Evanescent-Wave Pumped and Gain Coupled Whispering-Gallery-Mode Fibre Laser

Xiao-Yun Pu, Yuan-Xian Zhang and Li Feng
Department of Physics, Yunnan University, Kunming, Yunnan, China

1. Introduction

A novel Whispering–Gallery–Mode (WGM) fibre laser is demonstrated by pumping and gain coupling with evanescent-waves in this chapter. The properties of the fibre laser, including energy threshold, produced length and polarization of lasing emission have been investigated. Two important applications of the fibre lasers on optoelectronics, linearly polarized three-color lasing emission and single WGM lasing emission, are also demonstrated in this chapter. The chapter is composed by four parts. In part one, an evanescent wave pumped and gain coupled micro-cavity fiber laser is demonstrated by inserting a bare fused quartz fiber into a glass capillary filled with Rhodamine 6G dye solution, and its energy threshold properties, including the energy threshold varied with the refractive index of the dye solution for different fiber diameters and the produced length of lasing emission, are then investigated. In part two, the polarization properties of an evanescent-wave pumped WGM fibre laser are investigated. It is found that there are two kinds of polarization lasing beam emitting from the evanescent-wave pumped WGM fibre laser under two different pump conditions. In part three, WGM fibre laser, emitting linearly polarized three-color light, is demonstrated by pumping and gain coupling with evanescent waves. In part four, a coupled cylinder-cavity structure, which is used to increase the free spectral range of a WGM fiber laser, is demonstrated by binding two bare optical fibres together, and single WGM lasing emission is realized.

2. Part-I - Threshold property of Whispering-Gallery-Mode fiber lasers pumped by evanescent-waves

In Part I, the threshold properties of Whispering–Gallery–Mode (WGM) fiber lasers pumped by evanescent-waves are investigated. Evanescent-wave gain coupled circular microcavity lasers, such as cylindrical [1-6], spherical[7,8], capillary [9,10] and fiber knot [11] lasers, have generated much interest in recent years, which are due mainly to the fact that the gain media are distributed around their resonators and their potential applications in integrated optics, optoelectronics and optofluidics [12,13] etc. As the evanescent field of a WGM in a circular cavity extends into the gain medium, the gain can be coupled into the WGM that provides optical feedback required by lasing oscillations. To optically excite the gain molecules around a circular cavity, laser beams are usually pumped from the outside of the gain medium [1-5], this pumping configuration, called side-pumping scheme, suffers a low
pump efficiency, because the pump energy is absorbed by all of excited molecules, and only a small number of molecules residing in the WGM evanescent field contributes to the optical gain. To solve this problem, evanescent-wave pumping scheme has been used in circular cavities in recent years, such as bare optical fiber [6], capillary[9], and microfiber knot[11], which reduces lasing threshold from 200 µJ/pulse in the side-pumping scheme[1] to 9.2 µJ/pulse [9] and further to 100 nJ/pulse[11]. Optical gain in the evanescent-wave pumping scheme is produced by evanescent-waves on a fiber surface, the waves are created by a pump light that propagates within the fiber by total internal reflection. Due to a strong spatial overlap between the gain profile and the WGM evanescent field, a high pump efficiency and a long gain distance along the axis of the circular cavity have been achieved [6], which has been successfully used to invent a WGM fiber laser emitting three-wavelength-range lasing beams in a single optical fiber [14].

In the evanescent-wave pumping scheme, laser resonator is surrounded by a dye solution of low refractive index (RI), which acts not only as the gain medium, but also the cladding material for the pumping and circulating light in a microcavity. The penetration depth of pump light into the dye solution determines the gain value, the smaller RI difference between the cavity material and dye solution is, the larger gain is produced by evanescent-wave pumping scheme. Further more, the quality factor (Q value) of a resonator determines the cavity loss, a small RI difference between the cavity material and dye solution means a large cavity loss, which is not benefit to lasing oscillation. Therefore, the threshold property of an evanescent-wave pumped microcavity laser is affected strongly by the RI of cladding solution. However, few works, either the simulations or the experiments, have been reported to explore this important effect of the microcavity laser.

In this part, firstly, the optical gain of a microcavity fiber laser in the evanescent-wave pumping scheme is analyzed by introducing a Gaussian distribution function of pump light, a gain formula is derived. The energy losses related to a circular cavity, including cavity absorption, light scattering and leakage are considered, which leads to a quality-factor equation. Secondly, assuming the derived gain is equal to the energy loss, the energy threshold formula is achieved that is convenient to be compared with our experimental results. Based on the characteristics of frustrated totally internal reflection (FTIR) of pump light traveling along an optical fiber, an attenuated factor is introduced in the threshold energy formula, to achieve the equation for determining the produced length of lasing emission along the axial of the optical fiber. Thirdly, an evanescent-wave pumped and gain coupled WGM fiber laser is fabricated by inserting a bare fused quartz fiber (no cladding) into a glass capillary filled with Rhodamine 6G dye solution, the energy threshold properties of the laser, including the energy threshold varied with the RI of the dye solution for different fiber diameters and the produced length of lasing emission along the fiber axis, have been experimentally investigated. Fourthly, the experimental results are compared with the theoretical calculations, a summary of this work is given. Finally, the analytical formula for resonant line-width of WGM in a circular cavity is derived, which is arranged as the appendix at the end of this chapter.

2.1 Derivation of the energy threshold and the produced length of lasing emission

2.1.1 Optical gain in evanescent-wave pumping scheme

An optical fiber without cladding is immersed in a dye solution, longitudinally pumped by laser light along the fiber axis, pump beams inside the fiber are the meridian beams [15]
which can be drawn in XZ-plane as shown in Fig.I-1. When a pump beam experiences a total internal reflection at the interface of the fiber and the dye solution, its evanescent-wave ($E_p$) excites dye molecules and produces an optical gain around the fiber surface. Because fiber cross-section is a circular microcavity that supports WGM oscillation, the optical gain produced by the $E_p$ is within the WGM evanescent-wave ($E_w$), a strong spatial overlap between two evanescent-waves of $E_p$ and $E_w$ leads to a high pump efficiency in the evanescent-wave pumped WGM fiber laser.

![Fig. I-1. The schematic diagram of a WGM fiber laser pumped by an evanescent-wave.](image)

Pump light propagating within a bare fiber in the form of meridian beams, $\theta_1$: the entrance angle of a beam on the fiber end face, $\theta_i$: the incidence angle of the beam on the fiber side face, $E_p$ and $E_w$: the evanescent-fields of a pump light and a WGM.

The evanescence-wave intensity of the pump light can be calculated by [16]

$$I_p(r) = E_p^2(r) = I_0 \exp[-2k(\beta_1 + \beta_2)(r-a)], \quad (r \geq a), \quad (I-1)$$

Where $a$ is the fiber radius, $k = 2\pi / \lambda_p$ is the wave vector of the $E_p$, $\lambda_p$ is the wavelength of the pump light in vacuum space, $\beta_1 = [n_1^2 \sin^2 \theta_1 - n_2^2]^{1/2}$ is the attenuated factor induced by total internal reflection, $n_1$ and $n_2$ are the RIs of fiber core and cladding solution hereafter ($n_1 > n_2$), $\theta_i$ is the incident angle of the pump light on the fiber interface that is larger than the critical angle $\theta_c = \sin^{-1}(n_2 / n_1)$, $\beta_2 = \lambda_p \alpha_{\text{abs}}^{\text{p, out}}$ is the attenuated factor due to the absorption of $E_p$ by dye molecules, $\alpha_{\text{abs}}^{\text{p, out}}$ is the absorption coefficient of dye solution at the wavelength $\lambda_p$. Assuming the concentration of dye molecules to be $N_0$, the optical gain coefficient in the small signal condition can be written as

$$g(r) = C(\zeta, \lambda_p, n_2)N_0 e_p \exp[-2k(\beta_1 + \beta_2)(r-a)], \quad (r \geq a). \quad (I-2)$$

Where pump energy $e_{p0}$ is used to substitute the intensity of $I_0$ for the convenience of comparing the calculation with the experiment, $C(\zeta, \lambda_p, n_2)$ is a coefficient related to coupling efficiency of pump energy ($\zeta$), the fluorescence-quantum efficiency of dye molecules, which is a function of center wavelength of lasing emission ($\lambda_p$) and the RI for the clad solution ($n_2$). After integrating Eq. (2) along radial direction, the total optical gain can be expressed as
\[ G = \int_{a}^{\infty} g(r) dr = \int_{0}^{\infty} C(\xi, \lambda_c, n_2) N_0 \varepsilon_{p0} \exp\left[-2k(\beta_1 + \beta_2)R\right] dR \]

\[ = \frac{C(\xi, \lambda_c, n_2) N_0 \lambda_p \varepsilon_{p0}}{4\pi \left[ (n_1^2 \sin^2 \theta_i - n_2^2)^{1/2} + \lambda_p \alpha_{abs}^{p, out} \right]} . \] (I-3)

Since the pump-light source is usually a tightly focused laser beams \([6, 9, 11]\), each beam coupled into the fiber incidents upon the fiber side face with different angle \(\theta_i\).

\[ \sin^2 \theta_i = \int f(\theta_i) \sin^2 \theta_i d\theta_i \]

is used to substitute the term of \(\sin^2 \theta_i\) in Eq. (3), where the \(\theta_i^{\text{min}}\) is the minimum incident angle at fiber side face that relates to the maximum incident angle \(\theta_i^{\text{max}}\) at fiber end face as shown in Fig. I-1, \(f(\theta_i)\) is the distribution function of incident angle that is defined as the fraction of pump intensity per unit angle. In order to get the \(f(\theta_i)\), the intensity distribution of pump light on the fiber end face is assumed to be a Gaussian function, \(I(\theta_i) = I_0 \exp\left[-\tan^2 \theta_i / \tan^2 \theta_i^{\text{max}}\right] \). The \(f(\theta_i)\) thus can be expressed as

\[ f(\theta_i) = f_0 \exp\left[-\frac{\cos^2 \theta_i (1 - n_1^2 \cos^2 \theta_i^{\text{min}})}{\cos^2 \theta_i^{\text{min}} (1 - n_1^2 \cos^2 \theta_i)}\right] , \] (I-4)

Where \(f_0\) is the normalized factor that can be calculated by the numeral integration. For the purpose of comparison, a homogeneous distribution function \(f(\theta_i) = 1 / (\pi / 2 - \theta_i^{\text{min}})\) has been used to calculate the term of \(\sin^2 \theta_i\), the calculated optical gains for both distribution functions are shown in Fig.I-2. Let \(\sin^2 \theta_i\) be equal to \(\sin^2 \theta_i^{\text{max}}\), the calculated gain curves are also shown in Fig.I-2.

