mu\lambda} G^{\nu\rho\sigma} G^{\mu\lambda},
\end{equation}

with the leading-order contributions to the EDM and chromo-EDM coefficients in 2HDMs, $d_f$ and $\tilde{d}_f$, coming from 2-loop Barr-Zee diagrams, whereas $d_W$ is generated by the 2-loop Weinberg three-gluon operator \cite{68}. Full expressions can be found in refs. \cite{34, 69}. The chromo-EDM and Weinberg operators affect the neutron EDM via the running down to the nuclear scale $\Lambda_{\text{QCD}} \sim 1$ GeV, which we perform using the 1-loop RGEs for the Wilson coefficients \cite{70} and 4-loop QCD running of the strong coupling \cite{71}.

The results are to be compared to the current 90% C.L. limits for the electron and neutron EDM. For an illustration of the impact of the ACME improved measurement, we also show the constraints from the previous bound coming from experiments done with YbF molecules,

\begin{align}
|d_e^{\text{ACME}}| &< 8.7 \times 10^{-29} \text{ e} \cdot \text{cm}, \quad \text{[19]} \quad (2.6) \\
|d_e^{\text{YbF}}| &< 1.06 \times 10^{-27} \text{ e} \cdot \text{cm}, \quad \text{[72]} \quad (2.7) \\
|d_n| &< 2.9 \times 10^{-26} \text{ e} \cdot \text{cm}, \quad \text{[73]} \quad (2.8)
\end{align}

3 Electroweak phase transition and bubble wall velocity

3.1 Electroweak phase transition with a second Higgs doublet

A strong first order EWPT (as precisely defined in section 3.2) typically requires large couplings to the scalar particles, which in 2HDMs translates to sizable splittings among the scalar masses and/or between these masses and the overall (squared) mass scale of the second doublet, $M^2 \equiv \text{Re} (\mu^2)/s_{2\beta}$. Now, in order to avoid the decoupling limit of the second Higgs doublet or instabilities in the scalar potential it is required that $^3 M \sim v$. On the other hand, if $(H^0) \neq 0$ then $m_{H^0}$ is also required to be light in order to avoid a heavy particle getting a VEV and driving the transition, which would tend to reduce its strength, as occurs in the SM. A relatively heavy $H^0$ remains possible in the 2HDM alignment limit, where the phase transition is solely driven by $H^0$. In this context a tuned, degenerate 2HDM spectrum $m_{H^0} \simeq m_{A^0} \simeq m_{H^\pm} \gg M \sim v$ can still yield a strong EWPT.\textsuperscript{4} This scenario has been studied in \cite{25}, and we will not pursue it further here. Still, this highlights that the alignment limit always favours a strong EWPT within the 2HDM, and we will henceforth concentrate on this case for simplicity.

\textsuperscript{3}If $M \gg v$ and the scalar masses are light, some quartic couplings will be large (in absolute value) and negative, causing the scalar potential to be unbounded from below \cite{74, 75}.

\textsuperscript{4}For such a spectrum unitarity and perturbativity require $\tan \beta \simeq 1$, and any significant departure from this value closes the region of a strong EWPT \cite{76}. 

\hspace{1cm} – 5 –
Allowing for sizable splittings among the new scalars significantly enlarges the 2HDM region of parameter space where a strong EWPT is possible [29, 30]. Since electroweak precision observables require $H^\pm$ to pair with one of the neutral scalars, and $H^0$ needs to be light if 2HDM alignment is only approximate (for a strong EWPT to be viable), it follows that $A^0$ is the only scalar which is free to be heavy and induce the required large splittings. Thus, a strong EWPT scenario in 2HDMs generically has a hierarchical spectrum, with $m_{A^0} - m_{H^0} \gtrsim v$ and $M \sim m_{H^0} \sim v$ [29, 30].

Since flavour observables constrain $m_{H^\pm} > 480$ GeV in Type II 2HDM, we choose the pairing $m_{A^0} = m_{H^\pm}$, thus arriving at a benchmark scenario with $M = m_{H^0} = 200$ GeV, $m_{A^0} = m_{H^\pm} \simeq 480$ GeV (2HDM Type II in alignment).

