(July 7, 2018)

We present finite temperature ($T$) extension of the QED$_3$ theory of underdoped cuprates. The theory describes nodal quasiparticles whose interactions with quantum proliferated $hc/2e$ vortex-antivortex pairs are represented by an emergent U(1) gauge field. Finite $T$ introduces a scale beyond which the spatial fluctuations of vorticity are suppressed. As a result, the spin susceptibility of the pseudogap state is bounded by $T^2$ at low $T$ and crosses over to $\sim T$ at higher $T$, while the low-$T$ specific heat scales as $T^2$, reflecting the thermodynamics of QED$_3$. The Wilson ratio vanishes as $T \to 0$; the pseudogap state is a “thermal (semi-)metal” but a “spin/charge dielectric.” This non-Fermi liquid behavior originates from two general principles: spin correlations induced by “gauge” interactions of quasiparticles and fluctuating vortices and the “relativistic” scaling of the $T = 0$ fixed point.

Recent experiments [1, 2, 3] provide support for the view that the pseudogap state of copper oxides represents a phase-disordered superconductor [4]. This view is central to the QED$_3$ theory of underdoped cuprates [5] whose degrees of freedom, Bogoliubov-deGennes (BdG) quasiparticles and fluctuating $hc/2e$ vortex-antivortex pairs, and their mutual interactions are argued to capture the effective low energy physics of a $d$-wave superconductor in a doped Mott insulator. Within the pseudogap phase of high-$T_c$ cuprates this QED$_3$ theory assumes the role played by the Fermi liquid theory in conventional metals and superconductors. The theory possesses three major dynamical symmetries: relativistic and gauge invariance and chiral symmetry, all three emergent in nature [6]. Irrespective of whether the symmetric phase of QED$_3$ is the true $T = 0$ ground state of the system, these symmetries conspire to make its peculiar brand of quantum criticality a strongly attractive basin of influence on physical properties of the pseudogap state.

In this Letter we focus on the subset of such properties which are intrinsically important features of a condensed matter system: thermodynamics and spin response of the pseudogap state. Our primary aim is to stimulate experimental activity by providing explicit and testable theoretical predictions stemming from the theory of Ref. [5]. The summary of our results is as follows: first, in order to derive thermodynamics and spin susceptibility from QED$_3$ theory we generalize its form to finite $T$. This is a matter of some subtlety since, the moment $T \neq 0$, the theory loses its fictitious “relativistic invariance”. Second, we show that the theory predicts a finite $T$ scaling form for thermodynamic quantities in the pseudogap state and propose that this form be tested experimentally. Third, we determine the leading $T \neq 0$ scaling and demonstrate that the deviations from “relativistic invariance” are actually irrelevant for $T$ much less than the pseudogap temperature $T^*$, in the sense that the leading order $T \neq 0$ scaling of thermodynamic functions remains that of the finite-$T$ symmetric QED$_3$ [3]. These deviations from “relativistic invariance” do, however, affect higher order terms. Finally, we evaluate the uniform magnetic spin susceptibility $\chi$ and show that it is bounded by $T^2$ at low $T$ but crosses over to $\sim T$ at higher $T$, closer to $T^*$. Consequently, the Wilson ratio $R = \chi T/c_v$ vanishes as $T \to 0$: the QED$_3$ theory implies the non-Fermi liquid nature of the pseudogap state in cuprates. Such a state is a thermal (semi-)metal but a spin and charge dielectric. [6] Our results are thus suggestive of the breakdown of Wiedemann-Franz law in the pseudogap state.

The spin susceptibility of a $d$-wave superconductor vanishes linearly with temperature. A way to understand this result is to notice that the spin part of the ground state wavefunction, being a spin singlet, remains unperturbed by the application of a weak uniform magnetic field. However, the excited quasiparticle states are not in general spin singlets and therefore contribute to the finite temperature susceptibility. Because their density of states is linear at low energies, at finite temperature the number of quasiparticles that are excited is $\sim k_BT$, each contributing a constant to the Pauli-like uniform spin susceptibility $\chi$. Thus $\chi \sim T$.

