We perform extensive MD simulations of two-dimensional systems of hard disks, focusing on the on-collision statistical properties. We analyze the distribution functions of velocity, free flight time and free path length for packing fractions ranging from the fluid to the solid phase. The behaviors of the mean free flight time and path length between subsequent collisions are found to drastically change in the coexistence phase. We show that single particle dynamical properties behave analogously in collisional and continuous time representations, exhibiting apparent crossovers between the fluid and the solid phase. We find that, both in collisional and continuous time representation, the mean square displacement, velocity autocorrelation functions, intermediate scattering functions and self part of the van Hove function (propagator), closely reproduce the same behavior exhibited by the corresponding quantities in granular media, colloids and supercooled liquids close to the glass or jamming transition.

I. INTRODUCTION

A system of two-dimensional (2D) hard disks is one of the simplest models of a classical fluid. Despite the apparent simplicity, the transport properties and the nature of the phase transitions remain areas of active investigation ever since the pioneering work of Alder and Wainwright [1] some 50 years ago. The appearance of slow power-law decaying tails in the velocity autocorrelation function for moderately dense systems has deeply changed the classical understanding and the ensuing formulation of the kinetic theory (see for instance Refs. [2, 3]). Moreover, controversy about the nature of the fluid-solid transition occurring at higher densities has persistently involved generations of scientists, debating on whether its best representation is the Kosterlitz-Thouless-Halperin-Nelson-Young scenario [4, 5], or a first order transition [6, 7]. This debate seems to have only recently arrived to a conclusion thanks to the initial massive use of event-chain Monte Carlo algorithm [8], and by later adopting local Monte Carlo algorithm and event-driven molecular dynamics simulations [9].

A system may be followed via an external clock represented by continuous time $t$, or an internal clock associated with the number of collisions $n$ of each particle. The continuous time representation is said to be subordinated to the underlying collisional process [10]. Though the system is clearly characterized by collision events, a systematic analysis of this system in collisional representation, spanning from the fluid to the solid phase, is missing. To the best of our knowledge the only analytic and numerical studies in this sense concern the non-Poissonian nature of the number of collisions within a certain time interval in the dilute limit [11, 12]. In what follows we study statistical and dynamical properties of a 2D system of hard-disks in collisional representation, with packing fractions ranging from the fluid to the solid regimes.

The first part of our analysis focuses on the statistics of on-collision velocity, free flight time $\tau$ and the path undergone by a disk between subsequent collisions, the free path length $\langle |\xi| \rangle$. Within this context we study correlations between the $x$ and $y$ components of the velocity, and the dependence of free flight times on the on-collision velocities in systems with various packing fractions spanning from the fluid to the solid phase. We also compare our findings to the kinetic approach and Enskog theory, reporting inconsistencies even in the fluid phase. Furthermore, our analysis of $\langle \tau \rangle$ and $\langle |\xi| \rangle$ as a function of packing fractions has unveiled plateau-like regions corresponding to the fluid-solid coexistence phase, which to the best of our knowledge have not been reported.

The second part focuses on dynamics, comparing single particle dynamical observables in continuous time (as a function of $t$) and in collisional representation (as a function of the number of collisions, $n$). We find a full analogy, in spite of the fact that the process is not truly Poissonian [13]. We show that the velocity is never a Markovian process in either representations and in both fluid and solid phases [14]. Furthermore we have analyzed the mean squared displacement, intermediate scattering function and self-part of the van Hove function (or propagator) in both representations, showing remarkable similarities to glassy behavior.

We consider a 2D system of size $L_x \times L_y$ where $L_x$ ($L_y$) corresponds to the length in the $x$ ($y$) direction, consisting of $N$ hard disks with diameter $\sigma$. The packing fraction $\eta$ of the system is defined as the ratio between the area occupied by the disks, $N\pi\sigma^2/4$, and the available area $L_x \times L_y$, yielding $\eta = \frac{N\pi\sigma^2/4}{L_x \times L_y}$. In collisional representation we follow a single particle counting the collisions it undergoes with a collision index $n$. For a collision $n$ we now define the particle’s position $\mathbf{x}_n$, the external (continuous) time $t_n$, and the on-collision velocity $\mathbf{v}_n$.

We run event-driven molecular dynamics (MD) [15]
numerical simulations. Simulations start from a random configuration, according to the desired \( \eta \), obtained from NVT Monte Carlo simulations. The temperature is kept constant by scaling the magnitude of velocities of each hard disk such that the kinetic energy of the system agrees with the equipartition theorem. The system is rectangular, where the ratio between \( L_x \) and \( L_y \) is kept at \( \sqrt{3} \). Periodic boundary conditions are applied in both directions and the system length is adjusted to keep constant the number of particles \( N \), yielding the desired \( \eta \). We set \( k_B T = 1 \), \( \sigma = 1 \), and the lengths \( L_x \) and \( L_y \) are measured in units of \( \sigma \). Throughout this work we consider the following packing fractions: \( \eta = 0.3, 0.56, 0.695, 0.713, 0.72 \), plotted respectively in black, blue, red, green and magenta. We thus span the different phases: fluid phase for low \( \eta \), the coexistence phase for \( 0.69 \leq \eta \leq 0.723 \), and above that the solid phase (the maximum possible packing fraction is given by \( \eta = \pi/\sqrt{12} \approx 0.907 \)).

II. COLLISIONAL REPRESENTATION: STATISTICS

The analysis of collisional statistics is based on three fundamental observables: (i) Free flight times \( \tau_n = t_{n+1} - t_n \), the times between consecutive collisions. The index \( n \) represents the number of collisions suffered by a particle in the system. (ii) On-collision velocity \( v_{\text{coll}} \), the \( x \) and \( y \) components of the particle velocity between collisions. (iii) Free path length, namely the vector connecting the particle’s position on the \( n \)-th and \( (n+1) \)-th collisions: \( \xi_n = x_{n+1} - x_n \). We first focus on the statistics of these measurable observables by means of event-driven MD numerical simulations, identifying the stationary distributions and the corresponding average values of on-collision velocities, free flight times and free path lengths.

A. Instantaneous velocity distribution function

The distribution of instantaneous velocities of the disks in the continuous time representation is given by the Maxwell-Boltzmann equilibrium distribution function:

\[
\phi_{\text{MB}}(\mathbf{v}) = \frac{1}{2\pi k_B T} e^{-\frac{|\mathbf{v}|^2}{2k_B T}},
\]

where \( T \) is the system temperature and \( k_B \) is the Boltzmann constant. In collisional representation, however, it is known that the stationary distribution of on-collision velocities \( \phi_{\text{coll}}(\mathbf{v}) \) takes a different functional form [12] [13] [15].

\[
\phi_{\text{coll}}(\mathbf{v}) = \frac{1}{2\pi^{3/2} k_B^2 T} e^{-\frac{|\mathbf{v}|^2}{2k_B T}} I_0 \left( \frac{|\mathbf{v}|^2}{2k_B T} \right) I_1 \left( \frac{|\mathbf{v}|^2}{4k_B T} \right),
\]

where \( I_0 \) and \( I_1 \) represent the cylindrical modified Bessel functions of 0-th and 1-st order respectively. As shown in Fig. [1] (a) the collisional distribution exhibits wider tails, i.e. a higher probability for higher velocities, as compared to its continuous time counterpart. This discrepancy can be understood intuitively with the following argument: in continuous time representation, the velocity distribution is calculated across snapshots of the system at different intervals, therefore higher velocities will be counted less often since their respective free flight times are shorter on average, spanning across less consecutive snapshots. In contrast, in collisional representation each on-collision velocity is counted only once, upon collision.

The expression in Eq. (2) highlights two important features of the velocity collisional process. The first is that the collisional trajectory is an isotropic process, since the velocity distribution depends only on its speed. The speed distribution \( f_{\text{coll}}(|\mathbf{v}|) \) can indeed be derived from Eq. (2), yielding \( f_{\text{coll}}(|\mathbf{v}|) = 2\pi \phi_{\text{coll}}(\mathbf{v}) = \frac{1}{2\pi^{3/2} k_B T} |\mathbf{v}| \left( I_0 \left( \frac{|\mathbf{v}|^2}{2k_B T} \right) + \frac{|\mathbf{v}|^2}{2k_B T} I_1 \left( \frac{|\mathbf{v}|^2}{4k_B T} \right) \right) \).}

The second property highlighted by Eq. (2) is that the velocity components are correlated within the collisional process, i.e. \( \phi_{\text{coll}}(\mathbf{v}) \neq \phi_{\text{coll}}(v^x)\phi_{\text{coll}}(v^y) \) although \( \phi_{\text{coll}}(v^x) = \phi_{\text{coll}}(v^y) \) (where \( \phi_{\text{coll}}(\mathbf{v}) \) is the single component velocity distribution). The single component velocity distribution function can be obtained by integrating Eq. (2) over the other component, i.e. \( \phi_{\text{coll}}(v^x) = \int_{-\infty}^{\infty} dv^y \phi_{\text{coll}}(\mathbf{v}) \). The numerical evaluation of the integral expression of \( \phi_{\text{coll}}(v^x) \) is shown in Fig. [1] (a), perfectly reproducing the numerical data. We note that Maxwell molecules, interacting through a pairwise potential such as \( V(|\mathbf{r}|) \sim |\mathbf{r}|^{-2} \), exhibit identical behavior in both continuous time and collisional representations: they are both isotropic, and the \( x \) and \( y \) components are in fact uncorrelated, yielding the same Gaussian form of the velocity distribution functions as in Eq. (1)[21].

