**Abstract**

The aim of this study was to evaluate the efficacy and safety of prophylactic intraoperative bilateral uterine or internal iliac artery embolization in planned cesarean for pernicious placenta previa in the third trimester of pregnancy.

The patients with pernicious placenta previa were retrospectively included from January 2011 to May 2018, being divided into embolization group and control group. Intraoperative uterine artery embolization (UAE) or internal iliac artery embolization (IIAE) was undertaken to stop intrapartum and postpartum hemorrhage in embolization group.

There were no significant differences on age, pregnancy times, gestational age, neonatal weight, neonatal asphyxia, preterm delivery, low birth weight, and neonatal admission.\(^1\,7\)

**Keywords:** embolization, internal iliac artery, pernicious placenta previa, uterine artery

---

**1. Introduction**

Placenta previa refers to the placenta adjacent or overlying the internal cervical os, frequently complicated with placental accrete, increta or percreta.\(^1\,2\) If placenta implants on the previous cesarean scar, it predicts severe intrapartum hemorrhage.\(^3\) Placenta previa is often associated with previous uterine surgery, grand multiparity, recurrent abortions, previous curettage, advanced maternal age etc.\(^4\) Pernicious placenta previa imposes a high risk of hemorrhage and hysterectomy on mothers, and increases the rate of preterm delivery, low birth weight, and neonatal admission.\(^1\,3\,5\,7\)

Cesarean hysterectomy is the current standard of management of invasive placenta,\(^8\) but in cases of pernicious placenta previa, even hysterectomy might be difficult to control intractable hemorrhage.\(^9\,10\) The newly conservative methods of managing blood loss for pernicious placenta previa during cesarean have been introduced, including uterine or iliac arteries ligation, bilateral uterine artery embolization (UAE), or balloon occlusion of the internal iliac arteries or aortic artery.\(^9\,11\,13\,14\,16\,17\) Among the interventional procedures, selective UAE may be the first choice.\(^13\,14\,16\,17\) However, because of the uterus possibly supplied by one of the ovarian or aberrant arteries, selective UAE might fail to control the intractable bleeding.\(^18\) Additionally, if being too urgent to access uterine arteries, internal iliac artery embolization (IIAE) may be alternative. Four cases of bilateral IIAE were mentioned in 2 studies of UAE for abnormal placenta, but no detailed information is available.\(^13\,17\)

We aimed to evaluate the effectiveness and safety of prophylactic intraoperative UAE or alternative IIAE (when uterine arteries unavailable) in planned cesarean for pernicious placenta previa in the third trimester of pregnancy.
2. Methods

2.1. Setting
The First Affiliated Hospital of Soochow University is a tertiary care referral hospital, with multidisciplinary care for the treatments of pernicious placenta previa.

2.2. Patients
From January 2011 to May 2018, the database of our institution was retrospectively reviewed to identify all cases with pernicious placenta previa. Inclusion criteria were placenta previa cases that had complicated placental accrete, or increta with the placenta implanted on the site of the previous cesarean scar and following sonographic or magnetic resonance imaging (MRI) findings the placenta locating at the site of previous cesarean scar; and babies’ health were followed after discharge. Main outcomes were intraoperative blood loss, transfusion requirement, hysterectomy rate, endovascular or surgical complications, and significant postoperative morbidity. This study was performed with institutional review board approval. No consent was obtained from the participants, as it was a retrospective study. All the data were reviewed separately by 2 researchers. Any discrepancy would be sent to a senior researcher for the final agreement.

Descriptive statistics were used to describe the basic features of the data gathered from our study. Data were presented as percentages or mean ± SD. Statistical analysis was performed using Pearson χ² and Fisher exact tests. Value of P < .05 (2-sided) was considered as statistical significance. SPSS software version 22.0 (IBM, Armonk, NY) was used for all the data analysis.

3. Results
A total of 47 patients with pernicious placenta previa were enrolled in this study: the embolization group (n = 32) and the control group (n = 15). The mean maternal age was 33.25 years (26–41 years). There were no significant differences in age, gestational age, neonatal weight, and neonatal asphyxia, prenatal bleeding, placental implantation, and mortality between the embolized group and the control group (P > .05). The amount of intraoperative and postoperative bleeding in the embolization group was significantly greater than that in the control group (P < .05, Table 1).