When the superconducting phase order is destroyed by proliferation of unbound quantum vortex-antivortex pairs, the low-energy quasiparticles are strongly interacting. The interaction originates from the fact that it is the spin singlet pairs that acquire one unit of angular momentum in their center of the mass coordinate, carried by an $hc/2e$ vortex. This translates into topological frustration in the propagation of BdG “spinon” excitations. As a result, non-trivial spin correlations persist in the excited states of the phase-disordered $d$-wave superconductor. At low temperature these correlations can be described by an emergent U(1) gauge field [6] and lead to suppression of $\chi$ relative to its value for non-interacting BdG quasiparticles. We shall argue below that $\chi \lesssim T^2$.
Similarly, in a \textit{d}-wave superconductor, linear density of the quasiparticle states translates into a $T^2$ dependence of the low-$T$ specific heat. When the interactions between quasiparticles are included the spectral weight is transferred to multi-particle states. Within QED$_3$ theory, however, the strongly interacting IR (infra-red) fixed point possesses emergent “relativistic” invariance and the dynamical exponent $z = 1$. Furthermore, the effective quantum action for vortices in the phase-disordered pseudogap state, introduces an additional lengthscale, the superconducting correlation length $\xi_{\tau,\bot}$ (labels $\tau$ and $\bot$ stand for time- and space-like, respectively). At $T = 0$ this scale serves as a short distance cutoff of the theory and is generically doping ($x$) dependent. We then argue that under rather general circumstances in the vorticity 3-vector $\mathbf{v}$ Deep in the phase disordered pseudogap state the fluctuation 3-vector $\mathbf{v}$ is transferred to multi-particle states. Within QED$_3$ the effective quantum action for vortices, deep in the phase-disordered pseudogap state as we emphasize below, our Lagrangian reads

$$\mathcal{L} = \bar{\psi}(i\gamma_{\mu}\partial_{\mu} + \gamma_{\mu}a_{\mu})\psi + \mathcal{L}_0[a_{\mu}] ,$$

where the summation over $N$ fermion flavors is understood. The integration over Berry gauge field $a_{\mu}$ reproduces the interaction among quasiparticles arising from the topological frustration referred to earlier.

\textbf{Vorticity fluctuations:} Deep in the phase disordered pseudogap state the fluctuations in the vorticity 3-vector $b_{\mu} = \epsilon_{\mu\nu\lambda}\partial_{\nu}a_{\lambda}$ are described by the following “bare” Lagrangian:

$$\mathcal{L}_0[a_{\mu}] = \frac{K}{2} f_{\tau,\bot} \left( \frac{T}{\omega_n}, KT, K_{\tau}T \right) \frac{b_{\mu}^2}{\omega_n^2} + \frac{K^2}{2} f_{\tau} \left( \frac{T}{k}, \frac{T}{\omega_n}, KT, K_{\tau}T \right) b_{\mu}^2 , \quad (1)$$

where $\omega_n$ is Matsubara frequency, $K_{\tau}, K_{\tau}$ are related to the finite superconducting correlation length of the pseudogap state as $K_{\tau} \propto \xi_{\tau,\bot} / \tau_{\tau}$, $K_{\tau} \propto \xi_{\tau}$ [9] and we have also set $v_F = v_\Delta = 1$ for simplicity. $f_{\tau,\bot}$ are general scaling functions describing how $\mathcal{L}_0[a_{\mu}]$ is modified from its “relativistically invariant” $T = 0$ form as the temperature is turned on. They involve only the thermal length $\sim v_F/T$ and $K, K_{\tau}$ and satisfy the condition $f_{\tau,\bot}(0,0,0,0) = f_{\tau}(0,0,0,0) = 1$. Physically, the modifications embodied in $f_{\tau,\bot}$ are due to changes in the pattern of vortex-antivortex fluctuations induced by finite $T$. The explicit expressions for $f_{\tau,\bot}$ depend on the details of a particular model for phase disorder within the pseudogap state – as we emphasize below, however, our results are either completely insensitive to such details or reflect only the most general features of $f_{\tau,\bot}$.

