ABSTRACT

Planck is expected to answer crucial questions on the early universe, but it also provides further understanding on anomalous microwave emission. Electric dipole emission from spinning dust grains continues to be the favored interpretation of anomalous microwave emission. In this paper, we present a method to calculate the rotational emission from small grains of irregular shape with moments of inertia $I_1 \geq I_2 \geq I_3$. We show that a torque-free rotating irregular grain with a given angular momentum radiates at multiple frequency modes. The resulting spinning dust spectrum has peak frequency and emissivity increasing with the degree of grain shape irregularity, which is defined by $I_1; I_2; I_3$. We discuss how the orientation of the dipole moment $\mu$ in body coordinates affects the spinning dust spectrum for different regimes of internal thermal fluctuations. We show that the spinning dust emissivity for the case of strong thermal fluctuations is less sensitive to the orientation of $\mu$ than in the case of weak thermal fluctuations. We calculate spinning dust spectra for a range of gas density and dipole moment. The effect of compressible turbulence on spinning dust emission is investigated. We show that the emission in a turbulent medium increases by a factor from 1.2 to 1.4 relative to that in a uniform medium, as the sonic Mach number $M_s$ increases from 2 to 7. Finally, spinning dust parameters are constrained by fitting our improved model to five-year Wilkinson Microwave Anisotropy Probe cross-correlation foreground spectra, for both the Ha-correlated and 100-\textmu m-correlated emission spectra.

Key words: cosmic background radiation – diffuse radiation – dust, extinction – radiation mechanisms: non-thermal – radio continuum: ISM

1. INTRODUCTION

Cosmic microwave background (CMB) experiments (see Bouchet et al. 1999; Tegmark et al. 2000; Efstathiou 2003; Bennett et al. 2003) are of great importance for studying the early universe and its subsequent expansion. Precision cosmology with the Wilkinson Microwave Anisotropy Probe (WMAP) and Planck satellite requires a good model of the microwave foreground emission to allow the subtraction of microwave foreground contamination from the CMB radiation.

Three well-known components of the diffuse microwave Galactic foreground consist of synchrotron emission, free–free emission from plasma (thermal bremsstrahlung), and thermal emission from dust. However, in the microwave range of frequency from 10 to 100 GHz, anomalous emission which was difficult to reconcile with the components above was reported (Kogut et al. 1996a, 1996b).

An explanation for the anomalous emission was proposed by Draine & Lazarian (1998a, 1998b, hereafter DL98 model), where it was identified as electric dipole emission from rapidly spinning dust grains (hereafter spinning dust emission). Although spinning dust emission had been discussed previously (see Erickson 1957; Ferrara & Dettmar 1994), Draine & Lazarian were the first to include the variety of excitation and damping processes that are relevant for very small grains.

While the DL98 model appears to be in general agreement with observations (see Lazarian & Finkbeiner 2003; Finkbeiner et al. 2004), it did not account for a number of physical effects, namely, the non-sphericity of grain shapes, internal relaxation, and transient spin-up due to ion collisions.

The Planck Collaboration (2011b) has reported new observations of spinning dust emission in new environments. Spinning dust now provides a potential diagnostic tool for interstellar dust properties (shape, size distribution, and dipole moment). A comprehensive model of spinning dust for different grain shapes is required.

Recent studies showed that the correspondence of the DL98 model to observations can be improved by adjusting the parameters of the model. For instance, the five-year WMAP data showed a broad bump at $\sim$40 GHz in the Ha-correlated emission (Dobler & Finkbeiner 2008; Dobler et al. 2009). The $\sim$40 GHz frequency of the peak is higher than the value predicted ($\sim$23 GHz) by the DL98 model for standard parameters of the warm ionized medium (WIM). Dobler et al. (2009) showed that the bump is consistent with the DL98 model modified so that the characteristic dipole moment of grains is decreased and gas density of the WIM is increased, relative to the typical spinning dust parameters in Draine & Lazarian (1998b, hereafter DL98b).

Ali-Haïmoud et al. (2009) revisited the spinning dust model and presented an analytic solution to the Fokker–Planck (FP) equation that describes the rotational excitation of a spherical grain if the discrete nature of the impulses can be neglected.

Hoang et al. (2010, hereafter HDL10) improved the DL98 model by accounting for a number of physical effects. The main modifications in their improved model of spinning dust emission are as follows.

1. Disk-like grains rotate with the grain symmetry axis $\mathbf{a}_1$ not perfectly aligned with the angular momentum $\mathbf{J}$. The disaligned rotation of $\omega$ with $\mathbf{a}_1$ causes wobbling of the
grain principal axes with respect to $\omega$ and $J$ due to internal thermal fluctuations.

