DAS: Dynamic Adaptive Scheduling for Energy-Efficient Heterogeneous SoCs

A. Alper Goksoy, Anish Krishnakumar, Md Sahil Hassan, Allen J. Farcas, Ali Akoglu, Radu Marculescu, and Umit Y. Ogras

Abstract—Domain-specific systems-on-chip (DSSoCs) aim at bridging the gap between application-specific integrated circuits (ASICs) and general-purpose processors. Traditional operating system (OS) schedulers can undermine the potential of DSSoCs since their execution times can be orders of magnitude larger than the execution time of the task itself. To address this problem, we propose a dynamic adaptive scheduling (DAS) framework that combines the benefits of a fast (low-overhead) scheduler and a slow (sophisticated, high-performance but high-overhead) scheduler. Experiments with five real-world streaming applications show that DAS consistently outperforms both the fast and slow schedulers. For 40 different workloads, DAS achieves on average 1.29 \times speedup and 45\% lower EDP compared to the sophisticated scheduler at low data rates and 1.28 \times speedup and 37\% lower EDP than the fast scheduler when the workload complexity increases.

Index Terms—Domain-specific SoC (DSSoC), machine learning, scheduling, run-time classification, policy switching.

I. INTRODUCTION

Heterogeneous systems-on-chip (SoCs), such as Samsung Exynos and Nvidia® Xavier™, combine the flexibility benefits of general-purpose cores with the energy efficiency and performance of custom designs. An emerging example is domain-specific SoCs, which integrate hardware accelerators targeting the commonly encountered tasks (i.e., computational kernels) in the target domain [1].

DSSoCs present a new challenge to the classical scheduling problem due to their specialized pipelines that run domain-specific tasks in the order of nanoseconds, i.e., orders of magnitude faster than general-purpose cores [1]. Hence, achieving high performance with DSSoCs requires task scheduling algorithms that can execute in the order of nanoseconds. Fast and low-overhead scheduling is an effective way to minimizing performance and energy consumption overheads. However, while enabling fast decision-making, simple schedulers can make poor scheduling decisions, especially under heavy workloads.

At low data rates, a low-overhead (fast) scheduler outperforms a more sophisticated scheduler due to the simplicity of the scheduling problem. The number of concurrent tasks and the complexity of scheduling decisions grow with the data rate (heavy workload). Consequently, the overhead of making better decisions pays off, i.e., the sophisticated scheduler starts outperforming the simple one. Hence, there is an opportunity to exploit the tradeoff between the scheduling overhead and decision quality.

We propose a dynamic adaptive scheduling (DAS) framework that combines the benefits of both worlds, i.e., a simple scheduler with fast decision making and a sophisticated scheduler with high-quality scheduling decisions through an integrated decision support mechanism. Making a scheduling decision at the scale of nanoseconds is highly challenging since it requires a scheduler to load the relevant feature data and execute possibly complex decision criteria at the scale of nanoseconds. The following key observations enable us to design the DAS framework that outperforms both types of schedulers taken separately: First, the scheduling is not an ordinary process that may be called in the future with some probability. Instead, it will be called with 100\% certainty and use a subset of available performance counters, i.e., features used for scheduling. Hence, a background process prefetches the relevant features and writes them to a pre-allocated local memory location. Second, the same process can also determine whether a simple or a sophisticated scheduler with a higher overhead would perform better. If the lookup table (LUT) is preferred as the simple scheduler, the only extra delay on the critical path is the time it takes to access the LUT, which is 6 ns measured on Arm Cortex-A53. We run the sophisticated scheduler only if a complex decision is required at runtime.

The major contributions of this work are as follows:

• DAS framework that dynamically combines two schedulers and outperforms each of them taken separately;
• Low scheduling overhead: 4.2 nJ energy and 6 ns runtime for low to medium loads; 27.2 nJ energy and 65 ns runtime for heavy workloads;
• Experimental results with five streaming applications and profiling of scheduling overheads on a Xilinx Zynq ZCU102.

II. RELATED WORK

A variety of task scheduling algorithms, both static [2] and dynamic [3], [4] have been proposed in the literature. While the approaches in [2], [5] optimize the makespan of applications, completely fair scheduler (CFS) widely used in Linux-based OS aims to provide resource fairness to all processes [3]. Although this model works well for the client and small-server systems, DSSoCs demand a novel suite of efficient schedulers that execute with nanosecond-scale overheads. The scheduler complexity and overhead are discussed in [6], [7], [8]. Chronaki et al. [6] propose
two dynamic schedulers, named CATS and CPATH, that detect the longest and critical paths in the application, respectively. The benefits of the CPATH algorithm are rendered ineffective because of its higher scheduling overhead.