Thirty-two patients with pernicious placenta previa were treated by percutaneous transcatheter embolotherapy (UAE, n = 14; IIAE, n = 18) in planned cesarean. The mean maternal age was 32.75 ± 3.45 years. Average gravidity was 3.78 ± 1.21, and average parity was 2.20 ± 0.41. The mean gestational age was 253.65 ± 13.41 days. Thirty-one women had single-fetus pregnancies. Only 1 woman had twins pregnancy. Two (6.25%, 2/32) cases had underwent the second-time embolotherapy after 8 hours of cesarean surgery because of severe vaginal bleeding. The emergency postpartum hysterectomy was performed for 1 (3.12%, 1/32) case after failed embolotherapy because of uncontrolled massive hemorrhage and hypovolemic shock. However, 9 (9/31, 60.0%) cases had hysterectomy after cesarean
delivery in the control group. One case (3.13%, 1/32) died of diffuse intravascular coagulation because of hemorrhagic shock. Transient and self-remitted lumbosacral pain was present in 28 (95%, 28/32) patients and no other severe interventional complications were reported. The serum \( \beta\)-hCG decreased to normal in all patients after 1 month of delivery. The left 30 (93.75%, 30/32) patients with retained uterine had regular monthly cycles. All babies in 2 groups were healthy and no patient had further pregnancy at half to 5 years' follow-up.

4. Discussion

In this study, previous cesarean was present in all 47 cases, whose placenta just located on the cesarean scars. Prophylactic intraoperative UAE or IIAE (if uterine arteries unavailable or too urgent to access) in scheduled cesarean delivery was performed for these patients with pernicious placenta previa in the third trimester of pregnancy. Hysterectomy and reembolization rate were only 3.13% respectively. In 30 patients with uterine retained, their normal menstruations resumed at follow-up. No newborn mortality and severe interventional complications were reported. This strategy of UAE and alternative IIAE was considered as effective and safe. To our knowledge, this is the first study that assesses alternative prophylactic IIAE for UAE in a series of abnormal placenta patients undergoing interventional and conservative managements.

Previous cesarean has been best known as one of the major risk factors of placenta previa.\[4,19\] All patients had the history of cesarean in our study. The incidence of pernicious placenta previa is rising, primarily because of the high cesarean section rate in China. In a large sample study, placenta previa is significantly associated with the high risk of postpartum hemorrhage, blood transfusion, and hysterectomy.\[6\] For patients with pernicious placenta previa, early diagnosis and identification are essential.\[20\] The diagnostic choice for placenta previa is transabdominal and transvaginal ultrasonography and confirmed by

Figure 1. Ultrasound and radiological findings from Case No.16. (A) On sonographic ultrasound the placenta was located at the site of previous cesarean scar and overlaid the internal cervical os. (B) Before cesarean section, the long reverse catheters were placed to catheterize the uterine artery. (C) After fetal delivery, Alis forceps stopped bleeding of uterine incision temporarily. (D) Finishing all of sutures, the interventional radiologist reconfirmed that the embolization of bilateral uterine or internal iliac arteries had already achieved.
magnetic resonance images, which may better verify the extent of placental invasion. In our cases, pernicious placenta previa were strictly diagnosed by concurrent positive transabdominal and transvaginal ultrasonography imaging and intraoperative findings, in which the diagnostic pattern was supported by D'Souza et al.8

In our study, the success rate of the pelvic embolization was 93.75% and the procedure was unsuccessful for controlling intractable hemorrhage in only 1 woman (3.13% compared to 60.0% in control group), requiring emergency hysterectomy, and 1 case died of diffuse intravascular coagulation because of hemorrhagic shock. The hysterectomy rate was very similar to that of a previous study covering total 308 cases of placenta previa during a 8-year period.21 Other small sample studies reported higher hysterectomy rate, varying from 9% to 31%.8,12,13,17,18 Estimated blood loss in the embolization group during the surgery was numerically not much different from or even less compared with those of other studies.13,17,20,22

