Abstract Species that pass repeatedly through narrow population bottlenecks (<100 individuals) are likely to have lost a large proportion of their genetic variation. Having genotyped 92 Raso larks *Alauda razae*, a Critically Endangered single-island endemic whose world population in the Cape Verdes over the last 100 years has fluctuated between about 15 and 130 pairs, we found variation at 7 of 21 microsatellite loci that successfully amplified, the remaining loci being monomorphic. At 6 of the polymorphic loci variation was sex-linked, despite the fact that these microsatellites were not sex-linked in the other passerine birds where they were developed. Comparative analysis strongly suggests that material from several different autosomes has been recently transferred to the sex chromosomes in larks. Sex-linkage might plausibly allow some level of heterozygosity to be maintained, even in the face of persistently small population sizes.

Keywords Microsatellite polymorphism · Genetic bottlenecks · Raso lark · *Alauda razae* · Sex-linkage

Introduction

The study of small population genetics is of clear relevance to conservation, where low genetic diversity may be associated with reduced fitness (Spielman et al. 2004). However, the consequences of having low genetic diversity for species with persistently small populations, such as isolated endemics living in restricted habitats, are less clear. In particular, we need a better understanding of the extent to which low diversity may limit a species’ ability to adapt to new challenges, such as novel pathogens or climate change.

Genetic variation can be maintained in small populations in several ways. Lower organisms appear able to evolve higher mutation rates in response to need (Sniegowski et al. 1997). For higher organisms, a more likely mechanism involves balancing selection. Many studies report a link between particular genetic markers and some measure of fitness, particularly associated with resistance to pathogens (Acevedo-Whitehouse et al. 2005). Wherever such selection acts, neighbouring chromosomal regions will tend to have deeper gene trees and hence carry more variability (Charlesworth et al. 1997).

The Raso lark *Alauda razae* provides an interesting test case to ask how much variation can be maintained in a species with a tiny long-term effective population size. Since its description in 1898, this Cape Verdes endemic has been confined to the 7 km² island of Raso where intermittent counts have recorded population fluctuations between about 15 and 130 pairs, with the population sex
mutation rate, were screened for amplification and polymorphism in eight (Richardson et al. 2001). Thirty-five microsatellite loci were chosen either because they were available in our laboratory, or using information from the BIRDMARKER webpage (http://www.shef.ac.uk/misc/groups/molecol/deborah-dawson-birdmarkers.html). Loci showing good amplification and polymorphism (Tables 1, 2) were then used to genotype all 92 Raso lark samples. PCR reactions were carried out in a 10 μl volume containing 20–50 ng DNA, 0.2 mM of each dNTP, 0.5 μM of each primer, 10 mM Tris–HCl, 50 mM KCl, 1.5 mM MgCl₂ and 0.15 U Taq DNA polymerase (Roche Diagnostics GmbH, Mannheim, Germany), using a program of: 94°C for 1 min, 40 cycles of 94°C for 30 s, Ta for 45 s and 72°C for 45 s, followed by 72°C for 2 min (For locus specific Ta’s see Table 2). Fluorescently labelled PCR products were separated on an ABI 377 automatic sequencer and allele lengths determined using Genescan 3.1 software.