Scheduling algorithms proposed in \cite{DAS} combine the benefits of using multiple schedulers. They dynamically switch between three schedulers to adapt to varying job characteristics. However, the overheads of switching between policies are not considered when measuring scheduling overhead. A performance discussion of a round-robin scheduler (simple, low complexity) and the earliest deadline first (high complexity) schedulers and their applicability under different system load scenarios are discussed in \cite{DAS}. In contrast, we combine the low scheduling overhead of a simple scheduler and the decision quality of a sophisticated scheduler based on the system workload. To the best of our knowledge, this is the first approach that uses a novel runtime preselection classifier to choose between simple and sophisticated schedulers at runtime and thus enable nanosecond-scale overhead.

III. DYNAMIC ADAPTIVE SCHEDULING FRAMEWORK

A. Overview and Preliminaries

This work considers streaming applications that can be modeled by a data flow graph (DFG). Consecutive data frames are pipelined through the tasks in the graph. Unlike the current practice, which is limited to a single scheduler, DAS allows the OS to choose one scheduling policy \( \pi \in \Pi \subseteq \{F,S\} \), where \( F \) and \( S \) refer to the fast and slow (or sophisticated) schedulers, respectively. Once the predecessors of a task are completed, the OS can call either a fast (\( \pi = F \)) or a slow scheduler (\( \pi = S \)) as a function of the system state and workload. The OS collects a set of performance counters during the workload execution to enable two aspects for the DAS framework: (1) precise assessment of the system state, (2) desirable features for the classifier to dynamically switch between the fast and slow schedulers.

Table I presents the performance counters collected by DAS. For a DSSoC with 19 PEs, it uses 62 performance counters. The goal of the fast scheduler \( F \) is to approach the theoretically minimum (i.e., zero) scheduling overhead by making decisions in a few cycles with a minimum number of operations. In contrast, the slow scheduler \( S \) aims to handle more complex scenarios when the task wait times dominate the execution times. The goal of DAS is to outperform the optimization metrics (execution time and EDP) of both underlying schedulers by dynamically switching between them as a function of system state and workload.

Table I: Type of performance counters used by DAS framework

| Type            | Features                                                                 |
|-----------------|---------------------------------------------------------------------------|
| Task            | Task ID, Execution time, Power consumption, Depth of task in DFG, Application ID, Predecessor task ID and cluster IDs, Application type |
| Processing Element (PE) | Earliest time when PE is ready to execute, Earliest availability time of each cluster, PE utilization, Communication cost |
| System          | Input data rate                                                           |

overhead, we re-use a subset of the performance counters shown in Table I to make this decision, discussed in Section IV-B.

The OS periodically refreshes the performance counters to reflect the current system state. Each time the features are refreshed, DAS runs a lightweight classifier that determines if the fast or slow scheduler should be used for the next ready task. This decision will always be up to date since it is refreshed with the features that reflect the most recent system state. This way, DAS determines which scheduler should be called even before a task is ready for scheduling. Hence, the preselection classifier introduces zero latency and minimal energy overhead, as described next.

Offline Classifier Design: The first step to design the preselection classifier is generating the training data based on the domain applications known at design time. Each scenario in the training data consists of concurrent applications and their respective data rates (e.g., a combination of WiFi transmitter and receiver chains, at a specific upload and download speed). To this end, we run each scenario twice, as described in Figure 1.

First Execution: The instrumentation enables us to run both fast and slow schedulers each time a task scheduling decision is made. If the decisions of the fast \( (D_{F}) \) and slow \( (D_{S}) \) schedulers for a task \( T_{i} \) are identical, then we label task \( T_{i} \) with \( F \) (i.e., the fast scheduler) and store a snapshot of the performance counters. If the schedulers return different decisions, then the label is left as pending, and the execution continues by following the fast scheduler’s decision, as illustrated in Figure 1. At the end of the first execution, the training data contains a mixture of both labeled \( (F) \) and pending decisions.

Second Execution: The same scenario is executed, this time by always following the slow scheduler’s decisions. At the end of the execution, we analyze the target metric, such as the average execution time and energy-delay product. If the slow scheduler achieves a better result, the pending labels are replaced with \( S \) to indicate that the slow scheduler is preferred despite its larger overhead. Otherwise, we conclude that the fast scheduler’s lower overhead pays off and replace the pending labels with \( F \). An alternative to replacing all pending labels at once is evaluating each decision individually. However, this approach will not be scalable since the scheduling decision at time \( k \) affects not only the immediate action but also all the remaining execution flow.