![Fig. I-2. The calculated optical gains varied with the RI of cladding solution. The curves a-c: \(\theta_i^{\text{max}} = 3.8^\circ, \theta_i^{\text{min}} = 87.4^\circ\), the curves d-f: \(\theta_i^{\text{max}} = 15^\circ, \theta_i^{\text{min}} = 79.8^\circ\). HD: homogeneous distribution, GD: Gaussian distribution. In the calculations, \(n_1=1.458\) for the quartz fiber used in our work, \(\lambda_p=532\) nm, and \(\beta_2 = \lambda_p \alpha_{abs}^{p, out} = 0.062\) for the dye concentration of \(4\times10^{-3}\) M/L.](image-url)
The calculations indicate that (1) the optical gain increases with the increase of $n_2$ value and the incident angle $\theta_1$, (2) when the incident angle $\theta_1$ is small, the effect of distribution function on the optical gain is not obvious, however, the effect can not be neglected with the increase of the incident angle.

### 2.1.2 The cavity energy losses

Assuming the $Q_{abs}$, $Q_{leak}$ and $Q_{sca}$ to be the quality factors of a circular cavity related to the energy loss coefficients $\alpha_{abs}$, $\alpha_{leak}$ and $\alpha_{sca}$, which are caused by cavity absorption, light leakage and scattering, respectively, the total quality factor ($Q_{tol}$) of a WGM in a cylindrical cavity can be expressed as

$$
\frac{1}{Q_{tol}} = \frac{1}{Q_{abs}} + \frac{1}{Q_{leak}} + \frac{1}{Q_{sca}}
$$

(I-5)

The absorption loss ($\alpha_{abs}$) includes the losses inside the cavity ($\alpha_{abs}^{\text{in}}$, related to the inner field of a WGM) and outside the cavity ($\alpha_{abs}^{\text{out}}$, related to the evanescent field of a WGM). To calculate it, we assume an occupation factor ($\eta_\omega$) of a WGM in a circular cavity, which is defined as the ratio of the evanescent-field volume to that of the whole WGM [1]. The occupation factor can be written as

$$
\eta_\omega = \frac{\sigma}{a} \int_0^a |E(r)|^2 dr = \int_0^a |E(r)|^2 dr .
$$

For a TE wave in a cylindrical coordinate system shown in the top left of Fig.I-1, the EM field of a WGM in a cylindrical cavity can be written as [17],

$$
\tilde{H}(r) = A_1 J_n(n_1 k_n^l r) \tilde{e}_z , \quad (0 \leq r \leq a),
$$

(I-6a)

$$
\tilde{H}(r) = A_2 H_n^{(1)}(n_2 k_n^l r) \tilde{e}_z , \quad (r \geq a),
$$

(I-6b)

$$
\tilde{E}(r) = D_1 \left[ \frac{n}{n^2 r^2} J_n(n_1 k_n^l r) \tilde{e}_r - \frac{k_n^l}{n_1} J_n(n_1 k_n^l r) \tilde{e}_\phi \right], (0 \leq r \leq a),
$$

(I-6c)

$$
\tilde{E}(r) = D_2 \left[ \frac{n}{n^2 r^2} H_n^{(1)}(n_2 k_n^l r) \tilde{e}_r - \frac{k_n^l}{n_2} H_n^{(1)}(n_2 k_n^l r) \tilde{e}_\phi \right], (r \geq a).
$$

(I-6d)

Where $A_1$, $A_2$, $D_1$ and $D_2$ are constants; $a$ is the radius of the cavity; $J_n$ and $H_n^{(1)}$ are the $n^{\text{th}}$ Bessel and Hankel functions of the first kind, the derivative of the function denoted by a prime is respect to its argument hereafter; $k_n^l = 2\pi a / \lambda_n^l$ is the wave vector in vacuum for the $n^{\text{th}}$ angular mode number and $l^{\text{th}}$ radial mode order of a WGM. The occupation factors for $(l, n) = (1,745)$, $(1, 1530)$ and $(1, 2256)$, which correspond to fiber diameters $(2a = 93 \pm 1\mu m, 196 \pm 1\mu m$ and $296 \pm 1\mu m$) used in our work and the resonant wavelengths at $576.94$, $583.14$ and $583.72$ nm, have been calculated as the function of $n_2$ value, the calculated results are shown in Fig.I-3 as the violet dotted lines. The absorption coefficient is

$$
\alpha_{abs} = (1 - \eta_\omega)\alpha_{abs}^{\text{in}} + \eta_\omega \alpha_{abs}^{\text{out}},
$$

and the quality factor related to the $\alpha_{abs}$ thus can be written as
\[ Q_{\text{abs}} = \left( \frac{1}{Q_{\text{abs}}^{\text{in}}} + \frac{1}{Q_{\text{abs}}^{\text{out}}} \right)^{-1} = \left[ \alpha_{\text{abs}}^{w,\text{in}} \lambda_n^2 \left( 1 - \eta_{\text{w}} \right) + \alpha_{\text{abs}}^{w,\text{out}} \lambda_n^2 \eta_{\text{w}} \right]^{-1}. \]  

(I-7)

In the wavelength range of 560 to 580 nm, \( \alpha_{\text{abs}}^{w,\text{in}} = 2 \times 10^{-4} \) cm\(^{-1}\) in our calculation, \( \alpha_{\text{abs}}^{w,\text{out}} = 20.5 \) to 2.7 cm\(^{-1}\) for the dye concentration of 4\( \times 10^{-3} \) M/L, and 41.0 to 5.4 cm\(^{-1}\) for the concentration 8\( \times 10^{-3} \) M/L. The calculated \( Q_{\text{abs}} \) s varied with \( n_2 \) value are shown in Fig.I-3 as the red circular points.

For the TE wave, there are two boundary conditions at surface (\( r = a \)) of a cylindrical cavity,

\[ A_1 I_n(n_1 k_n^l a) = A_2 H_n^{(1)}(n_2 k_n^l a) \quad \text{and} \quad D_1 J_n(n_1 k_n^l a) = D_2 H_n^{(1)}(n_2 k_n^l a), \]

which can be deduced from Eq. (6). As \( A_1 D_2 = A_2 D_1 \), the characteristic Eq.(6) for TE wave is written as

\[ n_2^2 J_n(n_1 k_n^l a) = n_1^2 H_n^{(1)}(n_2 k_n^l a). \]  

(I-8)

Let \( x_{l,n} = 2 \pi / \lambda_n^l \) be the size parameter of a circular cavity of radius \( a \), based on Eq. (8), the \( Q_{\text{leak}} \) for a TE wave of a WGM can be calculated with the analytic asymptotic formula [18] shown in Eq. (9).

\[ Q_{\text{leak}} \approx \frac{\pi}{4} \left( n_1^2 - n_2^2 \right) x_{l,n}^2 \left| H_n^{(1)}(n_2 x_{l,n}) \right|^2 \left[ \left( \frac{n}{n_1 x_{l,n}} \right)^2 + \left( \frac{Y_n(n_2 x_{l,n})}{Y_n(n_2 x_{l,n})} \right)^2 \right]. \]  

(I-9)

The \( Q_{\text{leak}} \) s of (\( l, n \)) = (1,745), (1, 1530) and (1, 2256), have been calculated as the function of \( n_2 \) value, the calculated results are shown in Fig.I-3 as the green solid lines.

The value of \( Q_{\text{scat}} \) is of the order of \( 10^{12} \) for an ultrahigh-Q microsphere with smooth surface [19]. The \( Q_{\text{scat}} \) s may be degraded to the order of \( \sim 10^8 \) for the fibers used in our work, which corresponds to a scattering loss \( \alpha_{\text{scat}} \sim 2 \times 10^{-3} \) cm\(^{-1}\), and can be neglected by comparing with \( \alpha_{\text{abs}} \) that is in the range of \( 2 \) to 0.2 cm\(^{-1}\) within the wavelength range of 560 to 580 nm. Therefore, \( 1 / Q_{\text{tot}} \) = \( 1 / Q_{\text{abs}} + 1 / Q_{\text{leak}} \), and the total cavity energy loss is expressed as

\[ \alpha_{\text{tot}} \approx \frac{2 \pi n_1}{\lambda_n^l} \left[ \frac{1}{Q_{\text{abs}}} + \frac{1}{Q_{\text{leak}}} \right]. \]  

(I-10)

The \( Q_{\text{tot}} \) s have been calculated as the function of \( n_2 \) value, the calculated results are shown in Fig.I-3 as the blue solid lines.