Noting that the on-collision velocity is isotropic, and that the \( x \) and \( y \) components are statistically identical (even though they are correlated), we can henceforth limit our analysis to the single component \( x \) (or \( y \) without loss of generality), i.e. \( v_n \equiv v_n^x \) and \( \xi_n = x_{n+1} - x_n \).

B. Free-flight time distribution function

The probability distribution of free-flight times \( P(\tau) \) was first analyzed in Ref.s [13] [22] [23], where it was shown that it cannot be purely exponential, not even in the low density limit [22]. This is rooted in the fact that the characteristic free-flight time (or its inverse the collision frequency) of particles with a given velocity, \( \langle \tau(v) \rangle \), depend on the speed \(|\mathbf{v}| \). [13] [20]. To explain the non-exponential shape of \( P(\tau) \) analytically, we introduce the conditional
The conditional probability $P(\tau|v)$ is related to the viscosity of the system [22], and is therefore interesting to study. By introducing the single component conditional probability $p(\tau|v)$ (shown in Fig. 2(a)) we can also write:

$$P_{\text{coll}}(\tau) = \int_{-\infty}^{\infty} dv p(\tau|v) \varphi_{\text{coll}}(v).$$  (4)

For low $\eta$, it can be shown that $P(\tau|v) = \frac{1}{\langle \tau(v) \rangle} e^{-\tau/\langle \tau(v) \rangle}$ [13, 15], a consequence of the molecular chaos assumption, or *strosszahlansatz*, which holds in the dilute limit. In this limit the collisional dynamics of a tagged particle is exactly a Markov process in the space of velocities, where the hopping probability from velocity $v'$ to velocity $v$, given by $W(v|v')$, can be calculated analytically [16]. We find that also the single component distribution function $p(\tau|v)$ exhibits an exponential shape $p(\tau|v) = \frac{1}{\langle \tau(v) \rangle} e^{-\tau/\langle \tau(v) \rangle}$ in the dilute limit $\eta \to 0$, as can be appreciated in Fig. 2(a). However, though both the complete and single component conditional probabilities $P(\tau|v)$ and $p(\tau|v)$ are exponential in the dilute limit, it must be stressed that the characteristic free-flight time given a single component velocity, $\langle \tau(v) \rangle$ shown in Fig. 2(b), differs from $\langle \tau(v) \rangle$. Deviation of $P(\tau|v)$ from
a pure exponential is expected at large \( \eta \) due to the loss of the molecular chaos ansatz, and to the ensuing hopping dynamics which is no longer Markovian in velocity space. This deviation is clearly observed also in the single component \( p(\tau|v) \), as displayed in Fig. 2(a). In any case substituting Eq. (2) in Eq. (3) means that \( P(\tau) \) cannot be an exponential either, as shown in Fig. 3(a). The same argument can be specified to \( p(\tau|v) \) and \( \varphi_{coll}(v) \) in Eq. (4).

The characteristic free-flight time is defined as \( \langle \tau \rangle = \int_{-\infty}^{\infty} d\tau P(\tau) \). Substituting Eq. (4) or (5) yields \( \langle \tau \rangle = \int_{-\infty}^{\infty} d\tau v \varphi_{coll}(v) \) or \( \langle \tau \rangle = \int_{-\infty}^{\infty} d\tau \langle \tau \rangle \varphi_{coll}(v) \) accordingly. \( \langle \tau \rangle \) is displayed in Fig. 3(a) for different \( \eta \), spanning from the fluid to the solid regime. Interestingly, we observe a plateau associated to the coexistence phase consistent to a scenario where spatial regions with localized particles (crystallites) can be observed in between regions of mobile particles [17, 18, 24, 25, 25–37].

The relation between the characteristic free flight time \( \langle \tau \rangle \) and \( \langle \tau \rangle \) follows [13]:

\[
\langle \tau (v) \rangle \varphi_{coll}(v) = \langle \tau \rangle \varphi_{MB}(v). \tag{5}
\]

Changing to polar coordinates and integrating over the angle yields [13]:

\[
\langle \tau (v) \rangle_{f_{coll}(|v|)} = \langle \tau \rangle f_{MB}(|v|), \tag{6}
\]

We find that the same equality is valid for the single components, as detailed in Appendix A:

\[
\langle \tau (v) \rangle \varphi_{coll}(v) = \langle \tau \rangle \varphi_{MB}(v). \tag{7}
\]

Substituting in Eq. (7) the integral expression of \( \varphi_{coll}(v) \), and the numerical value of \( \langle \tau \rangle \) (Fig. 4(a)) leads to a semi-analytic estimate of \( \langle \tau (v) \rangle \), shown in Fig. 4(b) to be in excellent agreement with simulation data.

### C. Free-path length distribution function

The free-path length \( r \) is defined as \( |\xi| = |v| \tau \), and the single component obeys \( |\xi| = |v| \tau \). In this sub-section we analyze the single component free-path length distribution function \( P(|\xi|) \), displayed in Fig. 3(b) for several values of \( \eta \). In step with the analysis made for the free-flight distribution function in the previous sub-section, we can define a conditional free-path length distribution function as [13]:

\[
P(r|v) = \int d\tau \delta \left( \frac{r}{|v|} - \tau \right) \frac{P(\tau|v)}{|v|}. \tag{8}
\]

and, for the single component:

\[
p(|\xi||v) = \int d\tau \delta \left( \frac{|\xi|}{|v|} - \tau \right) \frac{p(\tau|v)}{|v|}. \tag{9}
\]

Using Eqs. (8) and (9) together with the analysis reported in the previous sub-section, it can be shown that in the low limit of \( \eta \), \( P(|\xi||v) \) and \( p(|\xi||v) \) are both exponentials [13]. At the same time, a marked deviation from the exponential form is expected for high \( \eta \) (as shown in Fig. 5(a)). The conditional mean free-path, given a velocity \( v \), is given by \( \langle |\xi(v)| \rangle = |v|\langle \tau(v) \rangle \), and \( \langle |\xi(v)| \rangle = |v|\langle \tau(v) \rangle \) for what concerns the single component reported in Fig. 5(b). Expressing \( \langle |\xi(v)| \rangle \) in terms of \( \langle \tau(v) \rangle \) allows the semi-analytical evaluation of the mean free-path single component, in excellent agreement with the numerics.

The free-path length distribution function is defined as:

\[
P(|\xi|) = \int_{-\infty}^{\infty} dv P(r|v) \varphi_{coll}(v), \tag{10}
\]

and has been the subject of an extensive numerical analysis in Ref. [38]. In this early study it was shown that: (i) \( P(|\xi|) \) is nearly exponential in the fluid and solid limit; (ii) the kinetic theory predicts a very accurate mean free-path at all packing fractions, namely \( \langle |\xi| \rangle_{kt} = \frac{\tau}{2\pi^{2/3} \eta} \); (iii)
the dimensionless free path distribution as a function of the rescaled free-path length, \( \langle |\xi|\rangle_{kt} P\left(\frac{|\xi|}{\langle |\xi|\rangle_0}\right) \), exhibits a nearly universal behavior, independent of \( \eta \); (iv) the rescaled free-path length distribution does not agree well with the zero density scaled distribution \( \langle |\xi|\rangle_0 P\left(\frac{|\xi|}{\langle |\xi|\rangle_0}\right) \), where \( \langle |\xi|\rangle_0 \) is the mean free-path achieved from the Enskog theory \[39\]. In step with Eq.\,(10), the single component path length distribution function is defined as:

\[
P(|\xi|) = \int_{-\infty}^{\infty} d|v| |\xi| P(|\xi|) \phi_{coll}(v).
\]