To handle the intrinsic space-time anisotropy, it is convenient to introduce two tensors

$$A_{\mu\nu} = \left( \delta_{\mu0} - \frac{k_{\mu}k_{\nu}}{k^2} \right) \frac{k^2}{k^2} \left( \delta_{\nu0} - \omega_n k_{\nu} / k^2 \right) ,$$

$$B_{\mu\nu} = \delta_{\mu\nu} \left( \delta_{ij} - \frac{k_{i}k_{j}}{k^2} \right) \delta_{ij} , \quad (2)$$

and rewrite the gauge field action as

$$\mathcal{L}_0[a_{\mu}] = \frac{1}{2} \Pi_A^0 a_{\mu} A_{\mu\nu} a_{\nu} + \frac{1}{2} \Pi_B^0 a_{\mu} B_{\mu\nu} a_{\nu} . \quad (3)$$

In the above equations $k_{\mu} = (\omega_n, \mathbf{k})$ i.e. $k^2 = \omega_n^2 + \mathbf{k}^2$. It is straightforward to show that

$$\Pi_A^0 = K_{\tau} f_{\tau} \left( \frac{T}{\omega_n}, KT, K_{\tau}T \right) \left( k^2 + \omega_n^2 \right) ,$$

$$\Pi_B^0 = K_{\tau} f_{\tau} \left( \frac{T}{k}, \frac{T}{\omega_n}, KT, K_{\tau}T \right) \omega_n^2 + \frac{K^2}{2} f_{\tau} \left( \frac{T}{k}, \frac{T}{\omega_n}, KT, K_{\tau}T \right) k^2 . \quad (4)$$

The gauge field $a_{\mu}$ couples minimally to $N$ Dirac spinors representing nodal BCS quasiparticles [9] ($N = 2$ for a single CuO$_2$ layer). Consequently, the resulting Lagrangian reads

$$\mathcal{L} = \bar{\psi}(i\gamma_{\mu}\partial_{\mu} + \gamma_{\mu}a_{\mu})\psi + \mathcal{L}_0[a_{\mu}]$$

where the summation over $N$ fermion flavors is understood. The integration over Berry gauge field $a_{\mu}$ reproduces the interaction among quasiparticles arising from the topological frustration referred to earlier.

\textbf{Specific heat and QED$_3$ scaling of thermodynamics:} The only lengthscale that appear in the thermodynamics are the thermal length $\sim v_F/T$, and the superconducting correlation lengths $K, K_{\tau}$. At $T = 0$, the two correlation lengths $K, K_{\tau}$ enter only as effective short distance cut-offs of the theory since the electronic action is controlled by the IR fixed point of QED$_3$. These observations allow us to write down the general scaling form for the doping-dependent free energy of the pseudogap state

$$\mathcal{F}(T, x) = -\frac{v_F^3}{v_F} \Phi_N (K_{\tau}x)T, K(x)T + \mathcal{E}_0(x) , \quad (6)$$

where $\Phi_N(x, y)$ is the thermodynamic scaling function and $\mathcal{E}_0(x)$ is the reference ground state energy. Note that we still maintain $v_F = v_\Delta$ for simplicity and will discuss Dirac cone anisotropy shortly. In the above scaling form $K_{\tau}$ is directly related to the $T \to 0$ finite superconducting correlation length of the pseudogap state, $\xi_{\text{sc}}(x)$ [9]. The ratio $K_{\tau}/K$ describes the anisotropy between time-like and space-like vortex fluctuations and is also a function of doping $x$. The scaling expressions for other thermodynamic functions can be derived from Eq. (6) by taking appropriate temperature derivatives.

We are interested in the low temperature regime ($T \ll T^*$) in which the thermal length $v_F/T$ is much longer than $K_{\tau}$ and $K (v_F/T \gg \xi_{\text{sc}}(x))$ or, equivalently, in the limit $\Phi_N (x \to 0, y \to 0)$. This is just the limit in which the free energy $\mathcal{F}(0)$ approaches the free energy of the finite temperature QED$_3$ and the precise form of $\Phi_N(x, y)$ becomes unimportant as long as $f_{\tau,\bot}$ remain finite as $T \to 0$. Consequently, $\Phi_N(x, y)$ should be regular at $x = y = 0$ and take on the value $C_{\text{QED}}$ which is a universal positive numerical constant within QED$_3$ [4, 10] (see Ref. 11, 12 for discussion of related issues). Therefore, we
finally find that, at $T \ll T^*$, $\mathcal{F} = -C_{\text{QED}} T^3 / v_F^2$, $S = 3 C_{\text{QED}} T^2 / v_F^2$, and $c_0 = 6 C_{\text{QED}} T^2 / v_F^2$.