The calculated results indicate that (1) for the fiber with a larger diameter (Fig.I- 3c, \( 2a = 296 \) μm), the \( Q_{\text{leak}} \) is always much larger than the \( Q_{\text{abs}} \), the \( Q_{\text{tot}} \) is determined mainly by the \( Q_{\text{abs}} \) as the result, the cavity loss increases smoothly with the \( n_2 \) value; (2) for the fiber with a small diameter (Fig.I- 3a , \( 2a = 93 \) μm), as the \( n_2 \) value increase, the \( Q_{\text{tot}} \) is also determined by the \( Q_{\text{abs}} \) if \( n_2 \) is smaller than 1.385, however, the \( Q_{\text{tot}} \) is determined mainly by the \( Q_{\text{leak}} \) if \( n_2 \) is larger than 1.385, which leads to a sharp increase of the cavity loss; (3) for the fiber with a medium diameter (Fig.I- 3b, \( 2a = 196 \) μm), the situation is between the cases (1) and (2).
Fig. I-3. Quality factors ($Q_{\text{tol}}$ in the blue solid line, $Q_{\text{leak}}$ in the green solid line and $Q_{\text{abs}}$ in red the circles points) and occupation factor ($\eta_w$ in the violet dotted line) varied with $n_2$ value. The calculated fiber diameters are 93 $\mu$m in Fig.I-3a, 196 $\mu$m in Fig.I-3b and 296 $\mu$m in Fig.I-3c.
2.1.3 The formulas of energy threshold and produced length of lasing emission

The threshold condition of lasing action is the gain equaling to the loss. Let Eq. (3) be equal to Eq. (10), the threshold energy can be expressed as

\[
\varepsilon_{th}^{p0} = \frac{4\pi[(n_1^2 \sin^2 \theta_l - n_2^2)^{1/2} + \lambda_p \alpha_{abs}^{p, out}]}{C(\zeta, \lambda_c, n_2)N_0 \alpha_p} \alpha_{tot} \\
= \frac{C(\zeta, \lambda_c, n_2)[(n_1^2 \sin^2 \theta_l - n_2^2)^{1/2} + \lambda_p \alpha_{abs}^{p, out}][Q_{abs} + Q_{leak}]}{N_0 \lambda_p \lambda_c Q_{abs} Q_{leak}}
\]

(Eq-11)

Due to the cladding solution is an absorption medium, the pump energy is gradually attenuated along the fiber axis (Z-axis). The energy attenuation is consistent with Beer’s law, \( \varepsilon_p(Z) = \varepsilon_{p0} \exp(-\alpha_{abs}^{p, Z}) \), where \( \alpha_{abs}^{p, Z} \) is the absorption coefficient of pump light that consists of two parts, the fiber absorption \( \alpha_{abs}^{p, in} \) and the cladding’s absorption \( \alpha_{abs}^{p, out} \). Therefore, the optical gain in Eq. (3) must be written as \( G(Z) = G(0) \exp(-\alpha_{abs}^{p, Z}) \) at the Z point. To calculate the \( \alpha_{abs}^{p, Z} \) value, similar to the definition of the \( \alpha_{abs} \) for a WGM, we define an occupation factor \( \eta_p \) for the pump light, which is the fraction of the evanescent-field intensity to that of the whole pump light. The \( \alpha_{abs} \) is then written as \( \alpha_{abs}^p = (1 - \eta_p)\alpha_{abs}^{p, in} + \eta_p\alpha_{abs}^{p, out} \).

The produced length of lasing emission along the Z-axis increases with the pump energy when the energy is larger than the threshold. For a given pump energy, there is a maximum produced length \( Z_{max} \), which corresponds to the optical gain at \( Z = Z_{max} \) equaling to the cavity loss, that is \( G(Z_{max}) = \alpha_{tot} \). The threshold energy at the position \( Z = Z_{max} \) is thus written as \( \varepsilon_{th}^{p0}(Z_{max}) = \varepsilon_{th}^{p0}(0) \exp(\alpha_{abs}^{p, Z_{max}}) \), and the produced length of lasing emission along the fiber axis can be expressed by the logarithmic function as

\[
Z_{max} = \frac{\ln[\varepsilon_{th}^{p0}(Z_{max})] - \ln[\varepsilon_{th}^{p0}(0)]}{(1 - \eta_p)\alpha_{abs}^{p, in} + \eta_p\alpha_{abs}^{p, out}}.
\]

(Eq-12)

Eqs. (11, 12) will be used to compare with the experimental results in Section 2.2.3 of this part.

2.2 Experimental results and discussion

2.2.1 Experimental setup

The experimental setup is shown in Fig.1-4 schematically. The laser beams (532.0 nm), generated by a frequency doubled and Q-switched Nd:YAG laser, was used as a pump light. The required pump energy was obtained by changing the polarization direction of a polarizer (P_1), and its power was monitored by a power meter (PM) through a beam splitter (BS). The polarizer (P_2) was used to determine the polarization state of the pump light. The lenses L_1 and L_2 were used to compress the size of the pump beams. A bare fiber (F_1, RI=1.458) was inserted into a long glass capillary (C, 1 mm in inner diameter, 120 mm in length), the open space between F_1 and C was filled with ethanol and ethylene-glycol mixed solution of the Rhodamine 6G dye with a concentration of 4×10^{-3} M/L. The RI of the mixed solution, acting as the cladding solution, was varied from 1.361 to 1.430 (measured by an
Abbe refractometer) by adjusting the volume ratio of the two solutions. The pump beam was longitudinally coupled into $F_1$ along the fiber axis by a lens ($L_3$) (focal length = 75 mm) with a conical angle of $2\theta_i = 7.6^\circ$. The beam would propagate within $F_1$ by FTIR if the entrance angle $\theta_i$ was smaller than the critical angle $\theta_{ic}$, which was 15.9° in our experiments. To make sure the pump beams within $F_1$ were all meridian beams, the incident direction of the pump beams was set to be along the axial direction of $F_1$.

The WGM lasing emission ($L_w$) from the rim of $F_1$ was recorded by a spectrometer (Spectrapro 500i) with an ICCD detector (PI-Max 1024RB) via an optical fiber $F_2$, which had a 0.05 nm spectral resolution when a grating of density 2400 g/mm was used. The intensity of $L_w$ was detected by a photo detector (PD, DSi200) after the lasing emission passing through an analyzer $P_3$ positioned on the Y-Z plane, the polarization state of the $L_w$ was checked by rotating $P_3$. The produced length of the $L_w$ along Z-axis was measured by a ruler, and the fiber sizes were measured by a reading microscopy with an accuracy of 1μm.

Fig. I-4. Schematic illustration of the experimental set up. $P_1$, $P_2$ and $P_3$: polarizer, BS: beam splitter, PM: Power meter, $L_1$, $L_2$ and $L_3$: lens, $F_1$: bare quartz fiber, $F_2$: optical fiber, C: glass capillary, $E_P$: evanescent field of pump light, $E_w$: evanescent field of WGM, $L_w$: WGM laser radiation.
2.2.2 Experimental results
As shown in the insert of Fig.I-5, the output intensities of a WGM fiber laser versus pump energies were measured at the position Z = 0 mm (fiber diameter 196 μm, $n_2 = 1.402$). When the pump energy was lower than 12.8 μJ/pulse, only a weak spontaneous fluorescence was observed around $F_1$, once the pump energy was higher than 12.8 μJ/pulse, a strong deep-yellow light emitting from the rim of $F_1$ was observed in the direction vertical to the $F_1$’s axis (X-Y plane), the energy (12.8 μJ) was the lasing threshold corresponding to the onset of the deep-yellow light. The intensity of lasing emission was found to reach its maximum (or minimum) when the polarization direction of $P_3$ are vertical (or parallel) to the $F_1$’s axis, meaning that electrical vectors of the lasing emission are perpendicular to the fiber axis, and the evanescent-wave pumped WGM lasing emission is a typical TE wave. When the pump energy was fixed at 100 μJ/pulse, the lasing spectrum recorded by the spectrometer was shown in the Fig. I-5. The interval between any pair of adjacent lasing peaks is about 0.39 nm, slightly larger than 0.38 nm that is calculated by $\Delta \lambda = \lambda^2/2\pi n_1$ (free spectral range). In the calculation of the $Q_{tol}$ in Section 2, the values of $\lambda_i^n$ and $(l, n)$ should be known in advance. Based on asymptotic formula (Eq. (13)) for the resonant positions of WGMs in cylindrical cavity [20-21], the modes in the lasing spectrum of TE wave in Fig.I-5 were assigned by the pair of numbers $(l, n)$, where $a_l$ is the root of Airy function.

$$\frac{2\pi a_l}{\lambda_n^l} n_1 \approx n + 2^{-1/3} a_l n^{1/3} + \frac{3}{10} 2^{-2/3} a_l^2 n^{-1/3} + 0^{2/3}. \quad (I-13)$$

For the fiber of diameter 196 μm and the resonant wavelength $\lambda_i^n = 583.14$ nm, $l$ and $n$ have been assigned by (1, 1525) as indicated in Fig.I-5. Using the same method, for the fibers of diameter 93 μm ($\lambda_i^n = 576.94$ nm) and 296 μm ($\lambda_i^n = 583.72$ nm), $l$ and $n$ have been assigned by (1, 745) and (1, 2256), respectively.