Eqs. \((10)\) and \((11)\) yield non-exponential-free path distribution functions for all \( \eta \) once the expressions for \( \phi_{coll}(v) \) and \( \varphi_{coll}(v) \) are substituted (see Fig. \(4\)b)). In the very dilute case this result coincides with the finding in Ref.\,[13]. In Fig. \(4\)b) we plot the average free-path with \( \eta \) ranging from the fluid to the solid phase:

\[
\langle |\xi|\rangle = \int_0^\infty d|\xi| P(|\xi|). \quad \text{As for the average free-flight time, the plateau can be considered as the signature of the coexistence phase \[17\]. In Appendix B the single component mean free-path furnished by the kinetic theory is shown to be \( \langle |\xi|\rangle_{kt} = \frac{\sigma}{2\pi^2 \eta} (\text{Eq.\,(B3)} \text{) and in the inset of Fig.\,(B)\,b), one can see that this estimate reproduces just qualitatively the numerical mean free-path \( \langle |\xi|\rangle \), in contradiction to what has been observed in Ref.\,[38]. As a consequence, no universal behavior is expected from the rescaled single component mean free path distribution \( \langle |\xi|\rangle_{kt} P\left(\frac{|\xi|}{\langle |\xi|\rangle_0}\right) \) (see Fig.\,(B)\,a)). Moreover, this rescaling does not provide a correct collapse of the numerical curves, neither when the kinetic theory estimate \( \langle |\xi|\rangle_{kt} \) is replaced by the true \( \langle |\xi|\rangle \), as displayed in Fig.\,(B)\,b). In Appendix B we also provide the mean free-path length estimate \( \langle |\xi|\rangle_0 \) which arises from the Enskog theory (see Eq.\,(B5)). Plotting the rescaled free-path probability distribution by \( \langle |\xi|\rangle_0 \) corroborates the finding of Ref.\,[38]:}
the agreement of the data with the zero-density limit is indeed unsatisfactory (Fig. 18(c)). In the insets of both panels of Fig. 4 we report the Enskog theory prediction for the mean free flight time and the mean free path, \( \langle \tau \rangle_0 \) and \( \langle \xi \rangle_0 \), respectively. The expressions furnished in Eqs. (B5) and (B6) do not describe the observed behavior also in the limit of very dilute systems.

Finally, defining the mean free path as \( \langle \xi \rangle = \int_{-\infty}^{\infty} dv \, \langle |v| \rangle \phi_{\text{coll}}(v) \) yields, in view of Eq. (12) and Eq. (10), the following relation:

\[
\langle |v| \rangle = \langle |v| \rangle_{\text{cont}} \langle \tau \rangle,
\]

or

\[
\langle |v| \rangle = \langle |v| \rangle_{\text{cont}} \frac{1}{\langle \eta \rangle}.
\]

for the single component. The same relation in Eq. (12) is imposed within the framework of the kinetic theory to define the mean free-path (see Eq. E2 and Ref. 10). Moreover, it has been rigorously validated also in one-dimensional elastic rod systems, also known as Jepsen's gases 111. Indeed, as in 1D the velocity distribution function is invariant upon elastic collisions 122, the Eq. (13) has been shown to hold for any type of distributions \( \varphi(v) \), not only for the Maxwell-Boltzmann distribution \( \varphi MB(v) \).

III. COLLISIONAL REPRESENTATION: SINGLE PARTICLE DYNAMICS

Our analysis now turns to the dynamical properties of the single particle, or tracer. In particular, we reinterpret the stochastic motion of a tagged particle in positional space \( x_n \) and velocity space \( v_n \), as a global collisional process, where the continuous time \( t \) is now replaced by the collisional index \( n \). Correspondingly, our analysis will extend to the study of the properties of \( \tau_n \).

In what follows, we will first consider the velocity autocorrelation function, discuss the mean squared displacement (MSD) and the connection among them through the Green-Kubo relation. We then continue to investigate autocorrelation functions of free flight path and free flight time. Lastly, we complete the picture by discussing the intermediate scattering function and the self-part of the van Hove function, or the propagator.

A. Velocity autocorrelation function

We wish to follow the argument of Markovianity and its intrinsic connection to the ansatz of molecular chaos in dilute systems. This issue is particularly important and compelling since it constitutes the fundamental hypothesis from which the on-collision velocity distribution function in Eq. (2) is derived, and which leads to the exponential shape of the free-flight time conditional probability distribution \( P(\tau|v) \) in the low density limit. Thus, let us briefly recall what is the theoretical framework in Refs. 12, 13, 15, that hinges on this assumption. The diluteness of the system guarantees the molecular chaos ansatz, meaning that the evolution of the tracer velocity distribution function \( \varphi(v) \) is governed by a linear Boltzmann equation. This, in turn, leads to the Maxwell-Boltzmann distribution \( \varphi MB(v) \) in the stationary regime. The analysis of the Boltzmann equation provided in Ref. [15] clarifies that the tracer undergoes a sequence of collisions, performing a Markov process in velocity space, whose transition rates \( W(v|v') \) are analytically calculated from the linear Boltzmann equation. Hence, the conditional characteristic free flight time \( \langle \tau(v) \rangle \) is obtained through the relation \( \langle \tau(v) \rangle^{-1} = \int dv' W(v|v') \).
Finally, substituting this in Eq. (5) yields the full expression of $\phi_{\text{coll}}(v)$ in Eq. (2). It is important to note that Eqs. (5) and (2) are generally valid, since they must hold for any $\eta$, not only in the dilute limit $\eta \to 0$. This means that the ratio $\phi_n(v) / \phi_{\text{coll}}(v)$ is a universal function of the speed $\Omega(v)$, independent of the packing fraction of the system. In view of these simple considerations, it is critical to verify whether the molecular chaos and/or Markovian assumptions are necessary and verified conditions in the dilute limit. However, since we restrict our analysis to the dynamical properties of single particles, we will focus on testing the Markovian assumption by studying the behavior of the velocity autocorrelation function (ACF) in collisional representation: $\langle v_0 v_n \rangle$. Furthermore, the Markov property leads to the exponential shape of $P(\tau|v)$ in the low $\eta$ limit, as is reported in Refs. [12, 13] and shown in Fig. 2(a).

It is instructive to compare the dependence of the velocity ACF $\langle v_0 v_n \rangle$ on the collision index $n$ to the dependence of its continuous time counterpart $\langle v(0)v(t) \rangle$ on $t$. In continuous time, velocity is known to be a non-Markovian process for any value of $\eta$. The pioneering numerical work of Alder and Wainwright [1, 2] in the dilute limit has shown that $\langle v(0)v(t) \rangle \sim t^{-1}$ for long times. The discovery of these persistent memory effects greatly influenced the further development of nonequilibrium statistical physics of liquid states, and it is often referred to as the "2D long-time tail problem" [4]. Several theories based on mode-coupling theory [38], nonequilibrium statistical mechanics [39] and a kinetic approach [50] have been devised to explain this surprising numerical finding, marking, in the latter case, the birth of the "Modern Era" of kinetic theory (see also the partial review in [3]). However, the exact form of the long-time tail is not fully understood [60]; while an earlier result [37] estimated the first correction to the $t^{-1}$ tail as $\ln(t/t_0)$, mode coupling theories [48, 49] and the renormalization group approach [50] have led to the prediction that the $t^{-1}$ decay corresponds to intermediate times, while at longer times the asymptotic decay takes the form of $(t\ln t)^{-1}$. Extensive numerical simulations carried out using a direct approach [51], a cellular automaton lattice gas model [52, 56] and an event-driven direct hard-disk simulation scheme [57] provided the evidence in favor of the $(t\ln t)^{-1}$ long-time behavior.

In Fig. 6(a) we report the single component velocity ACF $\langle v(0)v(t) \rangle$ for different $\eta$. In the inset one can appreciate the asymptotic $t^{-1}$ behavior for the lower $\eta$, while the accuracy of our event-driven simulations cannot clearly distinguish the predicted $(t\ln t)^{-1}$ for larger times. For higher $\eta$, well inside the coexistence region and the solid phase, it is possible to see how the velocity ACF exhibits negative antipersistent tails. This antipersistence is due to the backscattering resulting from the "caging effect", where particles are confined to transient cages, resulting in temporal anticorrelations in particle displacements. The cage effect has been observed in colloidal systems close to the glass transition [55, 52, 53] or granular systems close to the jamming transition [74, 75] and mainly connected to a reduction of the displacements of the particles trapped in the cages [25, 77]. Here we claim that velocity anticorrelations might reveal the presence of solid-like structures, characterizing the solid-fluid coexistence phase in hard-disk systems. We note that the focus here is not on the continuous time behavior summarized in Fig. 6(a), which is meant only to provide a confirmation of the overall behavior in continuous time, but rather on the behavior of the velocity ACF in collisional representation. In Fig. 6(b) we report $\langle v_0 v_n \rangle$ for several $\eta$. The inset shows that in the dilute limit $\langle v_0 v_n \rangle \sim n^{-1}$ for large times. The main panel displays the progressive approach from the persistent to the antipersistent regime as $\eta$ increases. These numerical results highlight the complete analogy between the asymptotic behavior exhibited by the velocity ACF in the continuous time and the collisional representations for any $\eta$. Most importantly, it demonstrates that the Markovian assumption for velocity in collisional representation is never fulfilled. In particular, surprisingly, it does not hold in the limit $\eta \to 0$, revealing that the Markov property is not a necessary condition for Eq. (2) to be valid. Nonetheless this is puzzling, since the exact expression provided by the Eq. (2) is derived by assuming the single particle collisional velocity process to be Markovian in the dilute limit.