We note that for $1 \leq \tan \beta \leq 5$ the quartic couplings are within the perturbativity bound, with $\max(\lambda_i) \approx 2\pi$, and tree-level unitarity is also satisfied [77–79]. In general, a sufficiently strong first order phase transition requires at least some couplings to be large, such that the theory is expected to become non-perturbative above $\Lambda \sim (\text{few}) \text{ TeV}$. We provide a more thorough discussion on perturbativity in appendix A. We also stress that 2HDM alignment allows for somewhat larger values of $m_{H^0}$ compatible with a strong EWPT, with a similar hierarchical 2HDM spectrum pattern. This hierarchical pattern can in fact be probed at the LHC through $A^0 \to ZH^0$ searches [30], which already constrain our above 2HDM benchmark scenario to $\tan \beta \gtrsim 1.8$ at 95 % C.L. from LHC Run 1 data [80].

3.2 Phase transition strength & bubble wall profile

Since baryogenesis is driven by diffusion processes in front of the bubble wall, we need to compute the temperature $T_n$ at which bubble nucleation actually starts, i.e. at which the probability of nucleating one bubble within the Hubble horizon $H^{-1}$ equals unity [9]. This can be obtained straightforwardly from the nucleation rate per unit volume [81]

$$\Gamma / \mathcal{V} \simeq T^4 e^{-S_3/T},$$

with $S_3$ the 3-dimensional action of the associated critical bubble. The action is computed here using a 1-loop approximation to the effective potential. Once bubbles nucleate, they quickly reach a close to planar steady state, and their profile can then be approximated by an hyperbolic tangent,

$$\begin{pmatrix} h_1(z) \\ h_2(z) \end{pmatrix} = \frac{v_n}{2} \begin{pmatrix} \cos \beta \\ \sin \beta \end{pmatrix} \left[ 1 - \tanh \left( \frac{z}{L_w} \right) \right],$$

(3.2)

where $L_w$ is the wall width and $v_n = \sqrt{h_1^2(T_n) + h_2^2(T_n)}$ is the VEV at the nucleation temperature. The phase transition strength is given by the ratio $v_n / T_n$, and one has a strong first order EWPT when $v_n / T_n \geq 1$. A similar expression to (3.2) holds for the CP violating angle $\theta(z)$ of eq. (2.2), which varies by $\Delta \theta$ along the bubble wall.

The bubble profile is a saddle point of the action $S_3$, and is therefore computed by solving the corresponding equations of motion (EoM) for $h_1(z)$, $h_2(z)$ and $\theta(z)$. While solving this equation is straightforward in a one-dimensional case, for which one can use a simple overshooting-undershooting method, in multi-field cases the problem becomes much more subtle, because one does not know a priori the path along which the shooting is to be performed. Different numerical solutions to this problem have been proposed in the
Figure 1. Phase transition strength (left) and wall thickness (right) as a function of fractional vacuum energy released in the plasma at nucleation temperature $T_n$ for the simplified toy model (dashed line), the corresponding 2HDM with $M = m_h/\sqrt{2}$, $\tan \beta = 1$ and degenerate masses (green solid line) and the hierarchical case considered throughout this work (blue solid line). Also shown are the wall velocities for the toy model (dot-dashed line).

literature [82–85]. Here we take a two-stepped approach inspired by [85]. First, a one-dimensional shooting is performed along the path of the valley connecting both minima of the scalar potential. The resulting profile is then used as a first approximation to the full solution, allowing us to linearize the right hand side of the EoMs by Taylor expanding $\nabla V$.

The discretized version of the EoMs then becomes a linear system of equations, which can be solved by simple (and computationally cheap) matrix inversion. We have verified that the solution obtained from this method does satisfy the EoMs. In fact, the first step alone provides a very good approximation to the profile parameters.

A top quark penetrating the bubble wall from the symmetric phase acquires a mass

$$m_t(z) = \frac{y_t h_2(z)}{\sqrt{2}} e^{-i \Theta_t(z)},$$

(3.3)

and therefore feels the bubble wall as a potential barrier. In the semiclassical approximation, the complex phase $\Theta_t$ leads to different dispersion relations for tops and anti-tops, which ultimately induces a non-zero chemical potential for left-handed baryons, $\mu_{B_L}$ [86]. The complex phases $\Theta_t$ and $\theta$ are related by [20, 26, 87]

$$\partial_\mu \Theta_t = -\frac{h_2^2(z)}{h_1^2(z) + h_2^2(z)} \partial_\mu \theta.$$  (3.4)

Note that due to this relation, which yields $\Delta \Theta_t = -\Delta \theta/(1 + \tan^2 \beta)$, there is a suppression for $\tan \beta \gg 1$.