The physical origin of the above form for the low temperature scaling can be illustrated by the expression for entropy consisting of the free fermion contribution and the part generated solely through gauge field (vortex fluctuation) mediated interactions \[10\]

$$S = NS_f^0 + S_{int} = N \zeta(T^2 - \frac{\partial}{\partial T} \Delta F),$$

where, for $N = 2$, $\zeta(T) = 9 \zeta(3) / 8 \pi v_F v_{\Delta}$ and

$$\Delta F = \sum_{X=A,B} \int \frac{d^2 k}{(2 \pi)^2} \int_{-\infty}^{\infty} d \omega \coth \left( \frac{\omega}{2 T} \right) \times \tan^{-1} \left( \frac{\Im \Pi_X^{\text{ret}}}{\Re \Pi_X^{\text{ret}} + \Re \Pi_X^{\text{pert}}} \right).$$

Note that we have traded the sum over Matsubara frequencies $\{\omega_n\}$ for an integral over real frequency $\omega$.\[13\]

The retarded fermion polarization function $\Pi_X^{\text{ret}}$ can be written as $N T P_X^\mu (|k|/T, \omega/T)$ while the bare gauge field polarization $\Pi_X^{\text{pert}}$ has the form $K T^2 P_X^\mu (|k|/T, \omega/T, KT, K T)$. By rescaling momenta and frequencies appearing in Eq. \[13\], we see that, in the low temperature limit $K T \ll 1$ ($T \ll T^*$ or $v_F/T \gg \xi_e(x)$), the bare gauge field polarization alters only the higher order corrections to the leading $S \sim T^2$ scaling of QED$_3$ which itself is determined exclusively by the fermion polarization. Equivalently, the finite temperature modifications \[11\] to the original QED$_3$ theory of nodal quasiparticles interacting through vortex-antivortex fluctuations are in effect corrections to the UV cutoff of the pure 2D quantum electrodynamics. However, the leading order scaling of the thermodynamics of pure QED$_3$ is dominated entirely by the IR fixed point, and is consequently independent of the UV cutoff.

**Spin susceptibility:**

The “topological” fermion spinors $\psi = [\psi_1 \psi_\tau]$, $\overline{\psi} = [\overline{\psi}_1 \overline{\psi}_\tau]$ allow us to express the physical fermion density $\rho = \overline{\psi} \gamma_0 \psi$ as a Dirac fermion density $\psi \gamma_0 \overline{\psi}$. Consequently, the theory connects correlations among topologically frustrated BdG spinors to charge fluctuations in QED$_1$. Such correlations suppress spin response in phase-disordered underdoped cuprates and at $T = 0$ one finds $\chi \sim q^2$. Of course, within pure QED$_3$ the charge fluctuations would still vanish even at finite $T$ since that system is always incompressible. Within the QED$_3$ theory of cuprates, however, we must now use the “non-relativistic” modified finite $T$ bare Lagrangian \[11\]. As shown bellow, this translates into a finite spin susceptibility whose precise value reflects the static limit of the scaling function $f_\tau$. This is in contrast to the thermodynamics where the leading low temperature behavior was determined by the pure “relativistically invariant” QED$_3$ and is insensitive to the specific structure of $f_{\tau,\perp}$.

To compute the spin-spin correlation function $\langle S_z(-k)S_z(k) \rangle$ we introduce an auxiliary source $J_{\mu}(k)$ and couple it to fermion three-current. Thus

$$\mathcal{L} [\psi, \overline{\psi}, a_{\mu}, J_{\mu}] = \overline{\psi} (i \gamma_\mu \partial_\mu + \gamma_\tau (a_\mu + J_{\mu})) \psi + \mathcal{L}_0[a_{\mu}],$$

and since it is the $z$-component of the spin that couples to the gauge field we have

$$\langle S_z(-k)S_z(k) \rangle = \frac{1}{Z[J_{\mu}]} \frac{\delta}{\delta J_{\mu}(-k)} \frac{\delta}{\delta J_0(k)} Z[J_{\mu}]igm|_{J_{\mu} = 0},$$