Finally let us compare the results obtained in 2D with the properties of Jepsen gas, mentioned earlier. In 1D, the velocity process in collisional representation (i.e. $\langle v_0 v_n \rangle$) is Markovian only in systems with bimodal (or dichotomic) velocity distributions, i.e., $\psi(v) = \frac{1}{2} \delta(v-c) + \delta(v+c)$ where $\delta(x)$ stands for the Dirac's delta function. The on-collision velocity process is non-Markovian for systems with any other distribution function, including $\psi_{MB}(v)$ [41]. On the other hand, in continuous time, the behavior of $\langle v(0)v(t) \rangle$ in 1D considerably differs from the collisional representation, in contrast to what we have shown in 2D. For bimodal velocity distribution functions the continuous time velocity ACF is strictly exponential [41, 42, 79], while weak memory effects of the form $\langle v(0)v(t) \rangle \sim -t^{-\gamma}$ result from velocity distribution functions such as Maxwell-Boltzmann [41, 42, 79, 80], uniform $\psi(v) = \frac{1}{2\sqrt{c}} \theta(v+c)\theta(v-c)$ [79] or $\psi(v) = \frac{c^2}{2}(c^2 + v^2)^{3/2}$ [42], where $\theta(x)$ and $c$ represent the Heaviside’s function and a constant respectively. For velocity distribution functions like the three-modal $\psi(v) = \mu \delta(v) + \frac{1-\mu}{2} \delta(v-c) + \delta(v+c)$ [41] or four-modal $\psi(v) = \frac{1}{4} \delta(v-c_1) + \delta(v+c_1) + \frac{1-\mu}{2} \delta(v-c_2) + \delta(v+c_2)$ [41] (0 < $\mu$ < 1, $c_1$, and $c_2$ constants), the memory effects are stronger: $\langle v(0)v(t) \rangle \sim -t^{-3/2}$. Based on the numerical evidence, it was argued in Ref. [41] that the non-exponential behavior observed in the velocity ACF in continuous time are ascribable only to the non-Markovian nature of the underlying collisional mechanism. This conjecture seems to be fulfilled also in 2D.
B. Mean squared displacement and free path autocorrelation function

We analyze the single particle mean squared displacement (MSD) in collisional representation and compare it to its counterpart in continuous time. For the sake of clarity, let us start by discussing the MSD in the common continuous time representation. The MSD is defined as

\[ \langle \delta x^2(t) \rangle = \langle |x(t) - x(0)|^2 \rangle. \]  \hfill (14)

We will be referring to Eq. (14) as the Einstein-Helfand expression, in clear connection to the well-established Einstein-Helfand formula for the diffusion coefficient \( D = \frac{1}{2} \lim_{t \to \infty} d(\delta x^2(t))/dt \) \[16, 81, 84\]. In Fig. 7(a) we report the outcome of our numerical simulations for several \( \eta \). After a transient ballistic regime, it is clearly seen that systems characterized by a lower \( \eta \) exhibit normal diffusion behavior, whereas, for higher \( \eta \), the MSD reaches a plateau which eventually turns into a linear regime. This plateau can be considered as further evidence of the caging undergone by a tracer during the coexistence phase and beyond, in analogy with colloids [58, 60, 85], supercooled liquids [68, 70, 73, 85], and granular systems [74, 76]. Due to the stationarity of the velocity process, the MSD can

\[ \langle \delta x^2(t) \rangle = \langle (x(t) - x(0))^2 \rangle = D \langle \delta v^2(t) \rangle = D \langle v(t) \rangle \langle v(t) \rangle = D v^2. \]  \hfill (15)

They both coincide, displaying normal diffusion for low PF and an intermediate slowdown (plateau) for PF in the coexistence phase and beyond, in analogy with the results shown in Fig. 7(a). (b) Transport coefficient defined as \( D_n = \sum_{m=0}^{\infty} \xi(m) \). For the higher PF shown, \( D(t) \) displays a “subdiffusive” decay in correspondence of the caging regime in panel (a) (see Ref. 78).
be also written as
\[ \langle \delta x^2(t) \rangle = 2 \int_0^t ds \langle v(0)v(s) \rangle (t-s), \] (15)

referred to as the Green-Kubo MSD expression, in relation to the definition of the diffusion coefficient according to the Green-Kubo relation, \( D = \int_0^\infty dt \langle v(0)v(t) \rangle \). Fig. (7a) shows the excellent agreement between the MSD calculated according to the Einstein-Helfand expression from Eq. (14) (solid lines) and that resulting from the Green-Kubo formula in Eq. (15) (dashed lines). The logarithmic tail of the velocity ACF shall lead to the weak divergence of the diffusion coefficient \( D \) in the long-time limit \( (D \sim [\ln(\infty) + \text{const}]^{1/2}) \). However, as stressed in Ref. [78], in spite of the enormous numerical effort devoted to the identification of the \( \langle v(0)v(t) \rangle \) logarithmic asymptotic regime, very little work has been dedicated to the study of its influence on the actual value of the diffusion coefficient. Indeed, the numerical simulations shown in Fig. (7a) seem to point out the absence of any correction to the linear behavior exhibited by the MSD, in agreement with the results reported in Refs. [77, 89]. However, plotting the time-dependent transport coefficient \( D(t) = \frac{1}{2} \frac{d \langle \delta x^2(t) \rangle}{dt} = \int_0^t ds \langle v(0)v(s) \rangle \), as shown in Fig. (7b), shows a small but persistent increase within the timescale corresponding to the linear region exhibited by the MSD, for which one would have expected a constant value. For \( \eta = 0.3 \) we observe \( D(t) \sim \sqrt{\ln(t)} \), consistent with the velocity ACF form \( \langle v(0)v(t) \rangle \sim (t\sqrt{\ln t})^{-1} \), and in contradiction to the numerical finding already present in one of the earliest numerical works on this subject [88]. For larger \( \eta \), \( D(t) \) exhibits a “subdiffusive” decay consistent with the appearance of negative tails of \( \langle v(0)v(t) \rangle \) (shown in Fig. (3a)) and with the corresponding plateau observed in the MSD (shown in Fig. (2a)) for intermediate times; asymptotically it approaches a constant value, in line with the asymptotic diffusive regime. The rigorous connection between anomalous diffusion and power-law tails exhibited in the MSD in Eq. (18). However, plotting the time-dependent transport coefficient \( D(t) \) for small \( \eta \) (see the inset of Fig. 9) and antipersistent as \( \eta \) increases. When calculated according to the Green-Kubo expression in Eq. (18), the MSD (dashed lines in Fig. 3a) is shown to coincide with the Einstein-Helfand expression in Eq. (16). In analogy with the continuous time analysis, the asymptotic \( n^{-1} \) regime should lead to the divergence of the MSD in Eq. (18). However, no appreciable deviation from the linear MSD trend is detected, albeit in the range for which \( \langle \xi_0 \xi_n \rangle \) displays the \( n^{-1} \) behavior. We now recast the Green-Kubo MSD expression in Eq. (18) by introducing the “symmetrized” free path autocorrelation function as \( \tilde{C}_{\xi \xi}(n) = \langle \xi_0 \xi_n \rangle - \frac{\langle \xi^2 \rangle \delta_{n,0} }{2} \) [78, 90]:

\[ \langle \delta x^2_n \rangle = 2 \sum_{m=0}^{n-1} \tilde{C}_{\xi \xi}(m)(n-m). \] (19)

FIG. 9: (Color online) Normalized free path length ACF. The non-Markovianity of the free path length is apparent both at low and high \( \eta \). For low \( \eta \) (inset) the \( 1/n \) behaviour is clearly shown, consistent with the velocity ACF in Fig. 3b. The systems with high \( \eta \) are displayed in the main panel, exhibiting a negative part, i.e. antipersistence due to the caging phenomenon.

and assuming the stationarity of the free-path process, one arrives at the Green-Kubo expression in collisional representation:

\[ \langle \delta x^2_n \rangle = n\langle \xi^2 \rangle + 2 \sum_{m=1}^{n-1} \langle \xi_0 \xi_m \rangle (n-m), \] (18)

where \( \langle \xi^2 \rangle = \int d\xi \xi^2 P(\xi) \). Hence, the numerical evaluation of Eq. (18) requires the calculation of the free-path ACF \( \langle \xi_0 \xi_n \rangle \), which is reported in Fig. 7. The observed behavior resembles that of the velocity ACF. Indeed, for any \( \eta \) the free-path process \( \xi_n \) is non-Markovian, with persistent asymptotic tails \( \propto n^{-1} \) for small \( \eta \) (see the inset of Fig. 9), and antipersistent as \( \eta \) increases. When calculated according to the Green-Kubo expression in Eq. (18), the MSD (dashed lines in Fig. 3a) is shown to coincide with the Einstein-Helfand expression in Eq. (16). In analogy with the continuous time analysis, the asymptotic \( n^{-1} \) regime should lead to the divergence of the MSD in Eq. (18). However, no appreciable deviation from the linear MSD trend is detected, albeit in the range for which \( \langle \xi_0 \xi_n \rangle \) displays the \( n^{-1} \) behavior. We now recast the Green-Kubo MSD expression in Eq. (18) by introducing the “symmetrized” free path autocorrelation function as \( \tilde{C}_{\xi \xi}(n) = \langle \xi_0 \xi_n \rangle - \frac{\langle \xi^2 \rangle \delta_{n,0} }{2} \) [78, 90]:

\[ \langle \delta x^2_n \rangle = 2 \sum_{m=0}^{n-1} \tilde{C}_{\xi \xi}(m)(n-m). \] (19)

