ABSTRACT

We present the discovery of a 70 kpc X-ray tail behind the small late-type galaxy ESO 137-001, in the nearby, hot (T = 6.5 keV) merging cluster A3627, from both Chandra and XMM-Newton observations. The tail has a length-to-width ratio of ~10. It is luminous (L_{0.5–2 keV} ~ 10^{41} ergs s^{-1}), with a temperature of ~0.7 keV and an X-ray M_{gas} of ~10^8 M_{⊙} (~10% of the galaxy’s stellar mass). We interpret this tail as the stripped interstellar medium of ESO 137-001 mixed with the hot cluster medium, with this blue galaxy being converted into a gas-poor galaxy. Three X-ray point sources are detected in the axis of the tail, which may imply active star formation there. The straightness and narrowness of the tail also imply that the turbulence in the intracluster medium is not strong on scales of 20–70 kpc.

Subject headings: galaxies: clusters: general — galaxies: clusters: individual (A3627) — galaxies: individual (ESO 137-001) — X-rays: galaxies

1. INTRODUCTION

The intracluster medium (ICM) has long been proposed to play a vital role in shaping the properties of cluster galaxies, especially through the stripping of cold galactic material. Ram pressure stripping is likely an important factor for galaxy transformation in rich environments (see, e.g., Gunn & Gott 1972; Quilis et al. 2000). Radio observations have long revealed an H i deficiency in cluster galaxies, which indicates stripping (e.g., Giovanelli & Haynes 1985). In X-rays, the stripped tails of late-type galaxies only began to be revealed by Chandra and XMM-Newton data (Wang et al. 2004; Sun & Vikhlinin 2005, hereafter SV05; Machacek et al. 2005). Recently, we carried out a systematic analysis of the X-ray thermal coronae of ~200 galaxies in 25 nearby (z < 0.05), hot (kT > 3 keV) clusters (M. Sun et al. 2006, in preparation). During our analysis, we find an X-ray tail in A3627, which is apparently associated with the late-type galaxy ESO 137-001. The narrowness and length of the tail make it the most dramatically stripped X-ray tail of a galaxy found to date.

A3627 is a nearby massive galaxy cluster in the core of the Great Attractor. Kraan-Korteweg et al. (1996) found, in a deep imaging and spectroscopic survey for galaxies behind the Milky Way, that A3627 (at a Galactic latitude of −7°2) is an extremely rich cluster, rivaling Coma and Perseus in mass and galactic content. A major cluster merger is implied by earlier X-ray observations from the Röntgensatellit (ROSAT) and the Advanced Satellite for Cosmology and Astrophysics that reveal a southeast–northwest cluster elongation (Fig. 1a) and a temperature gradient (5–8 keV) along the same direction (Böhringer et al. 1996; Tamura et al. 1998).

The radial velocity of ESO 137-001 is 4630 ± 58 km s^{-1}, almost the same as that of A3627 (4707 km s^{-1}, from the NASA/IPAC Extragalactic Database [NED]). In this Letter, we adopt the cluster redshift to calculate the distance of ESO 137-001. Assuming H_{0} = 70 km s^{-1} Mpc^{-1}, Ω_{M} = 0.3, and Ω_{Λ} = 0.7, the luminosity distance is 68.2 Mpc and 1" = 0.321 kpc. Uncertainties quoted in this Letter are 1 σ.

2. CHANDRA AND XMM-NEWTON DATA

The tailed X-ray source lies in a 15 ks Chandra observation of A3627 (ObsID 4956) performed with the Advanced CCD Imaging Spectrometer (ACIS) on 2004 June 14–15. No background flares were detected. Standard data analysis has been performed. The calibration files used correspond to Chandra Calibration Database version 3.1.0.

The source is also contained within an 18 ks XMM-Newton observation from 2004 August 12. The data were reduced with the Science Analysis System, 6.5.0. After removing large background flares, clean exposures of 17.8, 18.0, and 12.1 ks remain for the MOS1, MOS2, and PN CCDs, respectively.

3. THE TAILED X-RAY SOURCE

The XMM-Newton photon image and adaptively smoothed Chandra images are shown in Figures 1b–1d, which clearly show a long, narrow tail. The tail is only visible in the soft X-ray images. Its brighter southeast end is on the cluster galaxy ESO 137-001 (Fig. 1c). There are no other galaxies as bright as ESO 137-001 in the B band within 7′ of ESO 137-001 in the direction of the tail. Thus, we conclude that the extended X-ray source is physically associated with ESO 137-001.