**Results**

Thirty-three of the 35 microsatellite primers screened had been developed for other passerine species where cross-species and cross-family utility of primers is well established (Dawson et al. 2000), while the remaining two had been developed for non-passerine species, a plover Charadrius alexandrinus and the chicken Gallus gallus. Fourteen failed to amplify. Of the remainder, another 14 showed no variation but seven were polymorphic in Raso larks (Tables 1, 2). Of the polymorphic markers, six appear to be sex-linked. At four loci (Ase9, Ase37, Hru2, Mme12), all females were heterozygous while all males were homozygous for one, and only one, of the two female alleles. Despite our modest sample size, the probability of 61 males all being homozygous for an allele at frequency 0.83 \([=\frac{61 \times 2 + 31}{184}]\) is 1.6 \(\times 10^{-10}\), while the probability that all 31 females are heterozygous is 7.4 \(\times 10^{-18}\), giving a combined probability of 1.24 \(\times 10^{-27}\). However, given the likely presence of many relatives in such a small population, a more conservative calculation would be of the probability, given the observed numbers of heterozygotes and homozygotes, that these correspond perfectly to the two sexes. The chance that all 31 heterozygotes are female is given by \((31/92) \times (30/91) \cdots \times (1/62) \approx 3.3 \times 10^{-25}\), allowing extremely confident rejection of the null hypothesis that these are autosomal markers. The most parsimonious explanation of our data is that the W and Z chromosomes each carry one allele, this allele differing between the two chromosomes (in birds the female is the heterogametic sex). At one further locus (Ase 18), all females were heterozygous for allele 205 and another allele, while none of the males carried allele 205. Here, a similar calculation can be made (31 animals carry the 205 allele and these are all the 31 females), so it seems that the W chromosome is fixed for allele 205 while the Z chromosome is polymorphic, carrying one of six alleles,
but not allele 205. This locus is the only one at which we found more than two alleles, perhaps hinting that it lies near a gene where selection favours diversity. At the last putatively sex-linked locus (Cu14), all 31 females were 125 homozygotes while, of the males, 39 were ‘125:125’ homozygotes, two ‘127:127’ homozygotes and 20 ‘125:127’ heterozygotes. This pattern is highly unlikely for a neutral autosomal locus (all 31 females have the same genotype that is present in 71 of 92 animals, \( P = (71/91) \times (70/90) \times \ldots \times (40/62) = 0.000043 \). Arguably more likely is that the marker lies on the Z chromosome only. Then, by chance, all 31 females in our sample could have inherited a 125-carrying Z chromosome. This scenario is about 117.5 times as likely as an autosomal location, but nevertheless rather improbable (frequency of 125 allele = 0.843, \( P = 0.843^{31} = 0.005 \)). However, it should be remembered that our sample contains many relatives that are not independent observations, increasing the chance of a significant deviation from random expectation. The final locus (Calex 08) appears to be a normal autosomal locus with two alleles.

### Discussion

To find any appreciable microsatellite polymorphism in the Raso lark is rather unexpected, given the long-term small size of the population. That this preserved polymorphism is almost exclusively sex-linked is surprising for two reasons. First, none of these markers are reported to be sex-linked in the five species (Table 2) from which they were originally developed. This was confirmed by writing to the authors, asking them to re-test for evidence of sex-linkage; all replied in the negative. In addition, Ase9, Ase18 and Cuu4 have been mapped to chicken autosomes three, three and five, respectively (Dawson et al. 2006), confirming directly the lack of sex-linkage. Second, sex-linked loci are relatively rare. Surveying all issues of Molecular Ecology Resources in 2008, we found 413 new markers developed for 22 species of bird of which only 13 were sex-linked. Only a minority of studies explicitly test for sex-linkage, but of those that do, two large studies reveal 11 of 170 markers to be sex-linked (6.5%) (Jaari et al. 2008; Leder et al. 2008), significantly fewer \( \chi^2 = 39.9, \) using Haber’s correction, \( P < 0.001 \), than the six of seven we observed in Raso larks.

Our data further contrast with most other avian studies, which report sex-linked alleles on the Z chromosome only (Ellegren 2000), with all females being phenotypically homozygous (= hemizygous). This reflects the generally much larger size of the Z relative to the W chromosome (75 Mb: 0.26 Mb in chickens) (Dawson et al. 2006). W-linked loci are rare, though appear occasionally (Küpper et al. 2007). Our data reveal a radically different pattern, with, in all but locus Cu14, homologous alleles occurring on both the Z and the W chromosomes. By implication, Raso lark sex chromosomes differ markedly from those of other birds. A clue as to what has happened is given by Bulatova (1973), who observed enlarged sex chromosomes in three species of lark, suggestive of either a fusion or a translocation of chromosomal material between the sex chromosomes and one or more autosomes. The three
Table 2 Characteristics of seven polymorphic microsatellites in Raso lark (n = 92)