The threshold energies varied with the $n_2$ value were measured for three fibers with different diameters at the position Z = 0 mm, and the results were shown in Fig.I-6. For the fiber of diameter 296 μm, as shown in Fig.I-6 in green square points, threshold energies decrease monotonously with the increase of $n_2$ value, which is 25.0 μJ (the maximum) if $n_2 = 1.361$, and 13.4 μJ (the minimum) if $n_2 = 1.430$. For the fiber of diameter 93 μm, as shown in Fig.I-6 in the blue triangle points, threshold energies are not sensitive to the change of the cladding solutions when $n_2$ value is between 1.361 and 1.385, but increase sharply when $n_2$ value is larger than 1.385. For the fiber of diameter 196 μm, as shown in Fig.I-6 in the red circle points, the threshold energies decrease slowly with the increase of $n_2$ value when $n_2$ is between 1.361 and 1.410, beyond the value 1.410, the threshold energies increase sharply and there is minimum threshold value (12.0 μJ) when $n_2 = 1.412$.

The output intensities versus pump energies at the positions Z = 50 and 80 mm were measured as shown in Fig.I-7 (cladding solution is the same as that in Fig.I-5). The threshold energy is 100.0 μJ/pulse at Z = 50 mm (Fig.I-7a), while it is 190.0 μJ/pulse (Fig.I-7b) at Z = 80 mm, both values are much larger than 12.8 μJ/pulse measured at Z = 0 mm (Fig.I-5). The results indicate clearly that the threshold energy increases with the measured position (Z), which yields two important issues: first, what experimental law does the pump energy and produced length of lasing emission along the fiber axis follow? Second, which factors affect the produced length of lasing emission?
Fig. I-5. Lasing spectrum from the WGM fiber laser of a fiber diameter 196 μm. The output intensities of the laser versus pump energies are shown in the insert of the figure. The measured free spectral range is 0.39 nm indicated by a pair of arrows, and the assigned modes for each lasing peaks are indicated by brackets.

Fig. I-6. Threshold energies varied with the refractive index of cladding solution at the position of Z = 0 mm. Green square points: experimental data for the fiber of diameter 296 μm, red circle points: experimental data for the fiber of diameter 196 μm, blue triangle points: experimental data for the fiber of diameter 93 μm. Solid curves: theoretically calculated results.
Fig. I-7. The output intensities of a fiber laser versus pump energies at different fiber position (Z). Z = 50 mm in Fig.I-7a, and Z = 80 mm in Fig.I-7b.

To address the problems mentioned above, a contrastive experiment was carried out by using the fiber of diameter 196 μm. First, different dye concentrations were used with a fixed RI of cladding solution (ethanol, $n_2=1.361$), and the produced lengths versus the pump energies was measured as shown in Fig.I-8a ($c = 4 \times 10^{-3}$ M/L) and Fig.I-8b ($c = 8 \times 10^{-3}$ M/L). Second, the dye concentration is the same as that in Fig.I-8a, but the $n_2$ value is increased to 1.402, the produced lengths versus the pump energies was measured as shown in Fig.I-8c. The experimental data (red triangle points) in Fig.I-8 shows that the produced length increases dramatically when the pump energy is just larger than the threshold energy at Z = 0 mm, however, the increasing trend become slow when the produced length reaches a certain value, beyond this value, the produced length is almost saturated with the pump energy. Comparing Fig.I-8a with Fig.I-8b, the energy threshold at Z = 0 mm is shifted from 49.0 μJ/pulse in Fig.I-8a (low dye concentration) to 22.0 μJ/pulse in Fig.I-8b (high dye concentration), however, the produced length is decreased from 120 to 89 mm when the pump energy is fixed at 400 μJ/pulse. Comparing Fig.I-8a with Fig.I-8c, the energy threshold at Z = 0 mm is lowered from 49.0 μJ/pulse in Fig.I-8a ($n_2=1.361$) to 12.8 μJ/pulse in Fig.I-8c ($n_2=1.402$), however, the produced length is decreased from 120 to 97 mm when the pump energy is fixed at 400 μJ/pulse. The observed phenomena shown in Fig.I-6 and Fig.I-8 can be well explained by the theory described in Section 2.1.3.

### 2.2.3 Comparing experimental results with the theoretical calculation

The Eq. (11) is used to calculate the threshold energy varying with $n_2$ value at the position Z = 0 mm. Each parameter is known except the coefficient $C(\zeta, \lambda_c, n_2)$ in the Eq. (11). $C(\zeta, \lambda_c, n_2)$ is treated as $C(\lambda_c, n_2)$ for a fiber with certain diameter, since the coupling efficiency of pump energy is unchangeable, and $C(\lambda_c, n_2)$ is approximately treated as
Fig. I-8. The produced length of lasing emission versus pump energy. The $n_2$ value is fixed at 1.361, but the dye concentrations are $4 \times 10^{-3} \text{ M/L}$ in Fig. I-8a and $8 \times 10^{-3} \text{ M/L}$ in Fig. I-8b. The dye concentration is the same as that in Fig. I-8a, but the $n_2$ values is 1.402 in Fig. I-8c. The red triangle points with error bars are experimental data, the solid curves are theoretically calculated results for various fitting parameters ($\eta_p$).

$C(\lambda_c)$ when solvent effect in dye molecules is neglected. Pairs of experimental data $(n_2, \varepsilon_{p0}^{hl})$ and the related $Q_{tol}$ value are substituted into the Eq. (11) to determine $C(\lambda_c)$. For the fiber of diameter $2a = 296 \mu\text{m}$ at central wavelength $\lambda_c \sim 583.72 \text{ nm}$, $(n_2, \varepsilon_{p0}^{hl}, Q_{tol}) = (1.361, 21.5 \mu\text{J}, 2.21 \times 10^7)$, the determined $C = 6.07 \times 10^{20} (\mu\text{J. m}^{-1})$. For the fiber of diameter $2a = 196 \mu\text{m}$ at central wavelength $\lambda_c \sim 583.14 \text{ nm}$, $(n_2, \varepsilon_{p0}^{hl}, Q_{tol}) = (1.361, 25.0 \mu\text{J}, 1.66 \times 10^7)$, the determined $C = 5.30 \times 10^{20} (\mu\text{J. m}^{-1})$. For the fiber of diameter $2a = 93 \mu\text{m}$, three values $(n_2, \varepsilon_{p0}^{hl}, Q_{tol}) = (1.361, 15.5 \mu\text{J}, 1.19 \times 10^6), (1.386, 20.0 \mu\text{J}, 1.36 \times 10^5)$ and $(1.409, 256.1 \mu\text{J}, 1.85 \times 10^5)$ are chosen to suit the spectral shift with $n_2$ value, the determined $C(\lambda_c = 576.94 \text{nm}) = 2.33 \times 10^{19}$, $C(\lambda_c = 569.91 \text{nm}) = 3.86 \times 10^{18}$ and $C(\lambda_c = 564.92 \text{nm}) = 7.82 \times 10^{17} (\mu\text{J. m}^{-1})$, respectively. The calculated energy thresholds shown in Fig. I-6 fit the experimental data very well after the $C$ values are determined.
The dependence of energy threshold on \( n_2 \) value for the different fiber diameters can be understood when the properties of optical gain and cavity loss are considered simultaneously. Both optical gain and cavity loss increase with \( n_2 \) value, the increment of energy threshold can be expressed by Eq. (11) as

\[
\Delta e_{\text{th}}(n_2) = g(n_2)\Delta \alpha_{\text{tol}}(n_2) - |\Delta g(n_2)|\alpha_{\text{tol}}(n_2), \quad (I-14)
\]

where \( g(n_2) = 4\pi[n_2^2 \sin^2 \theta_i - n_2^2]^{1/2} + \lambda_p \alpha_{\text{abs}, \text{out}}^p |/CN_p \lambda_p \) is the factor related to optical gain. If \( |\Delta g|/g > \Delta \alpha_{\text{tol}} / \alpha_{\text{tol}} = |\Delta Q_{\text{tol}}|/Q_{\text{tol}} \), that is the relative increment of optical gain being larger than that of cavity loss, thus \( \Delta e_{\text{th}}(n_2) < 0 \), otherwise \( \Delta e_{\text{th}}(n_2) > 0 \).