where $Z$ being the quantum partition function. Now we set $a_{\mu} = a_\mu + J_{\mu}$ and integrate out both the fermions and the gauge field $a_{\mu}$. The correlations between $a_{\mu}'$ fields are described by the polarization matrix which to the order $1/N$ can be written in the form $\Pi_{\mu\nu} = (\Pi_A^0 + \Pi_A^F) A_{\mu\nu} + (\Pi_B^0 + \Pi_B^F) B_{\mu\nu}$. The resulting spin correlation function is then readily found to be

$$\langle S_z(-k)S_z(k) \rangle = \frac{\Pi_A^F \Pi_B^F}{\Pi_A^0 + \Pi_A^F} \frac{k^2}{k^2 + \omega_n^2},$$

where $\Pi_A^F$ denotes the fermion current polarization function. Due to the scale invariance of the (massless) topological fermion action, the time component of the retarded polarization function has the scaling form

$$\Pi_A^{F,\text{ret}} (|k|, \omega, T) = N T P_A^F \left( \frac{|k|}{T}, \frac{\omega}{T} \right),$$

where $P_A^F(x, y)$ is a universal function of its arguments and $N$ is the number of the four component Dirac fermion species ($N = 2$ for a single CuO$_2$ layer). In the static limit, $\omega \rightarrow 0$,

$$\lim_{y \rightarrow 0} \text{Re} P_A^F (x, y) = \frac{2 \ln 2}{\pi} + \frac{x^2}{24 \pi^2} + O(x^3); \quad x \ll 1$$

and

$$\lim_{y \rightarrow 0} \text{Re} P_A^F (x, y) = \frac{x}{8} + \frac{6 \zeta(3)}{\pi x^2} + O(x^{-3}); \quad x \gg 1$$

while

$$\lim_{y \rightarrow 0} \text{Im} P_A^F (x, y) = \frac{2 \ln 2}{\pi} + O \left( \frac{y^2}{x^2} \right); \quad x \ll 1.$$
The specific heat goes as \( c_v \sim T^2 \). Furthermore, we argued that at low temperatures the spin susceptibility is suppressed, \( \chi \lesssim T^2 \), due to correlations among BdG spinons mediated by an emergent gauge field \( a_\mu \). This implies a vanishing Wilson ratio and breakdown of the Fermi liquid behavior within the pseudogap state. Finally, the corrections to scaling arising from Dirac cone anisotropy were argued to be non-analytic, representing yet another manifestation of the strongly interacting character of the QED$_3$ brand of quantum criticality.

[6] Remarkably, the chiral symmetry can be spontaneously broken, naturally leading to antiferromagnetism and other fully gapped states: see I. F. Herbut, Phys. Rev. Lett. 88, 047006 (2002); Z. Tântanović, O. Vafek and M. Franz, Phys. Rev. B 65, 180511 (2002).
[7] In the absence of long range Coulomb interactions, there is an additional contribution to the low \( T \) thermodynamics from the Bogoliubov soft phase mode. However, this mode is lifted to plasma frequency once Coulomb interactions are accounted for and therefore it will not change the leading low-\( T \) thermodynamics.
[8] One finds that the pseudogap state is a charge dielectric by retracting the reasoning that leads to Eq. 11 but for the Doppler gauge field \( v_s^\perp \).
[9] \( C_{\text{QED}} \) depends only on \( N \), the number of Dirac fermion species. We are unable to determine \( C_{\text{QED}} \) analytically and will report on its numerical computation elsewhere.
[10] The original derivation of QED$_3$ theory \( \Phi \) mandates that the “free photon” contribution be absent from \( C_{\text{QED}} \) (and \( \Delta F \)) which contains only the parts contributed by free fermions and their interactions mediated by \( a_\mu \).

[14] Strictly speaking \( c \) is a function of \( KT \) and \( K_T \) and we cannot exclude its vanishing in the \( K_T \to 0 \) limit, depending on a specific model for the dual superfluid. In this sense our expression for spin susceptibility should be regarded as only an upper limit. Note that the thermodynamics remain unaffected by the specific form of \( f_{\perp} \) as long as the \( T \to 0 \) behavior defined below Eq. 11 remains in force. Therefore, the vanishing Wilson ratio for \( T \to 0 \) is a rather general result of our theory.