| Locus | Ta | # alleles | Allele length | Species where microsatellite first identified and found to be autosomal |
|-------|----|-----------|---------------|------------------------------------------------------------------------|
| Ase9  | 55 | 2         | 135, 139      | Acrocephalus sechellensis                                              |
| Ase18 | 55 | 7         | 203, 205, 214, 218, 220, 222, 224 | Acrocephalus sechellensis                                              |
| Ase37 | 50 | 2         | 214, 236      | Acrocephalus sechellensis                                              |
| Calex08 | 55 | 2         | 198, 228      | Charadrius alexandrinus                                               |
| Cuμ4  | 55 | 2         | 125, 127      | Catharus ustulatus                                                     |
| Hru2  | 50 | 2         | 119, 140      | Hirundo rustica                                                        |
| Mme12 | 50 | 2         | 165, 172      | Melospiza melodia                                                      |

Ase—Richardson et al. (2000), Calex—Küpper et al. (2007), Cuμ—Gibbs et al. (1999), Hru—Primmer et al. (1995), Mme—Jeffery et al. (2001)

species, bimaculated lark *Melanocorypha bimaculata*, greater short-toed lark *Calandrella brachydactyla (cinerea)* and shore lark *Eremophila alpestris*, all have much larger geographic ranges than the Raso lark. Moreover, Ase18 has been genotyped in skylarks *Alauda arvensis* (Hutchinson and Griffith 2008), where our re-analysis of the raw data reveals it is sex-linked, and in sparrows (*S. Griffith, unpublished data*), where we find it is autosomal.

With enlarged sex chromosomes, multiple markers showing a switch from autosomal to sex-linked patterns and allele distributions indicating homologous W and Z alleles, larks, and the Raso lark in particular, appear to have experienced wholesale transfer of material from the autosomes to the sex chromosomes. This transfer appears to have been recent, evidenced both by the unusually large sex chromosomes of some but not all larks, and by the presence of alleles on both the W and Z chromosomes. In most birds, the W chromosome is small, making sex-linked loci hemizygous and reflecting a frequent evolutionary pattern where one of the sex chromosomes tends to degenerate by mutation and loss of material (Charlesworth 1991; Rice 1994). Larks might be unusual in not suffering a degeneration of the W chromosome analogous to the widespread degeneration of the Y chromosome often seen in other animals (Charlesworth and Charlesworth 2000), and also in experimental studies where autosomal material deliberately fused to the sex chromosomes suffers degeneration (Bachtrog and Charlesworth 2000). However, it seems more likely to us that material from a recent autosomal translocation or fusion has had too little time for significant loss to occur. Since three of the six sex-linked loci could be mapped in the chicken genome, we can be confident that at least two autosomes are involved, not just one (an unlikely alternative is that two autosomes fused before a translocation to the sex chromosomes). Just why this has occurred remains unclear. The phenomenon of addition of autosomal material to the sex chromosomes, not dissimilar to that reported in humans (Lahn and Page 1999), appears to be shared by several species of lark including species with large ranges and population sizes (Bulatova 1973).

While the reasons for the transfer are unresolved, we note that it might plausibly provide a mechanism by which some level of heterozygosity could be maintained, even in the face of persistently small population sizes, the two sex chromosomes maintaining two lineages for all markers that reside on them. Small populations usually harbour little variability due to genetic drift, and this is particularly so for the sex chromosomes which, in the absence of strong diversifying selection, are expected to have smaller effective sizes than the autosomes. However, even though each of the sex chromosomes would tend quickly to become monomorphic in a small population, because the W and Z carry different copies, overall greater diversity would be maintained, at least until the W chromosome degeneration began in earnest. This remarkable observation of conserved sex-linked microsatellite diversity in the Raso lark highlights how rapidly genomic reorganisation can occur and provides a fascinating opportunity to study the evolution of autosomal material that has very recently come to lie on a well-established pair of sex chromosomes.