We now identify the on-collision transport coefficient \( D_n = \sum_{m=0}^{n-1} \tilde{C}_{\xi \xi}(m) \), and report it in Fig. 8b. This quantity dictates the \( n \)-dependence of the MSD in collisional representation as \( D(t) \) does for \( \langle \delta x^2(t) \rangle \), detailed in
the theorem in Appendix C. This theorem can be viewed as the extension to impact dynamics of the generalized Kubo theorem valid in continuous time. In particular when $D_n$ attains a constant value, one expects normal diffusion $(\Delta x_n^2) \sim n$ as displayed in Fig. 9a for low $\eta$. However, $D_n$ behaves as $\sim \sqrt{\ln n}$ for the lowest packing fraction $\eta = 0.3$, in complete analogy with the continuous time analysis reported in Fig. 7a, and in partial agreement with the observed persistent tails exhibited by the free path ACF $\xi_\tau(n)$ (Fig. 9b). When $D_n$ exhibits a decay in the form of a power-law, $\langle \Delta x_n^2 \rangle$ is sublinear in the collision index $n$. This is indeed the case for intermediate $n$ with large $\eta$, ultimately ascribable to the caging effect.

C. Free flight time autocorrelation function and free flight and free path cross correlation function

Since in collisional representation space and time can be studied separately, we now focus on the free flight time autocorrelation function defined as $C_{\tau \tau}(n) = \langle \tau_0 \tau_n \rangle - \langle \tau \rangle^2$. For an uncorrelated process one would expect $\langle \tau_0 \tau_n \rangle - \langle \tau \rangle^2 = \langle \tau^2 \rangle - \langle \tau \rangle^2 \delta_{n,0}$. However, the analysis in Sec. IIIA demonstrates that the time elapsed between subsequent collisions is velocity-dependent; this velocity, on the other hand, is a correlated process both at low and high packing fractions, as discussed in Sec. IIIA.

Therefore correlations should also characterize the discrete dynamics of free flight times of single particle, as indeed confirmed by the numerical outcomes in Fig. 10.

The expression for the time ACF $C_{\tau \tau}(n)$ is formally defined through the correlation

$$\langle \tau_0 \tau_n \rangle = \int d\tau_0 \cdots d\tau_n d\nu_0 \cdots d\nu_n \tau_0 \tau_n p(\tau_0, \cdots \tau_n | \nu_0, \cdots \nu_n) \phi_{coll}(\nu_0, \cdots \nu_n).$$

Hence as long as times depend on velocities, the uncorrelation of the velocity process implies the uncorrelation of the free flight times collisional dynamics and vice versa. Indeed, if we assume the on-collision velocities to be uncorrelated, i.e. $\phi_{coll}(\nu_0, \cdots \nu_n) = \phi(\nu)^n$, then we have

$$p(\tau_0, \cdots \tau_n | \nu_0, \cdots \nu_n) = p(\nu)^n \text{ yielding } \langle \tau_0 \tau_n \rangle = \langle \tau^2 \rangle$$

and therefore $C_{\tau \tau}(n) = \langle \tau^2 \rangle n \delta_{n,0}$.

Now, let us make the hypothesis that free flight times are independent of the velocities, i.e. $p(\tau_0, \cdots \tau_n | \nu_0, \cdots \nu_n) \equiv p(\tau_0, \cdots \tau_n)$. We want to discuss the implication of this simplification on the free path ACF. In general, since $\xi_n = \nu_0 \tau_n$, the free path ACF is expressed as $\langle \xi_0 \xi_n \rangle = \langle \tau_0 \tau_n v_0 \nu_n \rangle$, where

$$\langle \tau_0 \tau_n v_0 \nu_n \rangle = \int d\tau_0 \cdots d\tau_n d\nu_0 \cdots d\nu_n \tau_0 \tau_n v_0 \nu_n p(\tau_0, \cdots \tau_n | \nu_0, \cdots \nu_n) \phi_{coll}(\nu_0, \cdots \nu_n).$$

Consistent to our assumption, we obtain $\langle \xi_0 \xi_n \rangle = \langle \tau_0 \tau_n \rangle \langle v_0 \nu_n \rangle$. Moreover, if we make the additional hypothesis that $\tau_n$ is an uncorrelated process, the free path ACF transforms to $\langle \xi_0 \xi_n \rangle = \langle \tau \rangle^2 \langle \nu \nu \rangle$. Substituting this into Eq. 19 we then obtain:

$$\langle \Delta x_n^2 \rangle \simeq \langle \tau \rangle^2 \left[ n \langle \nu^2 \rangle + 2 \sum_{m=1}^{n-1} (\nu_0 \nu_m) (n-m) \right],$$

with $\langle \tau \rangle = \int_0^\infty d\tau P(\tau) \tau$ and $\langle \nu^2 \rangle = \int_0^\infty dv \phi_{coll}(v) v^2$. The former approximation corresponds to a Poisson process, as we will discuss in Sec. IV. We highlight that the only two assumptions made to define a Poisson process are i) independence between free flight times and velocities in collisional representation. ii) no memory effects characterizing the free flight collisional process. The numerical evaluation of the approximated MSD in Eq. 22 is reported in Fig. 11a and compared to the expression in Eq. 16, showing a satisfactory agreement only in the low packing fraction limit. For more dense fluids, the intermediate caging regime appears to be poorly captured by Eq. 22. The negative antipersistent part of the free path ACF (Fig. 9), is indeed less pronounced in the approximation $\langle \xi_0 \xi_n \rangle \simeq \langle \tau \rangle^2 \langle \nu \nu \rangle$.

We finally study the cross-correlation functions $\langle \xi_0 \tau_n \rangle$ and $\langle \tau_0 \xi_n \rangle$. Both vanish since $\langle \xi \rangle = 0$, we therefore consider the absolute values, i.e. $|\langle \xi_0 \tau_n \rangle|$ and $|\langle \tau_0 \xi_n \rangle|$. Fig. 12 shows $\langle |\xi_0| \tau_n \rangle$. The first term can be analyzed in the low packing fraction limit, reading:

$$|\langle \xi_0 \tau_0 \rangle| = \int_{-\infty}^{\infty} dv |v| \phi_{coll}(v) \int_0^\infty d\tau \tau^2 p(\tau | v),$$

where $p(\tau | v)$ is the conditional probability density of the uncorrelated velocities.
FIG. 11: (Color online) Poisson approximated expression for the MSD. (a) MSD in collisional representation for several η calculated according to the Poisson approximation in Eq. (22) (dashed lines). The solid lines refer to the Green-Kubo expression from Eq. (18), coinciding with the Poissonian approximation only in the low η limit. (b) MSD in continuous time representation using the first two terms of the Poisson formula appearing in Eq. (39) (dashed lines), and the Green-Kubo expression in Eq. (15) (solid lines). Here too the low η systems appear to be well captured by the approximated formula. The high η limit requires a complete determination of the correlations appearing in Eq. (38).

where we dropped the index 0 on the RHS, to simplify the notation. The conditional probability p(τ|v) is exponential for low η (see Fig. 2(a)), and substituting Eq. (7) we have:

\[
\langle |ξ_0|τ_n \rangle = 2\langle τ \rangle^2 \int_{-∞}^{∞} dv \ |v| \frac{\varphi_{MB}(v)}{\varphi_{col}(v)}.
\]  

(24)

In 1D (Jepsen gas), where \( \varphi_{col}(v) \equiv \varphi_{MB}(v) \), one obtains \( \langle |ξ_0|τ_n \rangle = 2^{3/2} \langle τ \rangle^2 \sqrt{\frac{k_B T}{π}} \).  

FIG. 12: Color online) Normalized cross correlation of free flight time and free path length.