ESO 137-001 is in a crowded field with many Galactic stars. The galaxy is bright in the optical B band but faint in the Two Micron All Sky Survey K band. The B-band luminosity is (2.3–4.0) × 10^{10} L_{⊙} from NED and HyperLeda, depending on the correction for internal extinction. The K-band luminosity is 1.4 × 10^{10} L_{⊙}. Assuming a K-band mass-to-light ratio of 0.73 (M/L)_{⊙} (Cole et al. 2001), the total stellar mass of ESO 137-001 is only 1.1 × 10^{10} M_{⊙}, which makes it ~5 times less massive than an L_{⊙} galaxy. The B–K color of ESO 137-001 is 1.0–1.6, much smaller than the B–K color of a typical early-type or late-type galaxy (3.7–4.0 and ~3, respectively; Jarrett 2000). Thus, ESO 137-001 is a very blue galaxy. Spectroscopic studies (Woudt et al. 1999, 2004) have revealed Hα, Hβ, [O iii] λ5007, and [N ii] λ6584 emission lines in the spectrum of ESO 137-001. Thus, we conclude that ESO 137-001 is a late-type galaxy with active star formation.

3.1. The Diffuse X-Ray Emission

To better quantify the properties of the tail, we measured Chandra surface brightness profiles along and across it.
(Figs. 1e and 1f). The surface brightness has been corrected for background (from the blank-sky background) and exposure. There is a sharp edge at its southeast end, with a brightness jump of a factor of ~3. The tail is detected to 3.7 (or 71 kpc) north of ESO 137-001. The width of the tail is ~25" (or 8 kpc). If we fit the profile across the tail with a Gaussian plus the local background, the derived full width at half-maximum is only 15.2 ± 2.3 arcsec. Thus, this feature is very narrow, with a length-to-width ratio of ~10.

Integrated Chandra and XMM-Newton spectra of the source were extracted from a rectangular region centered on the source (3.7 × 30" for Chandra and 4.1 × 50" for XMM). We were forced to use a larger extraction region for XMM, as the width of the tail is comparable to the half-power diameter of the XMM mirror (15°). Background was taken from surrounding regions, a 4.5 × 2' box for Chandra and a 5' × 2.5' box for XMM, excluding the source region. Within the source region, 230 ± 24 (point sources excluded), 967 ± 95, and 872 ± 103 net counts in the 0.5–2 keV band are collected from the ACIS, PN, and MOS instruments, respectively. The current data do not allow us to constrain the absorption. As the spectra are well fitted with Galactic absorption at low energies, we fixed the absorption at the Galactic value, 2 × 10^21 cm^-2. The solar photospheric abundance table from Anders & Grevesse (1989) is adopted. A lower energy cutoff of 0.5 keV is used to minimize the calibration uncertainties at low energies. The upper energy cutoff is 7 keV. Each spectrum was fitted with a MEKAL model. The abundance is very low, but the gas temperature is not sensitive to abundance (e.g., T = 0.66 ± 0.06 keV if Z = 1 Z☉). All spectra showed evidence for a hard X-ray excess, so a power-law component was included. Inclusion of the hard component lowers the gas temperature by 10%–20% but greatly improves the fit. The nature of this hard X-ray component is unclear. The expected unresolved contribution from active galactic nuclei (AGNs) is small. There may be some residual emission from the hot ICM, either mixed in the tail or due to the uncertain normalization of the background. Emission of unresolved X-ray binaries in the tail (see § 3.2) is another possibility. Regardless of the model used for the hard component, hot ICM (MEKAL), X-ray binaries, or AGNs (power law), the results for the gas properties are almost the same. The Chandra and XMM results are consistent, so we fitted them simultaneously. The gas temperature is ~0.7 keV (Table 1). We also derived temperatures in two regions, "head" and "trail," defined in Figure 1f. The trail is only marginally hotter (1 σ) than the head. There are some discrepancies between the derived Chandra and XMM luminosities, at the level of 20%–33%, which may be due to uncertainties in the back-
ground normalization (especially for XMM, where the background is higher).

The X-ray gas mass in the tail is estimated by assuming a 25° × 25° × 1.1° box for the head and a 2/6° long cylinder for the trail with constant density. From the normalization derived from the MEKAL fits, the average electron densities in the head and the trail are (1.8–3.5) × 10⁻²⁷ cm⁻³ and (0.7–1.7) × 10⁻²⁷ cm⁻³, respectively, while the X-ray gas mass is (0.7–1.3) × 10¹⁰ M☉ and (0.6–1.5) × 10¹⁰ M☉, respectively, where f is the filling factor of the X-ray gas. If the abundance in the head is 0.3 times solar (the value in the trail within 1 σ), the average electron density and the X-ray gas mass of the head drop by 40%. The filling factor may be large if the observed tail is really due to mixing of cold clouds and hot ICM (see § 4). Since the galaxy and cluster radial velocities are nearly the same, the projected length of the tail may be comparable to the actual length. Thus, the total X-ray gas mass is on the order of 10¹¹ M☉.