The above discussion highlights that the relevant input for the baryon asymmetry computation is the shape of the bubble profile, i.e. the wall thickness $L_w$, the phase transition strength $v_n/T_n$, and the total change in the top-quark’s CP violating phase, $\Delta \Theta_t$. In principle there is also a dependence on the wall velocity $v_w$, expected to be mild as long as the wall remains subsonic [25].

3.3 Bubble wall velocity

To estimate $v_w$ we consider a simplified model with four scalars acquiring masses from their coupling to a SM-like Higgs according to $m_s = \frac{\lambda (h^0)}{\sqrt{2}}$. This is equivalent to an aligned
2HDM with $M = m_h/\sqrt{2}$ and $\tan \beta = 1$, neglecting the self-interactions of the additional scalars. This latter simplification, together with the fact that the phase transition dynamics in this toy model involves only one scalar field, allows for a more straightforward solution of the EoMs for the scalar field, as is necessary to determine the wall velocity. The friction induced by the fluid is modelled by a single friction parameter, $\eta$, following [88]. In a first step, this parameter is determined at the runaway point [89, 90], corresponding to $\lambda = 2.29$. It is then extrapolated to weaker transitions by applying the scaling $\eta \sim \exp(-\sqrt{v/T})$ found in [88]. By construction, this procedure correctly reproduces bubble runaway, and leads to a reliable determination of the deflagration/detonation boundary, which is crucial for successful baryogenesis. We show in figure 1 a comparison of the relevant phase transition parameters, namely $v_n/T_n$, $L_w T_n$ and the fraction of vacuum energy density released in the phase transition in terms of radiation energy in the plasma [90],

$$\alpha_n \equiv \frac{\rho_{\text{vac}}}{\rho_{\text{rad}}}$$

for the toy model, the corresponding 2HDM with $M = m_h/\sqrt{2}$, and the hierarchical case considered in the rest of the paper. The parameter $\alpha_n$, which will be key for the computation of the GW spectrum from the EWPT, can also be seen as a measure of the phase transition strength: the stronger the transition, the more energy is released into the plasma, leading to greater $\alpha_n$. Also shown in figure 1 are the values of the wall velocity for the toy model, which show that bubble walls remain subsonic even for very strong transitions, $v_n/T_n \sim 4.0$ and $\alpha_n \sim 0.15$. This is the key feature allowing for simultaneous baryogenesis and a detectable stochastic GW signal from the EWPT in the 2HDM. The good agreement between the shape of the bubble profile in the toy model and in the 2HDM, together with the fact that both have the same number of degrees of freedom in the plasma with similar couplings, indicates that these values of $v_w$ can also be trusted as estimates for the wall velocity in the hierarchical 2HDM considered here.

## 4 Baryogenesis

To compute the baryon asymmetry we use the fluid approximation for the particle distribution functions, with the chemical potential and the fluid velocity as free-parameters. The corresponding linearized Boltzmann equations are then solved for the top, anti-top and bottom quarks, the other particles constituting the background [91]. The source of displacement from thermal equilibrium as well as of CP violation is the bubble profile, i.e. the parameters $v_n/T_n$, $L_w$ and $\Delta \Theta_t$. As discussed in section 3.2, the asymmetric transport of tops and anti-tops along the bubble wall leads to an excess of handedness in front of the wall, represented by a non-vanishing chemical potential, $\mu_{BL}$, for left-handed baryons, to be converted into a baryon asymmetry by the sphalerons (see [92] for more details).

The values of the relevant phase transition parameters entering the computation of the baryon asymmetry are shown in table 1, for varying pseudoscalar masses $m_{A^0}$ within the hierarchical benchmark discussed in section 3. Notice that for $m_{A^0} \gtrsim 480\text{ GeV}$ the phase transition is very strong, leading to very thin bubble walls, $L_w T_n \sim 1.5$. This may be problematic for the computation of the baryon asymmetry, since the formalism of top transport is based on a gradient expansion of the Kadanoff-Baym equations\(^5\) [93, 94] with a semi-classical approximation.