For the fiber of diameter \( 2a = 296 \) \( \mu \text{m} \), \( |\Delta g|/g \) is always larger than \( \Delta \alpha_{\text{tol}} / \alpha_{\text{tol}} = |\Delta Q_{\text{tol}}|/Q_{\text{tol}} \) when \( n_2 \) varying from 1.361 to 1.430, thus \( \Delta e_{\text{th}}(n_2) < 0 \), meaning that the energy threshold decreases monotonously with the increase of \( n_2 \), which is shown in Fig.I-6 as the green square points. For the fiber of diameter \( 2a = 93 \) \( \mu \text{m} \), \( |\Delta g|/g \) is slightly larger than \( \Delta \alpha_{\text{tol}} / \alpha_{\text{tol}} \) when \( n_2 \) varying from 1.361 to 1.385, thus \( \Delta e_{\text{th}}(n_2) \sim 0 \), meaning that the increased optical gain compensates the increased cavity loss and the energy threshold keeps stable; however, \( |\Delta g|/g < \Delta \alpha_{\text{tol}} / \alpha_{\text{tol}} \) after \( n_2 > 1.385 \), thus \( \Delta e_{\text{th}}(n_2) > 0 \), meaning that more pump energy is required to compensate the cavity loss and the threshold energy increases with the increase of \( n_2 \) value, which is shown in Fig.I-6 as the blue triangle points. For the fiber of diameter \( 2a = 196 \) \( \mu \text{m} \), \( n_2 = 1.412 \) is a critical RI that corresponding to \( |\Delta g|/g \sim \Delta \alpha_{\text{tol}} / \alpha_{\text{tol}} \). When \( n_2 < 1.412 \), \( |\Delta g|/g > \Delta \alpha_{\text{tol}} / \alpha_{\text{tol}} \), but \( |\Delta g|/g < \Delta \alpha_{\text{tol}} / \alpha_{\text{tol}} \) when \( n_2 > 1.412 \). Therefore, there is a minimum threshold energy at \( n_2 = 1.412 \), which is shown in Fig.I-6 as the red solid points.

Eq. (12) is used to calculate the produced length of lasing emission varied with pump energy. Fiber absorption coefficient \( (\alpha_{\text{abs}, \text{in}}^p) \) is 0.0002 \( \text{cm}^{-1} \), and the cladding absorption \( (\alpha_{\text{abs}, \text{out}}^p) \) is 1156 \( \text{cm}^{-1} \) (2312 cm\(^{-1}\)) at \( \lambda_p = 532 \) nm for dye concentration of \( 4 \times 10^{-3} \text{ M/L} (8 \times 10^{-3} \text{ M/L)} \). The occupation factor for pump light \( (\eta_p) \) is still an unknown value that is used as a fitting parameter in Eq. (12), the \( \eta_p \) value for fitting the experimental data best is considered as the true \( \eta_p \). The fitting results are shown in Fig.I-8. For the three experimental conditions of (1) \( c = 4 \times 10^{-3} \text{ M/L} \) and \( n_2 = 1.361 \) in Fig.I-8a, (2) \( c = 8 \times 10^{-3} \text{ M/L} \) and \( n_2 = 1.361 \) in Fig.I-8b, and (3) \( c = 4 \times 10^{-3} \text{ M/L} \) and \( n_2 = 1.402 \) in Fig.I-8c, Eq. (12) fits the experimental data best if \( \eta_p = 1.43 \times 10^4 \), \( 1.34 \times 10^4 \), and \( 2.85 \times 10^4 \), respectively. It is clear that the experimental data of \( Z_{\text{max}} \) and \( e_{\text{th}}^p(Z_{\text{max}}) \) follow Eq. (12) well.

Comparing Fig.I-8a with Fig.I-8b in the same \( n_2 \) value, a large dye concentration in Fig.I-8b will attenuate more evanescent field of the pump light, and reduce the penetration depth of the pump light into the cladding solution, leading the \( \eta_p \) value to lower slightly down from \( 1.43 \times 10^4 \) in Fig.I-8a to \( 1.34 \times 10^4 \) in Fig.I-8b. Based on \( \alpha_{\text{abs}}^p = (1-\eta_p)\alpha_{\text{abs}}^{\text{in}} + \eta_p\alpha_{\text{abs}}^{\text{out}} \), the calculated \( \alpha_{\text{abs}}^p \) values are 0.17 \( \text{cm}^{-1} \) in Fig.I-8a and 0.31 \( \text{cm}^{-1} \) in Fig.I-8b. A large absorption coefficient \( \alpha_{\text{abs}}^p \) of cause, will lead to a short produced length of lasing emission for a given pump energy. The energy threshold at the position \( Z = 0 \) mm is determined mainly by the dye concentration, the dye concentration in Fig.I-8b is twice as that in Fig.I-8a, therefore, the energy threshold at \( Z = 0 \) mm is reduced from 49 (\( c = 4 \times 10^{-3} \text{ M/L} \) in Fig.I-8a) to 22 \( \mu \text{J/pulse} \) (\( c = 8 \times 10^{-3} \text{ M/L} \) in Fig.I-8a).
Comparing Fig.I-8a with Fig.I-8c in the same dye concentration, a large $n_2$ value in Fig.I-8c implies a long penetration depth of the pump light into the cladding solution, which leads $\eta_p$ value to rise up from $1.43 \times 10^{-4}$ in Fig.I-8a to $2.85 \times 10^{-4}$ in Fig.I-8c, corresponding $\alpha_{\text{abs}}$ values to increase from 0.17 cm$^{-1}$ to 0.33 cm$^{-1}$. Based on Eq. (12), the produced length of lasing emission in Fig.I-8c will be shorter than that of Fig.I-8a for a given pump energy. The energy threshold at the position $Z = 0$ mm is determined mainly by $n_2$ value at this time, a large $n_2$ value implies a long penetration depth of pump light into cladding solution, and thus a large occupation factor $\eta_p$. When $\eta_p$ value increasing from $1.43 \times 10^{-4}$ in Fig.I-8a ($n_2=1.361$) to $2.85 \times 10^{-4}$ in Fig.I-8c ($n_2=1.402$), more dye molecules are excited by the given pump energy, it is reasonable that the energy threshold is reduced from 49 to 12.8 $\mu$J/pulse.

3. Part II - Polarization properties of an evanescent-wave pumped Whispering-Gallery-Mode fibre laser

In Part II, the polarization properties of an evanescent-wave pumped Whispering Gallery Mode (WGM) fibre laser evanescent-wave pumping scheme are investigated. The dye gain is produced by the evanescent field of the pump light, therefore, the polarization state of the evanescent field determines the vibration states of excited molecules, consequently the polarization properties of lasing emission of the evanescent-wave pumped WGM fibre laser. We find that when the pump beam is strictly along the axial direction of an optical fibre, the lasing emission is transverse electric (TE) wave and the electrical vector of emitting point is along the radial direction of the optical fibre, which forms a special radial polarized radiation; while the pump beam deviates from the axial direction of the optical fibre, both TE and transverse magnetic (TM) waves exist in the lasing emission, which forms a mixed polarization radiation with radial and axial polarized states. The radial polarization laser is useful in the application of photo-etching [22] and high resolution microscope [23], etc. We report on our experimental results and give the explanation for observed phenomenon in this part.

3.1 Experimental setup

The experiment setup is shown in Fig.II-1. A pulsed Nd:YAG laser ($\lambda=532$ nm, pulse width=7 ns) is used as a pump source. The pump laser beams pass two polarizers $P_1$ and $P_2$. $P_2$ is used to determine polarized state of the pump beams, while $P_1$ is used to change pump energy by rotating its polarization direction. Lenses $L_1$ and $L_2$ are used to shrink the pump beams size from original 8 mm to 1.5 mm. $F_1$ of diameter 196 $\mu$m is a barely optical fibre with the refractive index of 1.458. After being focused by lens $L_3$ (focal length =75 mm), the pump beams are end-fired into $F_1$ with an incident angle $\theta_i =1.2^\circ$. To make sure the pump light is meridian beams [15] when propagating in $F_1$, the axis of $F_1$ is adjusted strictly along the $z$-axis. The pump light will be skew beams [15] in $F_1$ when the angle between the axis of $F_1$ and the $z$-axis is about $10^\circ$.

The fibre $F_1$ is inserted into a glass tube $D$ with the inner diameter of 2 mm. A mixed solution of ethanol and ethylene glycol doped with Rhodamine 6G dye molecules is filled into the glass tube, and the concentration and refractive index of the dye solution are $3 \times 10^{-3}$ mol/L and 1.422, respectively. The pump beams will propagate within $F_1$ by TIR if the incident angle $\theta_i$ is smaller than 37.6$^\circ$. Evanescent field $E_p$ of the pump beams excite the dye
molecules in the dye solution, photons in evanescent field $E_{WGM}$ that belongs to a WGM of circular cavity built in $F_1$, stimulate the excited molecules, the $E_{WGM}$ also couples dye gain into the circular cavity [1, 2], and then forms lasing oscillation in the circular cavity with the support of the WGM. Lasing energy $L_{WGM}$ radiates from the rim of $F_1$ in the plane of $xy$, an optical fibre $F_2$ transmits part of the $L_{WGM}$ to the entrance slit of the spectrometer (Spectrapro 500i, ICCD: PI–MAX). The intensity of $L_{WGM}$ also can be detected by a photo detector PD (DSi200) after the lasing emission passing the polarizer $P_3$, which is positioned on the $yz$ plane. The angle between $P_3$ and the y-axis is defined as $\Phi$ which is zero as when $P_3$ is along in the y-axis direction. $\Phi$ can be adjusted by rotating $P_3$.