FIG. 13: (Color online) Intermediate scattering function. (a) Continuous time \( F_S(q,t) \) for several η calculated according to Eq. (25). The passage from the exponential decay to the stretched exponential regime, particular to caging in granular and colloidal systems is evident. (b) Collisional representation \( F_S(q,n) \), Eq. (26). The exhibited trend traces that of panel (a).
D. Intermediate scattering function

We now study a different dynamical function at the single particle level, the single component intermediate scattering function. In continuous time it is defined as:

\[ F_S(q, t) = \langle \cos [q (x(t) - x(0))] \rangle. \] (25)

This function is the real part of the \( x \) component of the single particle (incoherent) dynamic structure factor with a wave vector \( q \), \( F_S(q, t) = \langle e^{i q (r(t) - r(0))} \rangle \), and has been the subject of an extremely large amount of numerical and theoretical work in recent years. While a single exponential decay is expected for a normal fluid state, the emergence of a \( q \)-dependent 2-step decay at high packing fractions has been recognized to characterize the behavior of systems in different areas of physics, ranging from supercooled liquids and granular materials to glasses and colloidal systems [70, 76, 91–97]. Intuitively, this non-exponential regime (often referred to as a stretched exponential decay) should be related to the cage effect, which has been discussed as the main reason for the plateau-like exponential regime (often referred to as a stretched exponential domain [98]). In Fig. 13(a) we report the numerical results that for technical reasons is used in experiments in its one-dimensional form:

\[ G_S(x, n) = \langle \delta (x - [x(t) - x(0))] \rangle. \] (27)

Once again, if one neglects the early stage regime characterizing the ballistic behavior in the continuous time analysis, the decay exhibited by \( F_S(q, n) \) in Fig. 14(b) closely resembles that of \( F_S(q, t) \). In particular the exponential relaxation expected for the fluid state is recovered for low \( \eta \), while the stretched exponential decay appears to be more marked as \( \eta \) increases.

Inspired by the previous analogy between continuous time and collisional dynamical quantities, we study the intermediate scattering function in collisional representation, which takes the form:

\[ F_S(q, n) = \langle \cos [q (x_n - x_0)] \rangle. \] (26)

FIG. 14: (Color online) Self part of the van Hove function. (a) Continuous time \( G_S(x, t) \) for \( \eta = 0.3 \), calculated according to Eq. (27), for two different times \( t \) (solid lines). The dashed lines represent the Gaussian form \( \frac{1}{\sqrt{2\pi}\langle \delta x^2 \rangle_0} \exp(-x^2/2\langle \delta x^2 \rangle_0) \), where the values of \( \langle \delta x^2 \rangle_0 \) have been drawn from Fig. 7(a). (b) Collisional representation \( G_S(x, n) \) for \( \eta = 0.3 \), calculated according to Eq. (28), for two different values of \( n \) (solid lines). The dashed lines represent the Gaussian form \( \frac{1}{\sqrt{2\pi}\langle \delta x^2 \rangle_n} \exp(-x^2/2\langle \delta x^2 \rangle_n) \), where the values of \( \langle \delta x^2 \rangle_n \) have been drawn from Fig. 8(a).

E. Self part of the van Hove function

The last dynamical quantity that we study at the single particle level is the self part of the van Hove function [99]. This function is the equilibrium, canonically averaged, probability distribution of the particle displacements (the propagator), that for technical reasons is used in experiments in its one-dimensional form:

\[ G_S(x, t) = \langle \delta (x - [x(t) - x(0))] \rangle. \] (27)

Generally, in materials close to the glass or jamming transition and colloidal gelation, the non-Fickian character of the single particle displacements is indicated by three factors: (i) the relaxation functions decay...
non-exponentially, (ii) the MSD exhibits a subdiffusive plateau at intermediate time scales, (iii) the intermediate scattering function $F_2$ exhibits stretched-exponential decay, (iv) the self-part of the van Hove distribution function is non-Gaussian. In the previous sections we have provided the numerical evidence of the first three phenomena in both continuous time and collisional representation, and we now tackle the last one. Moreover, the deviation from the Gaussian form is generally interpreted as the key signature of the so-called dynamical heterogeneity [92, 94], i.e. when slow particles tend to cluster together forming cages, as well as faster particles forming fluid-like regions [28, 60, 65, 100, 102].

In Fig. (14a) we report the van Hove function from Eq. (27) calculated for $\eta = 0.56$, in the dilute regime (solid line). The dashed lines represent the Gaussian expression 

$$\frac{1}{\sqrt{2\pi(\delta x^2(t))}} e^{-\frac{x^2}{2(\delta x^2(t))}}$$

where the value of the MSD has been obtained from data in Fig. (7a). It is apparent that in this case the Fickian behavior is respected and the Gaussian form reproduces with remarkable accuracy the numerics at two different times. In Fig. (15a) the van Hove distribution function is displayed for $\eta = 0.695$, within the coexistence phase. $G_S(x,t)$ has been calculated at two different times according to the different stages attained by the MSD in Fig. (7a): within the subdiffusive plateau and the subsequent diffusive phase, once the tracer has escaped from the cage. In this case one can clearly see that the dashed lines accounting for the Gaussian Fickian behavior do not capture the tails of the van Hove function for times corresponding to the plateau region in Fig. (7a). When the dynamics is diffusive, the Gaussian behavior is instead restored. The appearance of non-Gaussian tails is even more apparent for $\eta = 0.713$ (Fig. 16a) where at short and larger times the exponential tails characterize the behavior of the van Hove function, suggesting that the particle dynamics can be represented by a number subsequent caging events. This is in line with the observation of plateaux-like regions detected in the MSD (Fig. 7a), and with the velocity ACF antipersistent tails observed in Fig. 6a.

Studying the single component van Hove function in collisional representation through the definition

$$G_S(x,n) = \langle \delta (x - |x_n - x_0|) \rangle$$

![FIG. 15: (Color online) Self part of the van Hove function. (a) Continuous time $G_S(x,t)$ for $\eta = 0.695$, calculated according to Eq. (27), for two different times $t$ (solid lines). The dashed lines represent the Gaussian form

$$\frac{1}{\sqrt{2\pi(\delta x^2(t))}} e^{-\frac{x^2}{2(\delta x^2(t))}}$$

where the value of the MSD has been drawn from Fig. (7a). Small but persistent deviations from the Gaussian expression in the tails of the distributions are displayed at both times. (b) Collisional representation $G_S(x,n)$ for $\eta = 0.3$, calculated according to Eq. (28), for two different values of $n$ (solid lines). The dashed lines represent the Gaussian form

$$\frac{1}{\sqrt{2\pi(\delta x^2_n)}} e^{-\frac{x^2}{2(\delta x^2_n)}}$$

where the values of $\langle \delta x^2_n \rangle$ have been drawn from Fig. 3a). Deviations similar to the continuous time case appear.

traces the behavior exhibited in continuous time. In Figs. (14b), (15b) and (16b) the solid lines represent the numerical data, whereas the dashed curves account for the Gaussian form

$$\frac{1}{\sqrt{2\pi(\delta x^2_n)}} e^{-\frac{x^2}{2(\delta x^2_n)}}$$

where $\langle \delta x^2_n \rangle$ is drawn from the results in Fig. (9a). For the lowest packing fraction the agreement observed in continuous time is respected. For $\eta = 0.695$ shown in Fig. 15b), the agreement between numerical curves and Gaussian expressions seems to be better for $n = 1000$ than $n = 30$. For $\eta = 0.713$ (Fig. (16b)) the exponential non-Gaussian tails characterize the subdiffusive regime as well as the ensuing diffusive phase. We also note the continuous-time propagator exhibits oscillations related to the disk packing, which seem to disappear in the collisional representation. This can be attributed to the fact that solid packing is a collective process, orchestrated with external time $t$.

IV. FROM COLLISIONAL TO CONTINUOUS TIME REPRESENTATION

We now wish to study the relation between continuous time and collisional representation. In Sec. III C we have
provided evidence that the free flight time $\tau_n$ evolves according to a non-Markovian dynamics, and this property is fulfilled by gases at any $\eta$. The distribution of times $t$ required for a particle to undergo $n$ collisions, i.e. the probability that a particle makes exactly $n$ collisions up to a time $t$, is given by:

$$P(n, t) = \int d\tau_0 \cdots d\tau_{n-1} dv_0 \cdots dv_{n-1} \delta \left( t - \sum_{i=0}^{n-1} \tau_i \right) P(\tau_0, \cdots \tau_{n-1}) \phi_{\text{coll}}(v_0, \cdots v_{n-1}).$$

Hence, the exact expression of $P(n, t)$ can be derived uniquely upon knowing the joint probability distribution of the velocities, and the ensuing conditional probability of the free flight times. Following Ref. [13], we take the Laplace transform of both sides of Eq. (29):

$$P(n, s) = \int d\tau_0 \cdots d\tau_{n-1} dv_0 \cdots dv_{n-1} e^{-s \sum_{i=1}^{n-1} \tau_i} p(\tau_0, \cdots \tau_{n-1}|v_0, \cdots v_{n-1}) \phi_{\text{coll}}(v_0, \cdots v_{n-1}).$$

Assuming the velocity process to be uncorrelated, the former Laplace transform then reads:

$$P(n, s) = \left[ \int dv P(s|v) \phi_{\text{coll}}(v) \right]^n,$$

where $P(s) = \int dv P(s|v) \phi_{\text{coll}}(v)$ is the Laplace transform of the free flight time distribution function $P(\tau)$ in Eq. (4). In the dilute limit, the exponential form of $P(\tau|v)$ leads to:

$$P(n, s) = \left[ \int dv \frac{1}{\langle \tau \rangle s \phi_{\text{coll}}(v) + \phi_{\text{MB}}(v)} \right]^n,$$

where we made use of Eq. (5). The same expression has been derived in Ref. [13] assuming the velocity collisional process to be Markovian, where the numerical Laplace inversion of Eq. (32), or analogously of $P(s)^n$, has been shown to closely agree with $P(n, t)$ extracted from simulations for $\eta$ in the fluid phase. This tells us that the uncorrelation assumption of the velocity collisional process hold in the dilute limit, if one considers $P(n, t)$ or $P(\tau)$ [13]. In the large packing fraction limit, however, this assumption fails and the inverse Laplace transform of Eq. (32) does not capture the probability $P(n, t)$.

