We report on evidence from lattice simulations that confinement is produced by dual superconductivity of the vacuum in full QCD as in quenched QCD. Preliminary information is obtained on the order of the deconfining phase transition.

1. Introduction

Confinement of color and the deconfining phase transition have been observed in numerical simulations on the lattice. In pure gauge theory, (SU(2) and SU(3)), the transition is well understood. \(\langle L \rangle\), the expectation value of the Polyakov line, is a good order parameter and \(\langle \tilde{L} \rangle\), the expectation value of the ’t Hooft line, is a good disorder parameter \([1]\); the corresponding symmetries are \(Z_N, \tilde{Z}_N\).

The situation is less clear in the presence of dynamical quarks (full QCD). There the symmetry \(Z_N (\tilde{Z}_N)\) is explicitly broken by the coupling of the quarks. In the chiral limit \(m_q = 0\) the chiral parameter \(\langle \bar{\psi} \psi \rangle\) would be a good order parameter for the chiral phase transition; however at \(m_q \neq 0\) also chiral symmetry is explicitly broken. Moreover it is not clear a priori what relation exists between chiral symmetry and confinement.

For a model QCD with two quarks \((N_f = 2)\) of equal mass \(m_u = m_d = m_q\) the phase diagram is schematically represented in Fig. 1. The line of phase transition in the plane \(m_q, T\) is defined by the maxima of susceptibilities \([2, 3]\), among which

\[
\chi_L = \int d^3x \langle L(\vec{x}, 0)L^+(\vec{0}, 0) \rangle \tag{1}
\]

and the susceptibility \(\chi_{ch}\) of the chiral order parameter

\[
\chi_{ch} = \int d^3x \langle \bar{\psi}\psi(\vec{x}, 0)\bar{\psi}\psi(\vec{0}, 0) \rangle. \tag{2}
\]

All of them have a maximum at the same value of \(T\), for a given \(m_q\), which defines the line in Fig. 1. For \(m_q > 3\) GeV, the maxima of \(\chi_L\) diverge proportionally to the volume \(V\),

\[\text{∗Speaker at the Conference (Email: digiaco@df.unipi.it). Partially supported by MIUR and by EC, FMRX-CT97-0122}\]
indicating a first order transition. At \( m_q = 0 \) there are theoretical reasons and numerical indications that the transition is second order \([4, 2, 3]\). At intermediate values of \( m_q \) the susceptibilities studied in \([2, 3]\) stay finite as \( V \to \infty \), and this is interpreted as a crossover.

In the usual approach to phase transitions the free energy (effective lagrangean in the language of field theory) depends on the order parameters in a form which is dictated by symmetry and by scale analysis. The susceptibilities which keep memory of the order of the transition are those of the order parameters. At intermediate quark masses neither \( \langle L \rangle \) nor \( \langle \bar{\psi} \psi \rangle \) are good order parameters.

Figure 1. Phase diagram for two degenerate flavours, \( m_u = m_d = m_q \).

Figure 2. \( \rho \) as a function of \( N_s \) for \( T < T_c \) (left-hand side). \( \rho \) as a function of \( N_s \) for \( T > T_c \): as \( N_s \to \infty \), \( \rho \to -\infty \) if the magnetic charge is non-zero and stays constant otherwise (right-hand side).

A good order parameter exists, which is the vacuum expectation value of a magnetically charged operator \( \mu \). \( \langle \mu \rangle \neq 0 \) signals dual superconductivity of the vacuum \([3, 5, 6, 7, 8]\). According to the ideas of ref.’s \([9, 10]\), dual superconductivity channels the chromoelectric
field acting between a $q\bar{q}$ pair into an Abrikosov flux tube, with energy proportional to the length, $V = \sigma r$.