Major complications of obstetrics interventional radiology included maternal thromboembolic event, pelvic hematoma and arteriovenous malformations, peritonitis, and endometritis. UAE may complicate vesicovaginal fistula. Buttok necrosis and paraplegia were present in a case after bilateral internal iliac artery embolization, which was an exceedingly rare adverse event. As for main IIAE, some studies reported catheter-related complications. Nevertheless, there was no maternal or fetal mortality related to IIAE.23,26,27 In our study, even >50% of patients undertook bilateral internal iliac arteries embolization but the above-mentioned major events were not reported. Well-equipped hospitals with skilled radiologists could prevent from severe adverse events. It is confirmed by our experiences that the procedure of UAE or alternative IIAE is safe for conservative management of abnormal placentation. Moreover, further pregnancies and fetal growth were not affected in 8 women with a history of bilateral IIAE for postpartum hemorrhage.28

We preferred to selectively embolize bilateral uterine arteries because UAE has proven to be very effective and is considered the first choice of treatment for patients with postpartum hemorrhage.16 But in some cases, if uterine arteries being not available or too urgent to access, IIAE was alternative. The alternative procedure was also applied by other authors11,17,23 because it may be difficult to access uterine arteries in the urgent situation of intrapartum bleeding, or because of arterial spasm. And that other pelvic branches (apart from uterine arteries) may supply blood flow of the uterine. To embolize the anterior iliac arteries bilaterally would be better than only the uterine arteries. The anterior division of IIA was often embolized. However, bilateral internal iliac artery embolization is also effective, without major complications,24,26 Although bilateral main IIA were temporarily embolized by gelatin sponge, pelvic vessels should reanalyze after dozens of days.

The use of balloon catheters to prevent post-partum hemorrhage in women with placenta accreta is controversial. Combining balloon occlusion with UAE appears to be beneficial, although main IIAE was alternative. The alternative strategy of UAE or alternative IIAE was even not inferior to combined prophylactic balloon occlusion with immediate embolization.

All the procedures of UAE or IIAE were carried out in a hybrid operating room at our hospital, to avoid extra transferring between angiography room and operation room. We think this is one of the key points to decrease procedure duration, prevent massive bleeding, and reduce fetal radiation exposure, as Konishi et al suggested.29 Intraoperative transporting may be unsafe because of nonstable hemodynamics, subsequently increased maternal mortality, and morbidity.8,29

In the management of placenta, we preferred to remove it as possible. This supports the idea that the success of conservative management depends on the amount of placental tissue left behind. Placenta left in situ at the time of delivery may potentially increase the risk of postpartum hemorrhage and hysterectomy. After the targeted arteries were surely embolized with blood flow markedly decreased, the placenta was removed by manual and piecemeal technique for the cases of adherent placenta in our study. Placenta removal and prophylactic antibiotics reduced hysterectomy rate and prevented complications of endometritis.

Fetal radiation exposure was present in our study group. Owing to the radiological machine, fetal radiation doses could

not be calculated. The section of catheter placement was optimized to reduce fetal radiation exposure. Related studies faced fetal radiation exposure. Kai et al. found that the fetal radiation doses ranged from 12.88 to 31.6 mGy in the time of angiographic catheterization and fetal exposure.

Yu et al. tried to conduct catheter insertion and UAE prophylactic internal iliac artery balloon occlusion. At doses of <50 mGy, the risk of harmful effects to the fetus is considered negligible. Yu et al. tried to conduct catheter insertion and UAE prophylactic internal iliac artery balloon occlusion. At doses of <50 mGy, the risk of harmful effects to the fetus is considered negligible. Thus, fetal radiation exposure is a challenge of interventional radiology in the Obstetrics. A hybrid operation room, high-quality fluoroscopy equipment, and optimized preoperative catheter placement are helpful to reduce the time of angiographic catheterization and fetal exposure.

Limitations of this study included the relatively small sample, retrospective design, and potential harm of fetal radiation exposure. Fetal radiation doses could not be measured, which failed to evaluate the risk of long-term harmful effects on babies. Antepartum MRI and later pathologic diagnosis were not performed to clarify placenta accreta/increta. The effectiveness of maximally adherent placenta - a case report and review of literature.