\(^5\)The transport equations are obtained from a gradient expansion of the diamond operator $\sim (\partial_k \cdot \partial_n)/2$, so the expansion parameter is $1/(2L_w T)$. 

---

---
Table 1. Phase transition parameters relevant for computing the resulting baryon asymmetry (section 4) and the gravitational wave spectrum (section 5), for various pseudoscalar masses $m_{A^0}$ in the hierarchical scenario presented in section 3. The values are given for fixed $\tan \beta = 2$, but only $\Delta \Theta_t$ is sensitive to $\tan \beta$ according to 3.4.

| $m_{A^0}$ [GeV] | $T_n$   | $v_n/T_n$ | $L_w T_n$ | $\Delta \Theta_t$ | $\alpha_n$ | $\beta/H_s$ | $v_w$ |

From $T_n \gg 1/L_w$ [95–97]. To account for possible deviations due to our approaching the extreme bound of validity of these approximations, we assume that the unforeseen effects lead to an overestimate of the BAU by a factor $\sim 2$. We note that for our kind of BSM scenario the final BAU has been shown to scale approximately as $L_w^{-1}$, down to very low values $L_w T_c \sim 2$ [92].

Moreover, the analysis of the BAU does not depend on the precise spectrum of the new scalars in the theory, so this scaling can be directly applied to the specific scenario under consideration. Then, we expect the final BAU to approximately scale as $\eta \sim (v_n/T_n)^4 L_w^{-1}$, so that by far the most important enhancement comes from the large values of $v_n/T_n$ rather than from small wall widths.

Figure 2 shows the minimum value of the complex phase $\delta_1 - \delta_2$ for which $\eta_{TB}/\eta_{\text{obs}} = 1$ as a function of $\tan \beta$, for $M = m_{H}\_0 = 200$ GeV and several values of $m_{A^0} = m_{H^\pm}$ within the range [450, 490] GeV, corresponding to the hierarchical 2HDM benchmark scenario presented in section 3. As expected, large values of $\tan \beta$ suppress the generation of the BAU due to eq. (3.4), whose effect has to be compensated by a larger value of $\delta_1 - \delta_2$ to keep $\eta_{TB}/\eta_{\text{obs}} = 1$. The impact of the recent order-of-magnitude improvement on the electron EDM bound from the ACME experiment is highlighted in figure 2 by showing also the exclusion curve (dotted-dashed blue) from the previous eEDM limit. We note that while the neutron-EDM was a competing bound before, the improvement from the ACME experiment now makes the eEDM to provide the dominant constraint by far. Also shown in figure 2 are the excluded regions from $\bar{B}_d - B_d$ mixing, corresponding to $\tan \beta \lesssim 1.16$, and from CMS searches for $A^0 \to Z H^0$ with LHC 8 TeV data [80], corresponding (for $m_{A^0} = 480$ GeV) to $\tan \beta \lesssim 1.8$. For $m_{A^0} \approx 480$ GeV there remains then an allowed window $1.8 \lesssim \tan \beta \lesssim 2.5$ for which the correct BAU could still be obtained in this scenario. In figure 2 we also present for illustration the results for $m_{A^0} < 480$ GeV, potentially excluded by the $\bar{B} \to X_s \gamma$ flavour

---

6 Note that the relevant velocity for baryogenesis is not really $v_w$, but the relative velocity between the bubble wall and the plasma in the deflagration front. The latter may be significantly smaller than $v_w$ [98] in our scenario, yielding a more robust velocity expansion.

7 While the CP-violating source scales as $1/L_w^2$, it also depends on $\bar{z}/L_w$ ($\bar{z}$ being the spatial coordinate upon which the source is integrated over, accounting for the fact that the source gets broader for larger wall thickness), which yields an explicit $1/L_w$ dependence of the BAU, only modified by the inclusion of the diffusion length. In our scenario we find this yields only a slight departure of the $L_w^{-1}$ dependence for very small $L_w T_n$ (see [92]).
Figure 2. EDM constraints for benchmarks described in text. The dash-dotted line corresponds to the eEDM bound before the ACME experiment. The black dashed lines correspond to the minimum CPV phase necessary for successful baryogenesis for $M = m_{H^0} = 200$ GeV and varying $m_{A^0} = m_{H^\pm}$.

bound. The values of the wall thickness in this case are somewhat larger, $L_w T_n \sim 2.5 - 3$, and we can be more confident about the validity of the gradient expansion (nevertheless the curves shown in figure 2 all take into account the conservative BAU factor $\sim 2$, discussed above, for consistency). However, for these values of $m_{A^0}$ the bounds from CMS searches are even more stringent, excluding $\tan \beta \lesssim 1.93$, while the eEDM upper bound on $\tan \beta$ is also stronger (as a result of a weaker EWPT), altogether closing the baryogenesis window for these masses.