In quenched QCD [6, 7, 8] a detailed analysis of $\langle \mu \rangle$ shows that the vacuum is indeed a dual superconductor for $T < T_c$ ($\langle \mu \rangle \neq 0$), and makes a transition to normal at $T_c$. Above $T_c$, $\langle \mu \rangle = 0$. As $T \to T_c^-$, $\langle \mu \rangle \simeq \tau^\delta \phi(a/\xi, \xi/N_s)$, with $\tau = (1 - T/T_c)$, $\xi \sim \tau^{-\nu}$ the physical correlation length and $N_s$ the linear spatial extension of the lattice. At the critical point $a/\xi \ll 1$ and can be put to zero, while the variable $\xi/N_s$ can be traded with $N_s^{1/\nu}$. As a consequence the scaling law $\langle \mu \rangle = \tau^\delta \tilde{\phi}(N_s^{1/\nu})$ holds. A better variable than $\langle \mu \rangle$ is $\rho = \frac{N_s}{\partial\beta} \log \langle \mu \rangle$, which is a susceptibility. In terms of $\rho$,

$$\langle \mu \rangle = \exp \left( \int_\beta^\beta \rho(\beta')d\beta' \right)$$  \hspace{1cm} (3)

The scaling law $\rho/N_s^{1/\nu} = f(T/N_s^{1/\nu})$ allows one to control the infinite volume limit $N_s \to \infty$, which is necessary to have a phase transition, and to extract $\nu$, $T_c$, $\delta$. For quenched QCD, $\langle \mu \rangle$ is equally good as $\langle \tilde{L} \rangle$ and is numerically coincident with it [1].

A similar analysis can be repeated for full QCD [11]. $\langle \mu \rangle$ is defined as in quenched and defines the same symmetry. Simulations have been done on $N_t \times N_s^3$ lattices with $N_t = 4$ and $N_s = 12, 16, 20, 32$. The time extension $N_t$ determines the transition temperature, the space extension $N_s$ is used to perform the finite size scaling analysis of the infinite volume limit. The first result is that for $T < T_c$, $\langle \mu \rangle \neq 0$ as $N_s \to \infty$. Indeed in that range of temperature, $\rho$ is $N_s$ independent (see Fig. 2). For $T > T_c$ instead $\rho \simeq -kN_s + c$ ($k > 0$) as $N_s \to \infty$ (see Fig. 2), i.e., by Eq. (3), $\langle \mu \rangle$ is strictly zero in the infinite volume limit.

Around $T_c$, again,

$$\langle \mu \rangle = \tau^\delta \phi \left( \frac{a}{\xi}, \frac{N_s}{\xi}, m_q N_s^\gamma \right).$$  \hspace{1cm} (4)
Figure 4. Values of $\rho$ at the peak as a function of $N_s^{1/\nu}$, with $\nu = 1/3$. The height of the peak clearly scales as $N_s^{1/\nu}$.

A new scale, $m_q$, appears which was absent in the quenched case. However the exponent $\gamma$ is known ($\gamma \approx 2.49$ [2, 3]) and simulations can be made choosing $m_q$ and $N_s$ such that $m_q N_s^\gamma$ in Eq. (4) is kept fixed. Then, neglecting $a/\xi$ again, the scaling law becomes

$$\langle \mu \rangle = \tau^\delta \phi \left(0, \frac{N_s}{\xi}, \text{const.} \right), \quad \rho / N_s^{1/\nu} = f(\tau N_s^{1/\nu}) .$$

The behaviour of $\rho$ around $T_c$ is shown in Fig. 3 for different values of $N_s$: it has a peak at $T_c$, Eq. (3) implies in particular that the values of $\rho$ at the peak ($\tau = 0$) $\bar{\rho}$, scale as $\bar{\rho} \propto N_s^{1/\nu}$, whence $\nu$ can be determined. The result is shown in Fig. 4: contrary to the common belief, the transition is first order. This result is still preliminary and will be cross-checked by more simulations, and by the use of improved actions. A scenario in which confinement is controled by one single order parameter $\langle \mu \rangle$ and by one and the same symmetry pattern (dual superconductivity) is appealing and meets the requirements of $N_c \to \infty$ arguments.