Let us consider the case in which the free flight time distribution takes the exponential form $P(\tau) = \frac{1}{\langle \tau \rangle} e^{-\tau/\langle \tau \rangle}$. In view of Eq. (4), we are implicitly assuming $P(\tau|v) = \frac{1}{\langle \tau \rangle} e^{-\tau/\langle \tau \rangle}$, i.e. a unique time scale characterizes the collisional process irrespective of the undergone velocity. This corresponds, de facto, to taking free flight times independent of velocities. We can thus write the former Eq. (4) as:

$$P(n, t) = \int d\tau_0 \cdots d\tau_{n-1} \delta \left( t - \sum_{i=0}^{n-1} \tau_i \right) P(\tau_0, \cdots \tau_{n-1}) \phi_{\text{coll}}(v_0, \cdots v_{n-1}).$$

and, if we make the further assumption of considering the free flight times to be uncorrelated, one finally obtains for the Laplace transform (30):

$$P(n, s) = \frac{1}{(\langle \tau \rangle s + 1)^n}.$$  \hspace{1cm} (34)

Inverting back in time domain, yields the Poisson formula [14]:

$$P(n, t) = \frac{1}{\langle \tau \rangle} \left( \frac{t}{\langle \tau \rangle} \right)^{n-1} e^{-t/\langle \tau \rangle} \cdot (n-1)!$$

which has shown a large discrepancy to Eq. (29) even in the dilute limit [13 14]. However, the collisional MSD expression in Eq. (22) derived in this framework seems to work fairly well in the low $\eta$ limit (see the black curve corresponding to $\eta = 0.3$ in Fig. 11 (a)).

We now turn to the average time between $n$ collisions, i.e. the first moment of $P(n, t)$, within the context of the Poisson approximation, i.e. using the Poisson approximated expression in Eq. (35). A straightforward calculation yields:

$$\langle t_n \rangle = n \langle \tau \rangle,$$

and, surprisingly, it reproduces very well the numerical values reported in Fig 17 not only for low $\eta$ but also for $\eta$ in the solid regime.

To conclude this section, let us turn to the single particle propagator. To obtain the self part of the van Hove function in continuous time of Eq. (27) from the corresponding function in collisional representation of Eq. (28), we have to recur to the well-known subordination relation [14]:

$$G(x, t) = \sum_{n=1}^{\infty} G(x, n) \Pi(n, t),$$

where $\Pi(n, t)$ is the single particle probability of having $n$ collisions at time $t$. The connection between the formerly introduced probability $P(n, t)$ in Eq. (28) and $\Pi(n, t)$ is given, for large $n$, by $\Pi(n, t) = \langle \tau \rangle P(n, t)$. Thus, the MSD can be easily cast ed in the following form:

$$\langle \delta x^2(t) \rangle = \langle \tau \rangle \sum_{n=1}^{\infty} \langle \delta x^2_n \rangle P(n, t).$$  \hspace{1cm} (38)

This expression constitutes the relation between the MSD in collisional representation and that in continuous time, but the rigorous evaluation at any $\eta$ requires the knowledge of the conditional probability distributions in Eq. (29). However, a semianalytical expression of the MSD in continuous time can be achieved if we use the Poissonian approximation. Thanks to Eq. (22) and Eq. (35) we have, after elementary algebraic passages:

$$\langle \delta x^2(t) \rangle = \langle \tau \rangle \langle \delta x^2 \rangle + \langle \tau \rangle \langle \delta x^2 \rangle t +
2 \sum_{n=2}^{\infty} \sum_{m=1}^{n-1} \langle v_0 v_m \rangle (n - m) \left( \frac{t}{\langle \tau \rangle} \right)^{n-1} e^{-t/\langle \tau \rangle} \cdot (n-1)!. \hspace{1cm} (39)$$
This approximated expression can be considered valid only in the low \( \eta \) regime and, as such, the three terms in it can easily be interpreted. The first term accounts for the ballistic regime, the second is the leading diffusive term which dominates the single particle dynamics after the first collision. The third term represents the logarithmic corrections expected for an hard-disk gas. It is interesting to notice that the second moment of the velocity \(<v^2>\) is obtained using the collisional stationary distribution of velocity \( \varphi_{col}(v) \), instead of the regular Maxwell-Boltzmann \( \varphi_{MB}(v) \). As a first approximation we neglect the logarithmic corrections in Eq. \((39)\) which are believed to play a significant role for large times (see the discussion in Sec. \[1B\]). In Fig. \[1\] we observe that the approximated Poisson formula \((39)\) accurately reproduces the MSD in continuous time for low \( \eta \), whereas it clearly fails to account for the high packing regime, as indeed is expected.

V. DISCUSSION

We have studied statistical and dynamical properties of a 2D system of hard-disks in collisional representation, with packing fractions ranging from the fluid to the solid phase. Throughout this paper we tried to place our results within a broader context, resulting in a comprehensive study of 2D hard disk systems. The first part of our analysis focused on the statistics of velocity, free flight time and the path undergone by a disk between subsequent collisions. We have provided the numerical and theoretical evidence that the velocity \( x \) and \( y \) components are correlated in collisional representation, together with the fact that free flight times are strongly correlated to the on-collision velocities. This result has previously been investigated \[12\] only in the low packing fraction limit, and we have extended it to the coexistence and solid phase. We have shown that kinetic and Enskog theory do not furnish correct expressions for the average free flight time \(<\tau>\) and path \(<|\xi|>\) as a function of the packing fraction \( \eta \), not even in very dilute systems. Furthermore our numerical analysis spanning packing fractions up to the high \( \eta \) limit has unveiled plateau-like regions of \(<\tau>\) and \(<|\xi|>\) corresponding to the fluid-solid coexistence region, which to the best of our knowledge have not been reported before.

The second part of this study has been devoted to the dynamical single particle properties in collisional representation, and the comparison to their continuous time equivalents. We have shown a full analogy between observables calculated in continuous time (as a function of \( t \)) and in collisional representation (as a function of the number of collisions, \( n \)), in spite of the fact that the process is not truly Poissonian \[13\]. We have shown that the velocity is never a Markovian process both in continuous time and collisional representation. This is attributed to the persistent memory effects characterizing the velocity autocorrelation function at low packing fractions, that eventually turn into antipersistent tails at high packing fractions. In particular, this finding contradicts the common assumption of Markovianity of velocity in the collisional representation at low packing fractions \[15\]. Furthermore we have analyzed the mean squared displacement, intermediate scattering function and self-part of the van Hove function, or propagator, both in continuous time and collisional representation, showing remarkable similarities with colloidal systems, glassy systems and supercooled liquids close to the glass or jamming transition. These analogies provide a strong indication that within the coexistence phase the simplistic hard-disk model captures properties of glassy behavior.

Finally our analysis shows that, according to the observable of interest, different approximations yield better descriptions of the data. Indeed we have shown that, although the system is generally non-Poissonian, at low packing fractions it can be fairly well described as a Poissonian model, i.e. considering uncorrelated free flight times independent of velocities. This approximation works well if one considers the mean squared displacements \(<\delta^2x(t)>\) and \(<\delta^2x_n>\) or the average time as a function of the number of collisions \(<t_n>\). On the other hand we have pointed out that a different approximation, considering the on-collision velocity process uncorrelated or Markovian but still correlated to the free flight times, provides excellent predictions in describing the probability \( P(\tau) \) at low \( \eta \), the probability \( \Pi(n,t) \) of having \( n \) collisions up to a time \( t \) in the dilute limit, or when one attempts to derive the on-collision stationary velocity distribution function \( \varphi_{col}(v) \) \[13\]. However, none of the former assumptions is entirely correct, since velocities are correlated in collisional representation at any \( \eta \), and they are also correlated with free flight times: therefore none of them can furnish an overall satisfactory theoretical framework, not even in the very dilute regime.