The discussion above emphasizes that, while baryogenesis is still possible within the 2HDM, quite strong phase transitions are required. Indeed, one expects the final asymmetry to be roughly proportional to $(v_n / T_n)^4$, so a boost in the phase transition strength helps reduce the required CPV phase and thus bypass the tight EDM constraints. In fact we can say that the usual bound for avoiding sphaleron washout in the broken phase, $v_n / T_n \gtrsim 1.0$, turns out being too mild, since EDM constraints alone require significantly stronger transitions if baryogenesis is to be successful. It is worth emphasizing, however, that the phase transition can only be made stronger at the cost of larger couplings, and one has to be careful not to put at risk the validity of the 1-loop expansion of the effective potential on which these results are based.

Before continuing, let us comment on the fact that similar results could have been obtained for an overall mildly heavier spectrum at the cost of tuning. As an example, for $M = m_{H^0} = 300$ GeV and $m_{A^0} = m_{H^\pm} \approx 555$ GeV one obtains $v_n / T_n = 4.513$, $L_w T_n = 1.625$, $\alpha_n = 0.159$ and $\beta / H_* = 662.85$, values all similar to those of our previously considered benchmark with $M = m_{H^0} = 200$ GeV and $m_{A^0} = m_{H^\pm} \approx 483$ GeV. While the eEDM

---

8This is the case for $m_{A^0} = m_{H^\pm}$. We however note that a small positive mass splitting $m_{H^\pm} - m_{A^0}$ is allowed by electroweak precision observables, such as to make the scenario $m_{A^0} \lesssim 480$ GeV potentially compatible with both constraints.
constraints are hardly affected by this amount of uplifting of the scalar spectrum, bounds from CMS $A^0 \to Z H^0$ searches get significantly weakened, being currently insensitive to such heavier spectrum. Note, however, that an increase in $M = m_{H^0}$ tends to weaken the phase transition, and has to be compensated by larger couplings, thus leading to larger values of $\beta/H_*$. As discussed in the next section, even stronger transitions would then be required in order to bring this parameter down to the point where the GW spectrum would be observable at LISA, which in turn would lead to faster walls, thus harming baryogenesis.

Finally, we stress that in the 2HDM of Type II considered here the Barr-Zee diagrams mediated by top and $W^\pm$ loops interfere destructively, with an optimal cancellation for $\tan \beta \sim 1$ [27, 33, 34], leading to milder eEDM constraints in this region as manifestly seen in figure 2. This cancellation does not take place in Type I 2HDM, where the EDM bounds are more severe for low $\tan \beta$, precisely where baryogenesis is optimal. This shows that accommodating successful baryogenesis in Type I 2HDMs is more challenging.

5 Gravitational wave spectrum

While baryogenesis takes place during the period of bubble expansion, gravitational waves start getting sourced at the end of the phase transition, when the bubbles collide and overlap. One such source is the uncolliding expanding envelopes of scalar field bubbles, since the bubbles’ spherical symmetry is broken by their partial overlap. For thermal phase transitions, such as the one we are considering here, where the bubble wall has reached a constant velocity long before the bubbles collide, the scalar field contribution is tiny and can be completely ignored. Practically the entire energy released by the transition goes into the plasma, as heat and fluid motion. As numerical simulations show [40], the collision of bubbles produces fluid perturbations mostly in the form of sound waves in the plasma, which act as a long lived, powerful source of gravitational waves, until they are switched off by the Hubble expansion. For sufficiently strong transitions one also expects that the sound waves turn into a stage of turbulence before a Hubble time [99, 100], with the turbulent fluid also acting as a GW source [41].