![Experimental setup](image)

Fig. II-1. Experimental setup

### 3.2 Experimental results and discussion

#### 3.2.1 Pump along the optical fibre’s axis

When pump beams are strictly in the axial direction of $F_1$, polarizer $P_2$ is set along the y-axis direction at first. Polarization properties of lasing beams are checked and recorded by PD together with another polarizer $P_3$, the background subtracted and normalized signals are shown in Fig.II-2. Fig.II-2 shows that the intensity of lasing emission (solid points with error bar) reaches its maximum when $P_3$ is set vertically to the $F_1$’s axis ($\Phi=0^\circ, 180^\circ$ and $360^\circ$), while it reaches its minimum when $P_3$ is set along the $F_1$’s axis ($\Phi=90^\circ$ and $270^\circ$). The curve in Fig.II-2 is drawn by Malu’ s Law, $I = \cos^2 \Phi$, the consistency between the curve and experimental data indicates that, when the pump beams are strictly along the $F_1$’s axis, the electrical vector of lasing emission is vertical to the fibre’s axis, and the evanescent-wave pumped WGM laser is of a typical TE wave lasing emission. To check the dependence of the lasing emission on the polarization of pump beams, the polarizer $P_2$ is reset along the x-axis and the middle between x and y-axis, respectively. The experimental results obtained are the same as that when $P_2$ is set along the y-axis direction, which indicates that the
polarization of evanescent-wave pumped WGM fibre laser is independent on the polarized state of the pump beams.

Removing out the polarizer $P_3$, the lasing spectrum is recorded with the spectrometer of grating density 2400 g/mm and is shown in Fig.II-3, which shows that the spectrum is consisted of a series of peaks with equal wavelength interval. The mode-assignment results (see text 2.2) also indicate that the spectral lines are the TE wave with the same radial mode order $l=1$ but different angular mode number $n$[24].

![Graph showing the law of WGM laser's intensity varied with polarized angels of polarizer $P_3$.](image)

**Fig. II-2.** The law of WGM laser’s intensity varied with polarized angels of polarizer $P_3$.

### 3.2.2 The form of radial polarization laser

When pump beams are in the fibre $F_1$’s axial direction, as shown in Fig.II-4-A, the beams are meridian beams that propagate within the fibre by TIR. Hereinafter, the pump beam in xy plane is taken as an example for discussing the polarization properties of the pump beams. When the pump beam travels to the interface of $F_1$, if the entrance angle $\theta$ is larger than the critical angle $\theta_c$, the beam will experience a Goos-Hänchen shift $d_g$[25] that is a length about a wavelength of the pump light $\lambda_p$, and then is totally reflected into the fibre by the interface. In the distance of $d_g$, the pump beam tunnels the fibre out a distance of $d_p$ that is also a length of $\lambda_p$, and then an evanescent field of the pump beam $E_p$ is formed outside $F_1$. $E_p$ is a traveling wave along the z-axis, but it can not travel along the x-axis [25], therefore, there is no electric field of $E_p$ existing in the z-axis and this characteristic is independent on the polarization of the pump beam. For the evanescent-wave pumped laser, since no electric field of $E_p$ exists in the z-axis, it is impossible to produce stimulated photons polarizing in the direction of z-axis. After dye gain is coupled into $F_1$, the WGM lasing oscillation and emission, of course, will lack the polarization element of z-axis, so the lasing radiation belongs to TE wave, of which electric field is strictly vertical to the axis of $F_1$.

WGM within a circular cavity is a kind of “Quasi-normal Mode” [26], meaning that part of energy in a WGM leaks tangentially out of the surface of the cavity in the way of evanescent-wave, which forms lasing emission in our situation as shown in the solid arrows of Fig.II-4-C. As both lasing emission and its electric vector are vertical to the axis of $F_1$,
Based on a simple geometrical consideration, all electric vectors of lasing radiation that emit from the same big circle of $F_1$, as shown in the dashed arrows of Fig.II-4-C, cross at the centre of the big circle. Therefore, when pump beam travels strictly along the axis of $F_1$, the lasing emission from evanescent-wave pumped WGM fibre laser is a special axial polarized emission of which emitting direction is vertical to the axis of $F_1$.

Fig. II-3. WGM lasing spectrum of TE wave acquired by pump beam being along a fibre’s axis.

Fig. II-4. Diagram for the formation of radial polarization laser.
3.2.3 Pump deviating from the optical fibre’s axis

When pump beams deviate from the axial direction of \( F_1 \), the lasing spectrum acquired by removing out the polarizer \( P_3 \) is shown in Fig.II-5-A. The spectrum is consisted of a group of weaker spectral lines and a group of stronger spectral lines, and each group is of the same wavelength interval. The lasing spectrum got by adding \( P_3 \) in the direction of \( y \)-axis is shown in Fig.II-5-B. The group of weaker lines vanishes completely in the spectrum, and the TE-wave spectrum remains. The lasing spectrum obtained by adding \( P_3 \) in the direction of \( z \)-axis is shown in Fig.II-5-C. The group of stronger lines almost vanishes in the spectrum, and the TM-wave spectrum remains. Fig.II-5 indicates that, when pump beam deviates from the fibre \( F_1 \)’s axis, both TE and TM waves exist in the lasing emission.

Fig. II-5. WGM lasing spectrum of TE& TM mixed wave acquired by pump beam deviating from the optical fibre’s axis laser by paraxial pumped.
3.2.4 The form of radial and axial mixing polarization laser

When pump beams are deviated from the optical fibre’s axis, as shown in Fig.II-6-A, the beams propagate as skew beams in the fibre $F_1$ along the $z$-axis. To analyse the property of the beams in the fibre, one of the beams with wave vector $\vec{k}$ is taken as an analytic sample. The vector $\vec{k}$ can be decomposed into $\vec{k}_{//}$ and $\vec{k}_\perp$, as shown in Fig.II-6-B in dashed arrow.
Evanescent-Wave Pumped and Gain Coupled Whispering-Gallery-Mode Fibre Laser

$k_{//}$ is a component that expresses a light beam propagating in the xy plane by TIR; while $k_{\perp}$ is a component that expresses a light beam propagating along the z-axis. For the beam expressed by $k_{//}$, both electric vectors, the vector being parallel to z-axis and the vector being vertical to z-axis, exist simultaneously in the fibre $F_1$, when the beam experiences TIR on the fibre’s interface, as shown in Fig.II-6-B, both electric vectors also exist in the evanescent field of pump beam. Because the dye molecules in the evanescent field of pump beam are excited by two different electric vectors, two kinds of stimulated photons, polarizing in the z-axis and in the xy plane, therefore, exist simultaneously in the evanescent field of WGMs of the circular cavity built in the optical fibre $F_1$. After the dye gain is coupled into the circular cavity, the WGM lasing oscillation and emission, of course, contain TE wave that is polarizing in the xy plane and TM wave that is polarizing along the z-axis. Combining with the analysis at the end part of this text 2.2, as shown in Fig.II-6-C, it can be concluded that the electric field of TE wave crosses at the centre of the circular cavity, while the electric field of TM wave is parallel to the z-axis; when pump beams are deviated from the axis of the optical fibre, the lasing emission from evanescent-wave pumped WGM fibre laser is a mixed polarization emission.

4. Part III - Linearly polarized three-color lasing emission from an evanescent wave pumped and gain coupled fibre laser

In Part III, an evanescent-wave pumped and gain coupled WGM fiber laser is introduced by inserting a bare quartz fiber (no cladding layer) into a glass capillary filled with dye molecules in a lower refractive index solution. Once the bare fiber is inserted into three glass capillaries filled with Rhodamine 6G, Rhodamine 610 and Rhodamine 640 dye solutions, respectively, WGM laser oscillations at the wavelengths of 567-575, 605-614 and 656-666 nm occur simultaneously, and a linearly polarized three-color lasing emission is achieved in a single optical fiber.

4.1 Experimental setup

The experimental setup is shown in Fig.I-4 schematically. An bare fiber ($F_1$, 196±1 μm in diameter, refractive index 1.458) was inserted into a long glass capillary (C, 1 mm in inner diameter), the residual space between $F_1$ and C was filled with ethanol and ethylene-glycol mixed solution doped by Rhodamine 6G dye with a concentration of $3\times10^{-3}$ M/L. The refractive index of the mixed solution, acting as the cladding solution of $F_1$, was 1.395 measured by an Abbe refractometer. The pump beam was longitudinally coupled into $F_1$ along the fiber’s axis by a lens (L) (focal length =75 mm) with a conical angle of $\theta_i =9.2^{\circ}$. The beam would propagate within $F_1$ by TIR if the conical angle $\theta_i$ was smaller than the critical entrance angle $\theta_{ic}$ which was 35.6° in our experiments. The evanescent field of the pump light ($E_p$) excites dye molecules in the mixed solution, thus the photons in evanescent field of WGM ($E_{WGM}$) of a circular cavity stimulate the excited dye molecules, and the $E_{WGM}$ also couples dye gain into the circular cavity at the same time. Supported by the WGMs, lasing oscillations occur in the circular cavity. The WGM lasing emission ($L_{WGM}$) from the rim of $F_1$ can be recorded by a spectrometer (Spectrapro 500i) equipped with an ICCD detector (PI-Max 1024RB) via an optical fiber $F_2$, it gives 0.05 nm spectral resolution when a grating of density 2400g/mm is used. The intensity of $L_{WGM}$ is
detected by a photo detector (PD, DSi200) after the lasing emission passing through an analyzer $P_3$ positioned on the $yz$ plane.