Appendix A: Single component mean free-flight times relation

Let us assume the sequence of velocities a particle acquires during \( N \) collisions is \( \{v_i\} \) where \( i \in [1,N] \). The
number of occurrences of some velocity $v$ is denoted:

$$n_v = \sum_i^N \int_{-\infty}^{\infty} dv \delta(v_i - v), \quad (A1)$$

and the total time spent on the velocity $v$ is then given by $T_v = \sum_i^N \int dv \delta(v_i - v)$. The velocity distribution function in collisional representation follows:

$$\varphi_{coll}(v) = \frac{n_v}{N}, \quad (A2)$$

and the velocity distribution function in continuous time can be approximated as:

$$\varphi_{MB}(v) = \frac{T_v}{\langle \tau \rangle}, \quad (A3)$$

Multiplying and dividing the RHS by $N$, substituting Eq. (A2) and realizing that $T_v$ can be approximated as $T_v = n_v \langle \tau(v) \rangle$ yields the relation:

$$\varphi_{MB}(v) = \frac{\langle \tau(v) \rangle}{\langle \tau \rangle} \varphi_{coll}(v). \quad (A4)$$

**Appendix B: Mean free-path and mean free flight time from kinetic and Enskog theory**

The familiar expression for the average free-flight time arising from kinetic theory for a system of elastic hard disks is [10]:

$$\langle \tau \rangle_{\text{kt}} = \frac{1}{4\pi k_B T n \sigma}, \quad (B1)$$

where $n$ is the density number, i.e. $n = \frac{N}{\pi \sigma^2}$. Recalling that the packing fraction is $\eta = n \pi \sigma^2 / 4$, we obtain

$$\langle \tau \rangle_{\text{kt}} = \frac{\sigma}{16 \eta} \sqrt{\frac{\pi}{k_B T}}.$$  

Fig. 4(a) shows that Eq. (B1) agrees with the numerical data only qualitatively (blue line). The mean free-path is defined as:

$$\langle |\xi| \rangle_{\text{kt}} = \frac{1}{4\pi k_B T n \sigma} \langle |v| \rangle_{\text{cont}} \langle \tau \rangle_{\text{kt}} = \frac{\pi \sigma}{2\eta} \sqrt{\frac{\pi}{k_B T}} \langle \tau \rangle_{\text{kt}}.$$  

The corresponding expression for the single component reads:

$$\langle |\xi| \rangle_{\text{kt}} = \frac{1}{4\pi k_B T n \sigma} \langle |v| \rangle_{\text{cont}} \langle \tau \rangle_{\text{kt}} = \frac{\pi \sigma}{2\eta} \sqrt{\frac{\pi}{k_B T}}.$$  

The mean free path value furnished by the Enskog theory for a system of 2D hard disks is given by:

$$\langle |\xi| \rangle_0 = \frac{\pi \sigma}{2\eta} \sqrt{\frac{\pi}{k_B T}} \langle \tau \rangle_0,$$  

where $Y[x] = (1 - \frac{\alpha}{16} x) / (1 - x)^2$ is the Enskog factor. Notice that the expression furnished in Eq. (B4) differs from the formula provided in Refs. 57 [103] by a factor $1/2$ to match the kinetic theory expression in Eq. (B2), as should be the case. The single component is then:

$$\langle |\xi| \rangle_0 = \frac{\sigma}{2\eta \sqrt{\pi}} \sqrt{\frac{\pi}{k_B T}} \langle \tau \rangle_0.$$  

The expressions in Eqs. (B5) and (B3) are displayed in the inset of Fig. 4(b), showing a non-satisfactory agreement with the average free path obtained in the numerical simulations (red and blue lines respectively). The mean free flight time can be obtained through:

$$\langle \tau \rangle_0 = \frac{\langle |\xi| \rangle_0}{\langle |v| \rangle_{\text{cont}}} = \frac{\sigma}{16 \eta \sqrt{\pi}} \sqrt{\frac{\pi}{k_B T}}.$$  

and is plotted in the inset of Fig. 4(a) with the expression in Eq. (B5) for the mean free path (red line).

**Appendix C: Generalized Kubo theorem in collisional representation**

Let us consider a discrete stochastic process $\xi_n$ such that $\langle \xi_n \rangle = 0$. The relation between the MSD and the symmetrized ACF is provided by Eq. (19), and brought again here:

$$\langle \delta x_n^2 \rangle = 2 \sum_{m=0}^{n-1} \tilde{C}_{\xi \xi}(m)(n - m). \quad (C1)$$

The on-collision transport coefficient $D_n$ is defined as:

$$D_n = \sum_{m=0}^{n-1} \tilde{C}_{\xi \xi}(m), \quad (C2)$$

and it is possible to study its behavior once the dependence of $\tilde{C}_{\xi \xi}$ on $n$ is defined. Two main situations can arise: (i) $D_n \sim \text{const}$, and (ii) $D_n \sim n^{1-\beta}$ ($\beta > 0$).

(i) Suppose that $\tilde{C}_{\xi \xi}$ is such that $D_n = \sum_{m=0}^{n-1} \tilde{C}_{\xi \xi}(m) \sim D$ with $D = \text{const}$. Hence from Eq. (C1) we have:

$$\langle \delta x_n^2 \rangle = 2D_n - 2 \sum_{m=0}^{n-1} \tilde{C}_{\xi \xi}(m)m. \quad (C3)$$

The second term on the RHS of Eq. (C3) is $\sum_{m=0}^{n-1} \tilde{C}_{\xi \xi}(m)m \leq Dn$, yielding:

$$\langle \delta x_n^2 \rangle \sim 2D_n \quad (C4)$$

for a large enough $n$.

(ii) Consider now a process for which $\tilde{C}_{\xi \xi}(n) \sim c_\beta n^{-\beta}$. The corresponding discrete transport coefficient is then given by $[104, 105]$:

$$D_n = c_\beta \left[ \zeta(\beta) \left( \frac{(n-1)^{1-\beta}}{1-\beta} - \beta \int_{n-1}^{\infty} dx x^{-\beta+1} \right) \right], \quad (C5)$$
where $\zeta(\beta)$ is the Riemann zeta function and $[\cdot]$ represents the integer part. Hence for large $n$ we can write $D_n \sim D + c_\beta n^{1-\beta}$ where $D$ is a constant. From Eq. (C1) it then follows:

$$\langle \delta x_n^2 \rangle \sim 2Dn + 2c_\beta \frac{n^{2-\beta}}{(1-\beta)(2-\beta)}.$$  \hfill (C6)

If $0 < \beta < 1$ the process is superdiffusive. Indeed $c_\beta$ is positive meaning that persistent memory effects characterize the free path $c_\beta$. Moreover $D_n$ diverges as $n^{1-\beta}$ according to Eq. (C5). If $1 < \beta < 2$ and $D = 0$ the process is subdiffusive. In this case $c_\beta < 0$, which defines the antipersistent tails of the symmetrized ACF $\tilde{C}_X(n)$. $D_n$ is positive and decays to zero as $n^{1-\beta}$. If $D \neq 0$ the process is diffusive and $D_n \sim D$. If $\beta \geq 2$, $D \neq 0$, one has normal diffusion and $D_n \sim D$.

FIG. 16: (Color online) Self part of the van Hove function. (a) Continuous time $G_S(x,t)$ for $\eta = 0.713$, calculated according to Eq. (27), for two different times $t$ (solid lines). The dashed lines represent the Gaussian form $\frac{1}{\sqrt{2\pi \langle \delta x^2(t) \rangle}} \exp \left( -x^2 / 2 \langle \delta x^2(t) \rangle \right)$, where the values of $\langle \delta x^2(t) \rangle$ have been drawn from Fig. 7(a). Deviations from the Gaussian form are clearly displayed: in particular, for the longer time corresponding to the asymptotic linear regime in Fig. 7(a) non-Gaussian tails are reminiscent of what is found in granular gases and colloids. (b) Collisional representation $G_S(x,n)$ for $\eta = 0.3$, calculated according to Eq. (28), for two different values of $n$ (solid lines). The dashed lines represent the Gaussian form $\frac{1}{\sqrt{2\pi \langle \delta x^2_n \rangle}} \exp \left( -x^2 / 2 \langle \delta x^2_n \rangle \right)$, where the values of $\langle \delta x^2_n \rangle$ have been drawn from Fig. 8(a). Deviations from the Gaussian diffusive form appear. Moreover non-Gaussian tails similar to those in panel (a) characterize the free path dynamics, for $n$ well beyond the plateau in Fig. 8(a). We note that oscillations present in the continuous, representing spatial order due to high packing fractions, are not apparent in the collisional representation, due to the decoupling of space and time (detailed in main text).
FIG. 17: (Color online) Average time after $n$ collisions, $\langle t_n \rangle$, for several $\eta$ (solid lines). Dashed lines correspond to the Poissonian approximation in Eq. (36).
FIG. 18: (Color online). Free path length probability distribution (appearing in Fig. 3(b)) rescaled by: (a) the kinetic theory expression (Eq. (B3)), (b) the average free path (Fig. 4(b)) and (c) the free path furnished by the Enskog theory (Eq. (B6)). None of them shows good collapse of the curves.