The temperature of the surrounding ICM (a 3° × 6° box, excluding the tailed source) was also measured. Since A3627 is behind the Galactic plane, the Galactic soft X-ray foreground is strong. This is proved by the 3–5 times higher than nominal flux in the R4–R5 band of the ROSAT All-Sky Survey image at the position of A3627. As there is no local background available, we used the blank-sky background and added a 0.2 keV MEKAL component (unabsorbed) to mimic the soft X-ray excess. The derived ICM temperature is 6.3±0.7 keV (Table 1). The error from the uncertainty in the temperature of the soft excess is included, as we allow it to vary from 0.1 to 0.4 keV (Markevitch et al. 2003). The ICM electron density from the ROSAT data (Böhringer et al. 1996) is ~1.4 × 10⁻³ cm⁻³ at the projected position of ESO 137-001. Within the uncertainties, the thermal pressure is the same inside and outside the tail, especially if the abundance is not that low.

3.2. X-Ray Point Sources in the Tail

There are three Chandra point sources right on the axis of the tail (P1–P3 in Fig. 1), with a total of 73 counts in the 0.5–10 keV band. Their combined spectrum is hard (Table 1). Within 3° of ESO 137-001, only an additional, fainter point source is detected. The possibility of having three background AGNs aligned in the narrow tail for this shallow observation is ~0.03%, based on the AGN number density derived from three Chandra pointings toward A3627. If P1–P3 are located in the tail, L_2-10 keV = 2.7 × 10⁴⁰ ergs s⁻¹ (the total), which is similar to the total L_2 of three ultraluminous X-ray sources in UGC 6697 (SV05). Since the ICM pressure cannot move stars, the most likely scenario is that there is active massive star formation in the tail, as the stripped clouds, away from their main heating source (the stellar UV radiation), can cool. Hα imaging and H I data are required in order to test this hypothesis.

4. DISCUSSION

The X-ray tail of ESO 137-001 is unique. Our systematic study covers a sky area of 3.1 deg² in 25 nearby hot clusters, but only UGC 6697 in A1367 has a similar tail. However, UGC 6697 is 8 times more luminous than ESO 137-001 in the K₁ band, and its tail does not extend significantly outside of the galaxy (SV05). Even the stripped X-ray tails known in cool clusters and groups (e.g., Machacek et al. 2005) are not as dramatic as the tail of ESO 137-001. The X-ray tail of ESO 137-001 is only the third known X-ray tail of a late-type galaxy in a hot cluster (after Wang et al. [2004] and SV05). While its proximity enables further detailed studies, the tail length and the X-ray point sources in the tail provide additional insight.

Long and narrow X-ray tails have been seen in simulations by Stevens et al. (1999) when the stripping happens gradually and gas is replenished in the galaxy. Similar H I tails have also been seen in other simulations (e.g., Quilis et al. 2000; Vollmer et al. 2001). Two 75 kpc Hα trails have been detected behind two small late-type galaxies in A1367 (Gavazzi et al. 2001), but no X-ray tails are seen in the XMM-Newton data. A 110 kpc, but tilled, H I tail was observed from NGC 4388 in Virgo (Oosterloo & van Gorkom 2005). The tail of ESO 137-001 cannot be the accretion wake of ESO 137-001, as the galaxy is too small and the ICM is too hot. The ESO 137-001 tail could be either the stripped X-ray gas of ESO 137-001 or cold material from ESO 137-001 (e.g., H I gas) mixed with hot ICM. The first scenario requires that the stripped tenuous X-ray gas survive all kinds of instabilities and yet remain distinct from the surrounding ICM for ~10⁸ yr, which is about the time needed for ESO 137-001 to travel from the end of the tail to its current position (71 kpc in projection) at a velocity of 1000 km s⁻¹ (the cluster radial velocity dispersion is 897 km s⁻¹). Mixing of cold interstellar medium (ISM) with hot ICM is preferred, as it is expected after the stripping of cold ISM. The average temperature after mixing (~0.7 keV) is (M_ICM T_ICM + MISM TISM)/(M_ICM + MISM), which gives MISM/M_ICM ~ 8 for T_ICM = 6.3 keV. Thus, the cold ISM dominates the mass but resides in a much smaller volume than the hot ICM before the mixing, if pressure equilibrium is assumed. The evaporation rate of the X-ray tail by the hot ICM is unconstrained within the uncertainties, especially if the mixing is still replenishing the ~0.7 keV X-ray tail.
As ESO 137-001 is not a massive galaxy, it should not be hard to remove its gas. According to the approximate criterion for ram pressure stripping by Gunn & Gott (1972), at a velocity of \( \sim \)800 km s\(^{-1}\) ISM with a density of 1 cm\(^{-3}\) can be removed, if \( n_{\text{ICM}} = 10^{-3} \) cm\(^{-3}\). From the approximation by Mori & Burkert (2000), the stripping process may take \( \gtrsim 10^9 \) yr, if the ISM density is greater than 1 cm\(^{-3}\). Thus, the timescale is long enough to explain the length of the observed tail, and short enough to explain the rarity of such long X-ray tails in late-type galaxies. As there may still be unmixed cold gas in the tail and galaxy, ESO 137-001 must have been a very gas-rich galaxy, with a gas fraction of \( \gtrsim 0.1 \). The star formation rate in ESO 137-001 should be high, based on its very blue color and emission-line spectrum. Therefore, ESO 137-001 resembles the blue dwarf galaxies in the Butcher-Oemler effect (Butcher & Oemler 1978). As there are no other bright cluster galaxies within 7\( ^\prime\) in the tail direction, the star formation in ESO 137-001 is likely triggered by the interaction with the A3627 ICM.