4.2 Experimental results and discussion
4.2.1 Three-color WGM lasing emission
It is found that the generating length of lasing emission along the $F_1$ increases with pumping energy by arranging pump configuration as described in the part I, in which the fiber $F_1$ was replaced by a thick fiber (288 $\mu$m in diameter) and the direction of the incident beam was still strictly along the axial direction of $F_1$. When the pumping energy equaled 20, 50 and 100 $\mu$J/pulse, the lengths of the lasing emission were 40, 90 mm and over 120 mm, respectively. Based on this, a longer gain length in evanescent-wave pumped WGM fiber laser, of course, can be utilized to build a multicolor WGM fiber laser [27]. That is to say, the fiber $F_1$ was inserted into three short glass capillaries (15 mm long) in series and their intervals between the capillaries were 5 mm. Rhodamine 6G, Rhodamine 610 and Rhodamine 640 dye molecules were dissolved in ethanol and ethylene-glycol mixed solution to obtain concentrations $5 \times 10^{-4}$, $2 \times 10^{-3}$ and $1 \times 10^{-2}$ M/L, respectively. The prepared dye solutions with an index of 1.422 were filled in the residual space between the $F_1$ and the capillaries. Evanescently pumped by 532 nm line of the pulsed YAG laser along the fiber’s axis, only a weak fluorescent light emitted out from the fiber when the pumping energy was 20 $\mu$J/pulse. The fluorescent spectrum was recorded by a spectrometer with a grating of density 150g/mm, which is the grey curve shown in Fig. III-1A. When pumping energy was 80 $\mu$J/pulse, we observed three-color (yellow, orange and red) WGM lasing emissions simultaneously in experiments, the emitting wavelengths from the fiber laser were in the ranges of 567-575 nm (Rhodamine 6G), 605-614 nm (Rhodamine 610) and 656-666 nm (Rhodamine 640) as shown in Fig. III-1A with the black curve. Since three-color WGM lasing emission from a single optical fiber was realized, a novel evanescent-wave pumped and gain coupled WGM fiber multicolor laser was demonstrated eventually.

To show the fine spectral structure of the three-color WGM lasing emission, the spectra were recorded with a grating of density 2400g/mm, and shown in Figs. III-1B, 1C, and 1D in the wavelengths 567-575 nm, 605-614 nm and 656-666 nm, respectively. The measured spectral intervals between two adjacent peaks are 0.246 nm (Fig.III-1B), 0.282 nm (Fig.III-1C) and 0.335 nm (Fig.III-1D), which can be compared with the calculated free spectral widths of WGMs in the used circular cavity. For a larger diameter fiber (288 $\mu$m in our case), the wavelength intervals (free spectral width) can be approximately calculated by [27] $\Delta \lambda = \lambda^2/2 \pi n_1$, where $a$ and $n_1$ are the radius and the refractive index of the used fiber, respectively. The calculated wavelength intervals are 0.247, 0.281 and 0.332 nm in the wavelength ranges of 567-575 nm, 605-614 nm and 656-666 nm, which accord well with the measured values.

4.2.2 Spatial overlap between evanescent wave of WGM and lasing gain
To explain the characteristic of the longer gain in an evanescent-wave pumped WGM fiber laser, the radial intensities of the WGMs in the used circular cavity and the evanescent field of pump light are calculated. For a TE wave in a cylindrical coordinate system shown in the top left of Fig.I-4, the electric field of a WGM in a cylindrical cavity can be written as (I-6c, 6d). For TM wave with radial mode number $l$ and angular mode number $n$, the WGM is
assigned by \( TM^l_m \), while it is assigned by \( TE^l_m \) for TE wave in this part. Two lasing lines at the wavelengths of 591.59 and 589.43 nm have been mode assigned \([20,28]\) as \( TE^1_{1500} \) and \( TE^2_{1490} \), which are chosen to calculate the distribution of radial intensity. Let \( a = 98 \ \mu m \), \( n_1 = 1.458 \), and \( n_2 = 1.395 \), the radial intensities \( I_{WGM}(r) \) for the two WGMs are calculated and shown in Fig.III-2.

Fig. III-1. Lasing spectra recorded by gratings with densities: 150g/mm (A) and 2400g/mm (B), (C) and (D). Panel (A) shows fluorescent (grey curve) and lasing (black curve) spectra emitting from a three-colour evanescent-wave fiber laser, and the laser structure with the capillaries \( C_1, C_2 \) and \( C_3 \) being filled with different dye solutions. Panels (B), (C) and (D) indicate lasing spectra emitted from \( C_1, C_2 \) and \( C_3 \) filled with Rhodamine 6G, 610 and 640 dye solutions, respectively.
Fig. III-2. Radial intensity distributions calculated for two WGMs assigned by $TE_{1500}^1$ (1, 1500) and $TE_{1490}^2$ (2, 1490), where the bumps at $r = a$ are caused by the discontinuity of TE wave, and the insert shows the intensities of evanescent waves for the pump light (solid triangles) and WGMs (black and grey curves).

The evanescence-wave intensity of the pump light is also calculated from [16]

$$I_p(r) = I_0 \exp[-2k\beta(r/a-1)a], \quad (r \geq a),$$  \hspace{1cm} (III-1)

where $\beta = [n_1^2 \sin^2 \theta/n_2^2 - 1]^{1/2}$, and $k = 2\pi n_2/\lambda_p$. Letting $I_0 = 1$, $\theta = 86.8^\circ$, $\lambda_p = 532$ nm, the calculated result is shown in the insert of Fig. 6 by solid triangles, for a convenient comparison, the normalized evanescent-wave intensities of the modes $TE_{1505}^1$ and $TE_{1490}^2$ are also presented. The curves in the insert show clearly that in the radial direction of the cylindrical cavity ($r \geq a$), the intensity distributions of the two WGMs overlap well with the distribution of evanescence-wave of the pump light. Because the lasing gain in the evanescence-wave pumped WGM fiber laser is excited by the evanescent field of the pump light, the spatial distribution of the lasing gain is the same as that of the pump light. Therefore, it is reasonable to attribute the longer gain distance and the higher pumping efficiency in evanescence-wave pumped WGM fiber laser to the good spatial overlap between the lasing gain and the evanescent field of WGMs in a circular cavity.

5. Part IV - Broadening free spectral range of an evanescence-wave pumped Whispering-Gallery-Mode fibre laser by Vernier effect

In Part IV, evanescence-wave pumping scheme is used in a WGM fibre laser, which is formed by inserting a piece of bare quartz fibre (without cladding) into a glass capillary filled with a dye solution of low refractive index, as shown in Fig.IV-1a. When the pumping light propagates along the fibre’s axis by total internal reflection, its evanescent-field excites a lasing gain around the fibre, and WGM lasing emission occurs as the pumping energy...
evanescent-wave pumped WGM fibre laser exceeds the threshold. To increase the FSR of WGM fibre laser, two optical fibres of different radii are bound together with their axes parallel to make a coupled cylinder-cavity structure (CCCS). Due to the Vernier effect [29-31], lasing occurs only when both cavities are in resonance at the same frequency, and the FSR of the CCCS is thus greatly enlarged.

Fig. IV-1. Schematic of evanescent-wave pumped WGM fiber laser is shown in (a), where $E_p$ and $E_{WGM}$ indicate the evanescent-fields of the pump light and WGMs, $L_{WGM}$ indicates the WGM lasing emission. The coupled cylinder-circular cavity is shown in (b), the master fiber provides the gain and make up a CCCS with the slave fibre. Note that the vertical and horizontal directions are drawn with different scales.

5.1 Experiment and results
The experimental setup is shown in Fig.IV-1a. A laser beam (355 nm), generated by a frequency tripled and Q-switched Nd:YAG laser, was used as the pump light. A bare fibre (refractive index 1.46) was inserted into a long glass capillary (1 mm inner diameter), and the open space between the fibre and the capillary was filled with ethanol solution doped by Coumarin 500 (LC 5010, Lambda Physik) dye with a concentration of $4 \times 10^{-3}$ Mol/L. The refractive index of the dye solution, acting as the cladding layer of the bare fibre, is 1.36 measured by an Abbe refractometer. The pump beam was coupled into the bare fibre along its axis with a conical angle $\theta_i = 7.6^\circ$. The beam would propagate within the bare fibre by total internal reflection if the conical angle $\theta_i$ was smaller than the critical entrance angle $\theta_{ic}$, that was $31.7^\circ$ in our experiments. The evanescent field of the pump light ($E_p$) excites dye molecules in the dye solution, thus the photons in evanescent field of WGM ($E_{WGM}$) of a circular cavity (formed by any cross section of the fibre) stimulate the excited dye molecules, supported by the WGMs, lasing oscillations occur in the circular cavity. It is worth noting that the evanescent-wave pumping scheme used in this work is different from those of references.
The ring cavity in reference [30] is composed by gain material and the gain is obtained by directly pumping the cavity, while the side-pumping scheme is used in reference [31]. The WGM lasing emission ($L_{WGM}$) from the rim of the fibre can be recorded via a detecting fibre by a spectrometer (Spectrapro 500i) equipped with a CCD detector (PI-Max 1024RB), which gives 0.05 nm spectral resolution when a grating of density 2400g/mm is used.