The training data is generated using 40 different workloads. Each workload is a mix of multiple instances of five applications, consisting of approximately 140,000 tasks in total and executed at 14 different data rates (Section IV-A). A higher data rate presents a larger number of concurrent applications contending for the same SoC resources. Then, we design a low-overhead classifier using machine learning techniques and feature selection methods, as described in Section IV-B and shown in Figure 1.

Online Use of the Classifier: At runtime, a background process
periodically updates a pre-allocated local memory with a small subset of performance counters required by the classifier. After each update, the classifier determines whether the fast F or slow S scheduler should be used for the next available task. When a new ready task becomes available, the features are already loaded, and we know which scheduler is a better choice. Therefore, DAS does not incur any extra delay on the critical path. Moreover, it has a negligible energy overhead, as demonstrated in Section IV.

C. Fast & Slow (Sophisticated) (F&S) Schedulers

The DAS framework can work with any choice of fast and slow scheduling algorithms. This work uses a LUT implementation as the fast scheduler since the goal of the fast scheduler is to achieve almost zero overhead. The LUT stores the most energy-efficient processor in the target system for each known task in the target domain. Unknown tasks are mapped to the next available CPU core. Hence, the only extra delay on the critical path and overhead is the LUT access. To profile the scheduling overhead, we developed an optimized C implementation with inline assembly code. Experiments show that our fast scheduler takes ~7.2 cycles (6 ns on Arm Cortex-A53 at 1.2 GHz) on average and incurs negligible (2.3 nJ) energy overhead.

The DAS framework uses a commonly used heuristic, earliest task first (ETF), as the slow scheduler [10]. ETF is chosen since it performs a comprehensive search to make a decision when the SoC is loaded with many tasks. It recursively iterates over the ready tasks and processors to find the schedule with the fastest finish time, as shown in Algorithm 1. Hence, its computational complexity is quadratic on the number of ready tasks.

IV. EXPERIMENTAL RESULTS

A. Experimental Setup

Domain Applications: The DAS framework is evaluated using five real-world streaming applications: range detection, temporal mitigation, WiFi-transmitter, WiFi-receiver applications, and a proprietary industrial application (App-I) [10], [11]. We construct 40 different workloads by mixing applications in different ratios for our evaluations. More information is provided in our github release for reproducibility [10].

Emulation Environment: One of our key goals in this study is to conduct a realistic energy and runtime overhead analysis. For this purpose, we leverage an open-source Linux-based emulation framework [11]. For our analysis, we incorporate LUT and ETF schedulers into this emulation environment. We generate a wide range of workloads — ranging from all application instances belonging to a single application to a uniform distribution from all five applications. We measure the trend between the number of tasks ready to be scheduled and the scheduling overhead of ETF on the Xilinx Zynq ZCU102. Based on these measurements, we generate a quadratic equation to formulate the ETF scheduling overhead. Later, we utilize this equation to evaluate the average execution time and the EDP of the DAS scheduler.

Simulation Environment: We use DS3 [10], an open-source domain-specific system-on-chip simulation framework, for the detailed evaluation of DAS. DS3 includes built-in scheduling algorithms, models for PEs, interconnect, and memory systems. The framework has been validated with Xilinx Zynq ZCU102 and Odroid-XU3 platforms.

DSSoC Configuration: We construct a DSSoC configuration that comprises clusters of general-purpose cores and hardware accelerators. The application domains used in this study are wireless communications and radar systems. The DSSoC used in our experiments uses the Arm big.LITTLE architecture with 4 cores each. We also include dedicated accelerators for fast Fourier transform (FFT), forward error correction (FEC), finite impulse response (FIR), and a systolic array processor (SAP). We include 4 cores each for the FFT and FIR accelerators, one core for the FEC, and two cores of the SAP. The FEC accelerates the execution of encoder and decoder operations. In total, the DSSoC integrates 19 PEs with a mesh-based network-on-chip to enable efficient on-chip data movement.