Tails such as that of ESO 137-001 may provide constraints on the turbulent velocity field in clusters. The ICM has long been suspected to be turbulent, although the evidence is sparse. Turbulent eddies on scales of 20–90 kpc have been reported in the Coma Cluster by Schuecker et al. (2004), who concluded that over 10% of the total ICM pressure is in turbulent form. Dolag et al. (2005) used a novel approach to treat the ICM viscosity and found that turbulent energy represents up to 8% of the thermal energy (on a scale of 70 kpc). If we assume that 15% of the ICM pressure is turbulent around ESO 137-001, the ICM velocity dispersion is \( \sim 435 \) km s\(^{-1}\). Each part of the tail is subject to turbulent pressure in random directions, which is \( 2r_{\text{ICM}}v_{\text{tur}}^2 \) per unit length, where \( r \) is the radius of the tail cylinder (\( \sim 4 \) kpc) and \( v_{\text{tur}} \) is the turbulent velocity. This pressure induces an acceleration \( a = 2r_{\text{ICM}}v_{\text{tur}}^2\pi r_{\text{tail}} \) in random directions for different parts of the tail. An eddy on a scale of \( R \) lasts for a time of \( \sim Rh_{\text{tur}}/v_{\text{tur}} \), which is \( \sim 10^8 \) yr for \( R > 20 \) kpc. This implies that large eddies last longer than the current age of the tail. The displacement of a part of the tail over a time interval of \( t \) is then \( at^2/2 \). The tail is straight and narrow from the end to the head, so we set an upper limit of 10’ on the displacement. Assuming thermal pressure equilibrium between the ICM and the X-ray tail (or \( \rho_{\text{tail}}/\rho_{\text{ICM}} = 9 \) from the temperature ratio), we have \( v_{\text{tur}} < 380[t/(0.05 \text{ Gyr})]^{-1} \) km s\(^{-1}\) on scales from 20 kpc to the length of the tail (or 70 kpc). This upper limit is still consistent with the lower limit from Schuecker et al. (2004), especially if ESO 137-001 moves very fast. Turbulence can also be generated as the gas-rich ESO 137-001 moves through the ICM. However, the Reynolds number is \( \sim 3M(L/\lambda) \), where \( M \) is the Mach number, \( L \) is the size of the galaxy, and \( \lambda \) is the mean free path of ions in the ICM. For unmagnetized gas, \( \lambda \sim 10 \) kpc \( \sim L \). Thus, unless magnetic field has reduced \( \lambda \) by more than a factor of 10, the motion of ESO 137-001 cannot drive turbulence in the trail.

Support for this work was provided by NASA grant NNG05GD52G, by NASA Long-Term Space Astrophysics grant NNG05GD82G, and by the Chandra X-Ray Center and the Smithsonian Institute.

Note added in proof.—We reduced the XMM Optical Monitor (OM) data after this Letter was accepted. ESO 137-001 is a luminous galaxy in the UV band. From the OM UVW1 and UVM2 data, we derived a star formation rate of \( \sim 10 M_{\odot} \) yr\(^{-1}\), which makes ESO 137-001 a starburst galaxy. The starburst is most likely triggered by the interaction with the A3627 ICM.
