The Ising and $q$-Potts models

Spin configuration $\sigma : V \rightarrow \{1, \ldots, q\}$. For $q = 2$, usually $\{-1, +1\}$.

Hamiltonian: $H(\sigma) := \sum_{(x,y) \in E(G)} \mathbb{1}_{\{\sigma(x) \neq \sigma(y)\}}$.

For $\beta = 1/T \geq 0$ inverse temperature, Gibbs measure on configurations agreeing with some given boundary configuration $\xi$ on $\partial V \subset V$:

$$P_\beta^\xi[\sigma] := \frac{\exp(-\beta H(\sigma))}{Z_\beta^\xi}, \text{ where } Z_\beta^\xi := \sum_{\sigma : \sigma|_{\partial V} = \xi} \exp(-\beta H(\sigma)).$$

This $Z_\beta$ is called the partition function.

Sometimes external field, favoring one kind of spin.

But it’s more interesting to vary $\beta$: decay of correlations? Effect of $\xi$?
The critical temperature of Ising

\[ \beta_c(\mathbb{Z}^2) = \ln(1 + \sqrt{2}) \approx 0.881374. \]

Onsager also showed that

\[ \mathbb{E}^{\xi}_{\beta_c}[\sigma(0)] = n^{-1/8 + o(1)} \text{ for } \xi = +1_{\partial B_n(0)}. \]
The random cluster model $\text{FK}(p, q)$

Fortuin-Kasteleyn (1969): for $\omega \in \{0, 1\}^{E(G)}$ and $\xi \in \{0, 1\}^{\partial E(G)}$ for $\partial E(G) \subset E(G)$,

$$P_{\text{FK}(p, q)}^\xi[\omega] = \frac{p|\omega|(1 - p)|E(G)\setminus\omega|q^{\text{clusters}(\omega)}}{Z_{\text{FK}(p, q)}}.$$

$q = 1$: Bernoulli($p$) bond percolation. $q \to 0$, then $p \to 0$: UST

For $q \in \{2, 3, \ldots\}$, Edwards-Sokal coupling: color each cluster independently with one of $q$ colors, then forget $\omega$: get $q$-Potts, with $\beta = \beta(p) = -\ln(1 - p)$. Partition functions are equal: $Z_{\text{FK}(p, q)} = Z_{\beta(p), q}$.

Therefore, $\text{Correl}_{\beta, q}[\sigma(x), \sigma(y)] = P_{\text{FK}(p, q)}^\xi[x \leftrightarrow y]$!

If $q \geq 1$, then increasing events are positively correlated: FKG-inequality.

For $q < 1$, there should be negative correlations, proved only for UST, which is a determinantal process.
Critical spin-Ising and FK-Ising on $\mathbb{Z}^2$

Fermonic observables, conformal invariance, convergence to SLE$_3$, SLE$_{16/3}$: Smirnov ’06, ’10, Chelkak-Smirnov ’10, Kemppainen-Smirnov ’11, etc.

FK-Ising RSW estimates for rectangles by Duminil-Copin-Hongler-Nolin ‘10.

Separation of interfaces, quasi-multiplicativity of arm probabilities, pivotal exponents by Duminil-Copin & Garban ‘12?:

$$\alpha_{FK}^{(2)}(n) = n^{-35/24 + o(1)} \quad \text{and} \quad \alpha_{Ising}^{(4)}(n) = n^{-21/8 + o(1)}.$$
The FK\((p, q)\) heat-bath dynamics

I.i.d. Poisson clocks on edges. Not quite local stationary dynamics:

\[
P^G_{p,q}[e \text{ is on } | \omega \text{ on } G \setminus \{e\}] = \begin{cases} 
p & \text{if } \{x \leftrightarrow y\} \text{ in } G \setminus \{e\} \text{ and } \omega(x) = \omega(y) = 1 \\
\frac{p}{p+(1-p)q} & \text{otherwise.}
\end{cases}
\]

Open problem. Does this make sense on infinite \(\mathbb{Z}^2\)? (Information leaking from infinity?) Limits of dynamics on finite boxes do exist (using monotonicity, Grimmett 1995), but they are non-Fellerian processes. Are they given by these local transition rules?
The near-critical ensemble in $\text{FK}(p, q)$

Want a monotone coupling as $p$ varies, i.e., random $Z \in [0, 1]^{E(G)}$ labeling such that $Z_{\leq p} \subset E(G)$ is FK$(p, q)$, preferably Markov in $p$. Asymmetric heat-bath is not good. Instead, Grimmett '95: define a Markov chain $Z_t$ on labelings with the right stationary measure.