The amplitude of the GW spectrum depends crucially on the amount of energy released in the phase transition and available to be converted into GWs, i.e. the $\alpha$ parameter in eq. (3.5). Another important quantity is the (approximate) inverse duration of the phase transition, $\beta$, given in terms of the Hubble rate by

$$\frac{\beta}{H_*} = T_* \frac{d(S_3/T)}{dT} \bigg|_{T_*},$$

where $T_* \approx T_n$ is the finalisation temperature at which the phase transition completes.\footnote{More precisely, we find that typically $T_f \approx 0.96 T_n$, leading to an approximate 75% difference in $\beta/H$. However, using the finalisation temperature actually leads to an overestimate of the average bubble radius during collision and consequently of the GW spectrum. We therefore choose to adopt a conservative approach and compute the spectrum at $T_n$.}

Typically, for an electroweak phase transition $\beta/H_* \sim \mathcal{O}(100 - 1000)$. If $\beta$ is large, the bubble nucleation rate increases rapidly with the temperature, and the true vacuum then fills the entire space due to bubble nucleation at various different regions. On the other hand, a small $\beta$ means that the nucleation rate remains approximately constant for the duration of the phase transition, and space is filled by the expansion of the bubbles nucleated at $T_n$. In fact, the bubble radius during collision is $R_* \sim v_w/\beta$, and since GWs are sourced by the...
energy in the moving walls and the accompanying fluid motion, a large signal demands small values of $\beta$.

Because we are focused on deflagrating bubbles, the main source in our case are the sound waves accompanying bubble expansion and collision [39, 40]. This is because the fluid continues to oscillate and source GWs even after the transition has completed, leading to an amplitude enhancement by a factor $\mathcal{O}(\frac{\beta}{v_T}) \sim 100 - 1000$ as compared to the spectrum obtained with the envelope approximation. A thorough analytic treatment of this case is still lacking (see however [100]), but numerical simulations indicate that the amplitude of the spectrum and its peak frequency can be written as [99]  

$$ h^2 \Omega_{sw} \simeq 2.65 \times 10^{-6} \frac{1}{v_w} \left( \frac{H_*}{\beta} \right) \left( \frac{\kappa_v \alpha}{1 + \alpha} \right)^2 \left( \frac{100}{g_*} \right)^{\frac{1}{4}}, \quad (5.2) $$

$$ f_{sw} \simeq 1.9 \times 10^{-2} \text{mHz} \left( \frac{\beta}{v_H} \right) \left( \frac{T}{100 \text{ GeV}} \right) \left( \frac{g_*}{100} \right)^{\frac{1}{5}}. \quad (5.3) $$

Here $\kappa_v$ is the efficiency in converting the released vacuum energy into bulk motion of the fluid, which can be found in ref. [90] and $g_* \approx 106.75$ is the number of relativistic degrees of freedom in the plasma.

We show in figure 3 the GW spectrum generated by our benchmark scenario with varying values for $m_{A^0} = m_{H^\pm}$, with the values of the parameters relevant for obtaining

Figure 3. Gravitational wave spectrum for differing values of $m_{A^0} = m_{H^\pm}$. The solid colored lines are the prospective sensitivity for different LISA configurations (see the text and ref. [99] for more details).

\footnote{Note that shock waves are expected to develop at a time scale $\tau_{sh} \sim \frac{1}{v_T} \sqrt{\frac{\kappa_v \alpha}{1 + \alpha}}$ [99, 100], which in our case is not necessarily much larger than the lifetime of the acoustic source, $\tau_{sw} \sim H_*^{-1}$ [40], so their effects (including some conversion of acoustic energy into vorticity) would have to be taken into account. However, the dynamics of turbulence generation from sound waves is still poorly understood, and it is difficult to estimate the impact of this effect on the results presented here. We will proceed with the linear sound wave approximation, keeping in mind that more work is needed to fully understand the GW spectrum generated from very strong phase transitions such as the ones considered here.}
the peak amplitude (5.2) and frequency (5.3) given in table 1. Figure 3 also shows the prospective sensitivity for different LISA configurations [99, 101]. The LISA Pathfinder mission has successfully established the noise levels expected for the full experiment (N2), and the configuration with three arms (six links, L6) has already been fixed. Thus, the remaining free parameters to be determined are the arm lengths (between 1–5 MKm, A1–A5) and the duration of the mission, which we set at 5 years (M5). For illustrative purposes we also include the sensitivity curve for two arms (four links, L4) with 2 MKm length each (A2). Our results are in the same range as those found e.g. in refs. [102, 103] for various other models, provided the phase transition is quite strong, as also in our case.