Fig. IV-2. WGM fiber lasing spectrum from a bare optical fibre of diameter $D_1 = 91 \mu$m is shown in (a), the measured FSR is 0.633 nm as indicated by the arrows. The spectrum from the bare optical fibre of diameter $D_2 = 85 \mu$m is shown in (b), the measured FSR is 0.675 nm as indicated by the arrows. The combination of spectra (a) and (b) in the same wavelength region is shown in (c). Two arrows in (c) indicate the overlapping positions of the WGM resonant wavelengths of the two fibers.
Two types of fibres with diameter $D_1 = 91 \, \mu m$ and $D_2 = 85 \, \mu m$, measured by a microscope with 1 $\mu m$ uncertainty, were prepared by etching two bare quartz fibres of original diameter 100 $\mu m$ in a diluted HF-acid solution. After supersonic cleaning in ethanol, one of the fibres was inserted in the glass capillary filled with ethanol dye solution. The fibre was evanescently pumped by the 355 nm laser beam along its axis, and WGM lasing spectra were investigated. For the fibre with a diameter $D_1 = 91 \, \mu m$ ($D_2 = 85 \, \mu m$), lasing emission was observed when the pumping energy was larger than 25 $\mu J$ (30 $\mu J$), and the lasing spectrum was recorded as shown in Fig.IV-2a (Fig.IV-2b) with the pumping energy fixed at 100 $\mu J$. The measured average FSR in the spectral range from 504 to 516 nm was 0.633 nm for the fibre of $D_1 = 91 \, \mu m$, while it was 0.675 nm in the spectral range from 506 to 513 nm for the fibre of $D_2 = 85 \, \mu m$. When the two spectra (Fig.IV-2a and 2b) are merged together in the same wavelength region, as shown in Fig.IV-2c, it is found that two pairs of peaks corresponding to WGM resonant wavelengths overlap, and the overlapping wavelengths are 503.3 nm and 513.4 nm as indicated in Fig.IV-2c by the dashed arrows.

![Lasing spectra from the CCCS](https://www.intechopen.com)

Fig. IV-3. Lasing spectra from the CCCS. The spectra $(a)$ and $(b)$ were acquired by setting a detecting fibre at different positions along the axis of the CCCS. The wavelength values shown in the figure are the same as the overlapping positions of the WGM resonant wavelengths in Fig.IV-2(c).
After the single fibre experiments, the two fibres (we called the fibre of $D = 91 \, \mu\text{m}$ in diameter as master fibre, and the fibre of $D_2 = 85 \, \mu\text{m}$ in diameter as slave fibre) were bound together with their axes parallel by two fine hairs to form a CCCS. The CCCS was then inserted in the same glass capillary as shown in Fig.IV-1b, evanescently pumped by the 355 nm laser beam along the axis of the master fibre (pumping energy was fixed at 100 $\mu$J), the lasing emissions were observed along the rims of both fibres, and the lasing spectra recorded were shown in Fig.IV-3. The CCCS suppresses most of WGM resonant peaks shown in Fig.IV-3. However, a strong lasing peak appears at 503.3 nm and a weak peak appears at 513.4 nm, where two pairs of peaks overlap together as shown in Fig.IV-2c. When the detecting fibre was moved to another position along the master fibre’s axis, as shown in Fig.IV-3b, we obtained another lasing spectrum similar to that shown in Fig.IV-3a from the CCCS, in which most of WGM resonant peaks have been suppressed, such that a strong lasing peak appears at 513.4 nm and a weak peak appears at 503.3 nm. The wavelength difference between the strong and the weak peaks is 10.1 nm. This value, corresponding to FSR of the CCCS, is 16 and 15 times larger than that of the master and slave fibres, respectively. That is FSR is broadened by using the CCCS. The lasing peaks around 503.3 and 513.4 nm are possibly caused by the partial overlap of resonant frequencies between the WGMs of the main and the slave fibres.

### 5.2 Discussion and conclusion

Let $D$ and $m$ be the diameter and the refractive index of a circular cavity, respectively, the WGM resonant condition can be approximately written as $\pi D m = N \lambda$, where $\lambda$ is resonant wavelength, $N$ is an integer. For the master and the slave fibres, the resonant conditions are given by,

$$\pi D_1 m = N_1 \lambda_1 , \quad (IV-1)$$

$$\pi D_2 m = N_2 \lambda_2 \quad (IV-2)$$

For a CCCS composed by two circular cavities, based on Vernier effect, the resonance occurs only at the same wavelength of both cavities satisfies resonant condition, which leads to $\pi(D_1 - D_2)m = (N_1 - N_2)\lambda_{\text{CCCS}}$, where $\lambda_{\text{CCCS}}$ is the resonant wavelength of the CCCS. Therefore, the FSR of the CCCS can be written as,

$$\text{FSR}_{\text{CCCS}} = \delta \lambda_{\text{CCCS}} = \frac{\lambda_{\text{CCCS}}^2}{\pi(D_1 - D_2)m} . \quad (IV-3)$$

Instead of using the measured diameters of the two fibres, we utilize the spectral diameter defined by $D' = \lambda^2 / \pi m \delta \lambda$ to calculate $\delta \lambda_{\text{CCCS}}$, where $\delta \lambda$ is the measured FSR from the lasing spectrum shown in Fig.IV-2. For the master and the slave fibres, the spectral diameters are $D_1' = 89.6 \, \mu\text{m}$ ($\delta \lambda = 0.633 \, \text{nm}$) and $D_2' = 84.0 \, \mu\text{m}$ ($\delta \lambda = 0.675 \, \text{nm}$), respectively. Substituting the values of $D_1$ and $D_2$, together with $m = 1.46$ into equation (3), the calculated $\delta \lambda_{\text{CCCS}}$ is 10.28 nm for $\lambda_{\text{CCCS}} = 513.4 \, \text{nm}$, and 9.87 nm for $\lambda_{\text{CCCS}} = 503.3 \, \text{nm}$. The average value of $\delta \lambda_{\text{CCCS}}$ is 10.08 nm, which is very close to the measured FSR of the CCCS.
A broad FSR can also be obtained by using a single fibre of small diameter. For example, the diameter must be reduced to about 6 \( \mu m \) to obtain the same FSR as the CCCS used in this work. However, a fibre of small diameter means a low efficiency to couple the pumping energy into the fibre, as well as a decrease in its quality factor due to a larger leakage loss, especially when the cavity is immersed in a liquid solution.

The difference between the geometric diameters \( D_1 = 91 \mu m, D_2 = 85 \mu m \) and the spectral diameters \( D_{1s} = 89.6 \mu m, D_{2s} = 84.0 \mu m \) is mainly caused by the property of intensity distribution of WGMs. Most of photons in a WGM don’t travel strictly along the inner surface of a circular cavity, but slightly inside the surface. Therefore, the spectral diameter \( D_{is} \) calculated by the measured FSR of a circular cavity is always smaller than its geometric diameter \( D_i \).

6. Chapter summary

Threshold property of the novel WGM fiber lasers pumped by an evanescent-wave has been investigated. The laser has been fabricated by inserting a bare fused quartz fiber into a glass capillary filled with dye solution, and its energy threshold properties, including the energy threshold varied with the RI of the dye solution for different fiber diameters and the produced length of lasing emission, are experimentally studied. We find that the energy threshold is very sensitive to the change of the refractive index of dye solutions and the fiber diameter, and the produced length of lasing emission is dependent on dye concentration and the refractive index of dye solutions. Based on the characteristic of evanescent-wave pumping scheme, we derive the threshold energy formula of the WGM fiber lasers from the general theory of WGM microcavity laser. Based on the characteristic of frustrated totally internal reflection of light traveling along the fiber, we obtain the equation to determine the produced length of lasing emission according to the characteristic of FITR of light traveling along the fiber. The calculated results with our theory fit the experimental data very well.

The polarization property of lasing emission, for the evanescent-wave pumped WGM fibre laser, is related closely to the light-pump conditions. When pump beams travel strictly along the axis of the optical fibre, only TE wave exists in lasing emission, and the electric vector of the lasing emission goes along the radial direction of the fibre, which forms a special radial polarization emission whose emitting direction is vertical to the fibre’s axis. When pump beams are deviated from the axis of the optical fibre, both TE and TM waves exist in lasing emission, which forms a special emission mixed with radial and axial polarization emission, and the emitting direction is also vertical to the fibre’s axis.

For an evanescent-wave pumped and gain coupled WGM fiber laser, the dye gain is excited by the evanescent wave of the pumped light, distributed around the fiber and coupled into WGMs of a circular cavity. A good spatial overlap between the dye gain and the evanescent fields of WGMs leads to a high pumping efficiency and a longer gain distance along the fiber, and linearly polarized three-color lasing emissions from a single optical fiber can be realized by immersing the fiber into three different dye solutions, where may be found a potential application in multicolor display.

Evanescent-wave pumping scheme has been successfully used to excite WGM fibre laser. A coupled cylinder-cavity structure has been fabricated by binding two bare optical fibres.
together, and the measured FSR of the laser emission from the CCCS is effectively broadened. This structure can be used to obtain a single mode lasing emission in an evanescent-wave pumped WGM fibre laser.

This book presents a comprehensive account of the recent advances and research in optical fiber technology. It covers a broad spectrum of topics in special areas of optical fiber technology. The book highlights the development of fiber lasers, optical fiber applications in medical, imaging, spectroscopy and measurement, new optical fibers and sensors. This is an essential reference for researchers working in optical fiber researches and for industrial users who need to be aware of current developments in fiber lasers, sensors and other optical fiber applications.