Set $T_e(Z) := \inf \{p : \text{endpoints of } e \text{ are connected in } Z_{\leq p} \setminus \{e\}\}$.

If $e$ rings at time $t$, then, to get the right conditional distribution on $e$ in $Z_{\leq p}$, need

$$P[Z_t(e) \leq p] = \begin{cases} p & \text{if } p \geq T_e(Z_{t-}) \\ \frac{p}{p+(1-p)q} & \text{if } p < T_e(Z_{t-}) \end{cases}.$$

We can get this simultaneously for all $p$ by defining this update rule for $Z_t(e)$. Makes sense if $q \geq 1$. Note Dirac point mass at $T_e(Z_{t-})$.

First difference from asymmetric heat-bath: from specific heat (variance of energy) computation on $\mathbb{Z}^2$, density of edges in $Z_{\leq pc+\epsilon} \setminus Z_{\leq pc}$ is not $\asymp \epsilon$, but $\epsilon \log(1/\epsilon)$ for $q = 2$, and polynomial blowup for $q > 2$. 
Onsager vs pivotal

From Onsager ‘44 magnetization results: \( P_{\mathbb{Z}^2, 2}^{\mathbb{Z}_2} [0 \longleftrightarrow R] = R^{-1/8 + o(1)} \)
and \( P_{\mathbb{Z}^2, 2}^{\mathbb{Z}_2 + \epsilon, 2} [0 \longleftrightarrow \infty] = \epsilon^{1/8 + o(1)} \). This gives a correlation length \( \epsilon^{1+o(1)} \). But DC & G computed \( 1/(2 - \xi_4) = 24/13 \), which is much larger!

Hence, correlation length is not given by amount of pivotal at criticality. Stability in near-critical window fails, the changes are faster. How come?

Conclusion: Any monotone coupling is very different from asymmetric heat bath. When raising \( p \) in the monotone coupling, open bonds do not arrive in a uniform, Poissonian way, but with self-organization, to create more pivotal and build long connections. Would contradict Markov property in \( p \), unless there are clouds of open bonds appearing together.

We don’t understand geometry of clouds, but at least can see directly that they are happening, due to the Dirac mass in the update rule. Intuitively: good to open many edges together, without lowering number of clusters.
Computing the correlation length

Smirnov's fermonic observable $F = F_p$ for any medial edge $e \in E_\diamond$:

$$F(e) := \mathbb{E}_{p,2}^{G,a,b} \left( e^{iW_\gamma(e,e_b)} 1_{e \in \gamma} \right),$$

where $\gamma$ is the exploration interface from $a$ to $b$, and $W_\gamma$ is the winding.
**Relation to connectivity:** if \( u \in G \) is a site next to the free arc, and \( e \) is the appropriate medial edge next to it, then \(|F(e)| = P_{p,2}^{G,a,b}(u \leftrightarrow \text{wired arc})\).

**Massive harmonicity (Beffara-Duminil-Copin):** if \( X \) has four neighbors in \( G \setminus \partial G \), then \( \Delta_p F(e_X) = 0 \), where the operator \( \Delta_p \) is

\[
\Delta_p g(e_X) := \frac{\cos[2\alpha]}{4} \left( \sum_{Y \sim X} g(e_Y) \right) - g(e_X),
\]

with some \( \alpha = \alpha(p) \), equalling 0 iff \( p = p_c \).

**Complicated boundary conditions.** But, at \( p_c \), \( H(e^+) - H(e^-) := |F(e)|^2 \), this \( H \) approximately solves a discrete Dirichlet boundary problem, hence \( P_{p_c,2}^{G,a,b}(u \leftrightarrow \text{wired arc}) \simeq (\text{harmonic measure of wired arc seen from } u)^{1/2} \), and can compute that crossing probabilities are between 0 and 1.

At \( p \neq p_c \), need harmonic measure w.r.t. massive random walk, killing particle at each step with probability depending on \( \cos(2\alpha) \), roughly \( |p - p_c|^2 \).

\(|p - p_c| < \frac{c}{n}\): during the roughly \( n^2 \) steps to boundary, particles dies with probability bounded away from 1, so everything is roughly the same.