It is interesting to note that the values for $\beta/H_*$ obtained in the 2HDM are significantly larger (for comparable values of $\alpha$) than those usually found in other models considered in the GW literature [99, 104]. This is because $\beta/H_*$ is essentially determined by the temperature dependence of the effective potential, which increases with the number of degrees of freedom present in the plasma, as well as with the strength of their couplings. Indeed, the hierarchical 2HDM considered here involves relatively strong couplings, with the mean field contribution to the thermal potential leading to thermal Higgs masses $m_{T^2}/T^2 \sim \frac{\lambda^3}{4} \simeq \frac{2\pi}{3}$, larger than in weakly coupled scenarios such as supersymmetric extensions.

Finally, we stress that there is some degree of tuning in the results for the GW spectrum, regarding the detectability by LISA. For $m_{A^0} = 480$ GeV the spectrum is still outside the detectability range of even the most powerful prospective LISA configuration; for $m_{A^0} = 487$ GeV the walls are already supersonic and no baryogenesis would be possible; and for $m_{A^0} \gtrsim 492$ GeV the symmetric vacuum is metastable and no electroweak symmetry breaking takes place.

6 Conclusions

We have argued for the possibility that a first order electroweak phase transition could yield the observed baryon asymmetry of the Universe and, at the same time, generate a gravitational wave spectrum observable at LISA. This may be seen as a “proof of principle” for the compatibility of both phenomena, which can coexist for rather strong transitions with relatively slow expanding bubbles, as occurs in 2HDM scenarios. We emphasize that the recent improvements in our understanding of GWs sourced by acoustic waves as well as of the prospective LISA sensitivity were vital for the results presented here. In particular, although the amplitude enhancement by a factor $O(\beta/H_*)$ coming from long-lasting sources of GWs has been known for a while [41], a reliable estimate of the dependence of the spectrum with the phase transition parameters and the wall velocity, given in (5.2), could only be achieved with very recent data from extensive numerical simulations [40]. First steps towards an analytic understanding of the problem have been made in [100], but further investigation on the shape of the spectrum is granted, especially for very strong phase transitions.

We have also shown that 2HDMs remain viable candidates for explaining the baryon asymmetry of the Universe, even after the recent stringent bound on the electron EDM by the ACME collaboration. Our findings indicate that very strong phase transitions are necessary in order to sufficiently boost the final asymmetry and avoid such constraints, namely $v_n/T_n \gtrsim 4.0$ (evaluated at the nucleation temperature). A key feature of 2HDMs, allowing for the results obtained in this work, is that even in these cases the bubble wall can be subsonic. We also note that these very strong transitions lead to very thin bubble walls, $L_w T_n \sim 1.5$, which is borderline in terms of validity of the semi-classical approximation used in the transport
equations. We have assumed that these effects could lead to an enhancement in the final asymmetry up to a factor $\sim 2$. Still, for the BSM scenario under consideration the final BAU has been shown to approximately scale as $\eta \sim (v_n/T_n)^2 L_w^{-1}$ [92] down to values $L_w T_c \sim 2$, so that by far the most important enhancement comes from the large values of $v_n/T_n$. Finally, it is perhaps most important to note that the experimental constraints on these scenarios are severe, and a significant future increase in the sensitivity of LHC $A^0 \to ZH^0$ searches and/or another order-of-magnitude improvement of the eEDM bound will decisively test the 2HDM in so far as baryogenesis is concerned.

Acknowledgments

We like to thank MIAPP for hospitality and an inspiring atmosphere, where this work started, and we thank Germano Nardini and Kimmo Kainulainen for insightful discussions. Note added: while this paper was being prepared for publication, a similar work appeared in the literature claiming the viability of having baryogenesis with a detectable gravitational wave spectrum in the context of a singlet extension [105]. We note that the way friction is modelled in that work does not seem to lead to a consistent implementation of the runaway phenomenon, thus casting doubt on whether it will lead to a reliable determination of the deflagration/detonation boundary, as is crucial for baryogenesis.