B. Exploration of Machine Learning Techniques and Feature Space for DAS

Machine Learning Technique Exploration: We explore different classifiers to co-optimize the classification accuracy and model size towards our minimal overhead goal. Specifically, we investigated support vector classifiers, decision tree (DT), multi-layer perceptron (MLP), and logistic regression (LR). The training process with support vector classifiers with simple kernels exceeded 24 hours, rendering it infeasible. The latency and storage requirements of the MLP (one hidden layer and 16 neurons) did not fit the budgets of low-overhead requirements. Therefore, these two techniques are excluded from the rest of the analysis. Table II summarizes the classification accuracy and storage overheads for the LR and DT classifiers as a function of the number of features. DTs achieve similar or higher accuracies compared to LR classifiers with lower storage overheads. While a DT with depth 16 that uses all features achieves the best classification accuracy, there is a significant impact on the storage overhead, which in turn influences the latency and energy consumption of the classifier. In comparison, DTs with depth 2 and 4 have negligible storage overheads with competitive accuracies (>85%). Hence, for the DAS framework, we adopt the DT classifier with depth 2.

Feature Space Exploration: We collect 62 performance counters in our training data. A systematic feature space exploration is performed using feature selection and importance methods.

| Classifier | Tree Depth | Number of Features | Classification Accuracy (%) | Storage (KB) |
|------------|------------|--------------------|----------------------------|--------------|
| LR         | -          | 2                  | 79.23                      | 0.01         |
| LR         | -          | 62                 | 83.1                       | 0.24         |
| DT         | 2          | 1                  | 63.66                      | 0.01         |
| DT         | 2          | 2                  | 85.48                      | 0.01         |
| DT         | 4          | 6                  | 85.51                      | 0.03         |
| DT         | 16         | 62                 | 91.65                      | 256          |

Cortex-A53 cores running at 1.2 GHz.

C. Performance and Scheduling Overhead Analysis

This section compares the DAS framework with LUT (fast), ETF (slow), and ETF-ideal schedulers. ETF-ideal is a version of the ETF scheduler which ignores the scheduling overhead. It helps us establish the theoretical limit of achievable execution time and EDP. Out of the 40 workloads described in Section II-B, we choose three representative workloads for a detailed analysis of the execution time and EDP trends. These workloads represent different data rates, which are a function of the applications in the workload. Workload-1 (Figures 2d,e) presents low data rate, workload-2 (Figures 2f,a) presents moderate data rates, and workload-3 (Figures 2b,d) represents a high data rate workload.

Figures 2d–c (Figures 2f–e) compare the execution times (EDP) of DAS, LUT, ETF, and ETF-ideal. For workloads 1 and 2, the SoC is not congested at low data rates. Hence, DAS performs similar to LUT. As data rates increase, DAS aptly chooses between LUT and ETF at runtime. Its execution time and EDP is 14% and 15% lower than LUT, and 15% and 42% lower than ETF. For workload-3, the execution time and EDP of ETF are significantly higher than LUT. DAS chooses LUT for >99% of the decisions and closely follows its execution time and EDP.

This study is extended to all 40 workloads. At low data rates, DAS achieves 1.29× speedup and 45% lower EDP compared to ETF, and 1.28× speedup and 37% lower EDP than LUT, when the workload complexity increases. In summary, DAS consistently performs better than either one of the underlying schedulers, successfully adapts to the workloads at runtime, and aptly chooses between LUT and ETF to achieve low execution time and EDP.

The left axis of Figure 3 plots the decision distribution of DAS. It uses LUT for all decisions at the lowest data rate and ETF for 95% of decisions at the highest data rate. At a moderate workload of 1352 Mbps, DAS still uses LUT for 96% of the decisions. The secondary axis of Figure 3 shows the energy overhead of using different schedulers. As DAS uses LUT and ETF based on the system load, its energy consumption varies from that of LUT to ETF. The average scheduling latency overhead of DAS under heavy workloads is 65 ns, and the energy overhead is 27.2 nJ.

We also compared DAS against a heuristic that chooses the fast scheduler when the data rate is less than a predetermined threshold and uses the slow scheduler otherwise. The threshold is chosen judiciously by analyzing the training data used for DAS. Simulation results show that the heuristic closely follows LUT (fast) and ETF (slow) schedulers below and above the data rate threshold, respectively. In contrast, DAS consistently outperforms both schedulers and achieves on average 13% lower execution time than the heuristic across all data rates.

V. CONCLUSION

In this paper, we presented a dynamic adaptive scheduling framework that combines the benefits of fast and sophisticated schedulers for heterogeneous SoCs. DAS achieves an overhead that is as low as 6 ns (4.2 nJ) for a wide range of workload scenarios and on average, 65 ns (27.2 nJ) for heavy workloads for wireless communication and radar system applications. Hence, our approach paves the way for DSSoCs to leverage their potential better to enable peak performance and energy-efficiency of domain applications.