A Perturbativity and running couplings

In this appendix we briefly discuss the robustness of the perturbative expansion used in our analysis by investigating the behaviour of the running couplings. Defining $\mathcal{D} \equiv 16\pi^2 \frac{d}{d[\log M]}$, the full 1-loop RGEs for a $Z_2$ symmetric 2HDM read [51]

\begin{align}
\mathcal{D}g_s &= -7g_3^3, & \mathcal{D}g &= -3g^3, & \mathcal{D}g' &= 7g'^3, \\
\mathcal{D}\lambda_i &= \left( \frac{9}{2}\lambda_i^2 - 8g_3^2 - \frac{9}{4}g^2 - \frac{17}{12}g'^2 \right) \lambda_i, \quad (A.2) \\
\mathcal{D}\lambda_1 &= 12\lambda_1^2 + 4\lambda_2^2 + 4\lambda_3\lambda_4 + 2\lambda_4^2 + 2|\lambda_5|^2 + \frac{3}{4}(3g^4 + g'^4 + 2g^2g'^2) - 3\lambda_1(3g^2 + g'^2), \\
\mathcal{D}\lambda_2 &= 12\lambda_2^2 + 4\lambda_3^2 + 4\lambda_3\lambda_4 + 2\lambda_4^2 + 2|\lambda_5|^2 + \frac{3}{4}(3g^4 + g'^4 + 2g^2g'^2) - 3\lambda_2(3g^2 + g'^2 - 4\lambda_1^2) - 12\lambda_1, \quad (A.3) \\
\mathcal{D}\lambda_3 &= (\lambda_1 + \lambda_2)(6\lambda_3 + 2\lambda_4) + 4\lambda_3^2 + 2\lambda_4^2 + 2|\lambda_5|^2 + \frac{3}{4}(3g^4 + g'^4 - 2g^2g'^2) - 3\lambda_3(3g^2 + g'^2 - 2\lambda_1^2), \\
\mathcal{D}\lambda_4 &= 2(\lambda_1 + \lambda_2)\lambda_4 + 8\lambda_3\lambda_4 + 4\lambda_3^2 + 8|\lambda_5|^2 + 3g^2g'^2 - 3\lambda_4(3g^2 + g'^2 - 2\lambda_1^2), \\
\mathcal{D}\lambda_5 &= (2\lambda_1 + 2\lambda_2 + 8\lambda_3 + 12\lambda_4)\lambda_5 - 3\lambda_5(3g^2 + g'^2 - 2\lambda_1^2). \quad (A.5)
\end{align}
where $g_s, g$ and $g'$ are respectively the SU(3)$_c$, SU(2)$_L$ and U(1)$_Y$ couplings, and $m_t \equiv \lambda_t v/\sqrt{2}$ defines the top Yukawa coupling. The full 2-loop RGEs can be found in ref. [106].

Our analysis here will focus on the benchmark $M = m_{H^0} = 200$ GeV and $m_{A^0} = m_{H^\pm} = 487$ GeV, which yields the largest couplings of all cases considered in this work, namely

$$\lambda_1 = \lambda_2 \simeq 0.2578, \quad \lambda_3 \simeq 6.762, \quad \lambda_4 = \lambda_5 \simeq -3.252. \quad (A.8)$$

We run the couplings starting both from $m_{H^0} = 200$ GeV and $m_{A^0}$. In the former case, the heavier scalars contribute to the running even below their threshold, so the result is more stringent than what one would obtain by properly decoupling and taking threshold effects into account, which is beyond the scope of the present work. The exact 1- and 2-loop running will be closer to the case $\mu_0 = m_{A^0}$, simply due to our choice $m_{H^\pm} = m_{A^0}$, which yields three new heavy and only one light d.o.f. The results are presented in figure 4. Black lines correspond to $\mu_0 = m_{A^0}$ and red lines to $\mu_0 = m_{H^0}$. The dot-dashed line corresponds to the scale at which the 1-loop running couplings grow larger than $4\pi$, whereas the dashed lines show this same scale obtained with the 2-loop RGEs. We stress that this scale merely indicates the point at which the theory enters a strongly coupled regime. The scale which indicates the complete breakdown of the theory, when it ceases to be a good EFT, is rather indicated by the Landau pole, which is plotted in solid lines for the 1-loop running. In the worst case scenario, for the parameters considered in this work the 1-loop running couplings become non-perturbative for $\Lambda \gtrsim 3 - 4$ TeV. Moreover, comparison of the dashed and dot-dashed curves shows that 2-loop contributions tend to soften the running, so the actual Landau pole is still at higher scales.