2. Distribution functions for grain angular momentum and velocity are obtained exactly using the Langevin equation (LE) for the evolution of grain angular momentum in an inertial coordinate system.

3. The limiting cases of fast internal relaxation and no internal relaxation are both considered for calculation of the angular momentum distributions and emissivity of spinning dust.

4. Infrequent collisions of single ions which deposit an angular momentum larger than the grain angular momentum prior to collision are treated as Poisson-distributed events.

The wobbling disk-like grain has anisotropic rotational damping and excitation. Such an anisotropy can increase the peak emissivity by a factor of $\sim 2$, and increases the peak frequency by a factor of 1.4–1.8, compared to the results from the DL98 model.

The effect of the grain wobbling on electric dipole emission was independently studied by Silsbee et al. (2011) using an FP equation approach, but they disregarded the effects of internal relaxation and transient spin-up by infrequent ion collisions.

Earlier models of spinning dust emission dealt with axisymmetric grains having moments of inertia $I_1 > I_2 = I_3$ (see HDL10; Silsbee et al. 2011). An axisymmetric grain with angular momentum $J$ radiates in general at four frequency modes $\phi, \psi, \phi$, and $\psi$, where $\phi = J/I_2$ is the angular frequency of precession of the grain symmetry axis $a_1$ about $J$ and $\psi = J \cos \theta (1/I_1 - 1/I_2)$ with $\theta$ being the angle between $J$ and $a_1$ is the angular frequency of the grain rotation about its symmetry axis $a_1$. For an “irregular” (i.e., triaxial) grain with $I_1 > I_2 > I_3$, in addition to the precession of the grain axis of maximum moment of inertia $a_1$ (hereafter axis of major inertia) or of the grain axis of minimum moment of inertia $a_3$ (hereafter axis of minor inertia) around the angular momentum $J$, the grain principal axes wobble with respect to $J$. This wobbling, which is different from the wobbling due to the internal thermal fluctuations studied in HDL10 for the disk-like grain, can result in a more complex emission power spectrum, so that it modifies the spinning dust emission. We will quantify this effect in Section 3.

Very small grains (smaller than 20 Å) are important for spinning dust emission. But also within this range of grain size, the grain dust temperature has strong fluctuations due to absorption of UV photons (Greenberg 1968; Draine & Anderson 1985). As a result, they cannot be characterized by a single equilibrium temperature and are described by a temperature distribution function (Draine & Li 2001). The temperature fluctuations induce wobbling of the grain axes with respect to the angular momentum and modify the spinning dust spectrum. This issue is addressed in Section 5.1.

We also investigate spinning dust emission in the presence of compressible turbulence. An increase of the spinning dust emission arises as a result of the nonlinear dependence of emissivity on gas density.

The seven-year WMAP data (Gold et al. 2011) and Planck early results (Planck Collaboration 2011a, 2011b) appear to support spinning dust emission as a source of the anomalous microwave emission in new regions with a wide range of physical parameters. The WMAP thermal-dust-correlated spectra in Gold et al. (2011) for two regions within the Galactic plane indicate that spinning dust emission should peak around 22 GHz. However, the improved model of spinning dust developed by HDL10 predicted a peak frequency above $\sim 30$ GHz, for most environment conditions using the same physical parameters as in DL98b. We explore the parameter space for the HDL10 spinning dust model and characterize spinning dust parameters by fitting to the latest observation data.

The structure of this paper is as follows. In Section 2, we present the assumptions and notations adopted throughout this paper. In Section 3, we describe the torque-free motion of an irregular grain and the exchange of vibrational–rotational (V-R) energy. The power spectrum and spinning dust emissivity for irregular grains are presented in Section 4. In Section 5, we investigate the influence of grain temperature fluctuations, dipole moment orientation, and explore the parameter space of gas density and magnitude of dipole moment for spinning dust emissivity. Section 6 is devoted to the effects of fluctuations of gas density due to compressible turbulence on spinning dust emission. Constraints on spinning dust parameters obtained by fitting theoretical model to the Hα-correlated and thermal-dust-correlated emission spectra are presented in Section 7. Discussion and summary of principal results are given in Sections 8 and 9, respectively.

2. ASSUMPTIONS AND NOTATIONS

2.1. Assumptions

In the present paper, we follow the same assumptions for grain size distribution and rotation dynamics as in HDL10. The grain size $a$ is defined as the radius of a sphere of equivalent volume. Unless stated otherwise, we assume throughout the paper that grains smaller than $a_2 = 6 \times 10^{-8}$ cm are planar and grains larger than $a_2$ are approximately spherical. We adopt rotational damping and excitation coefficients due to gas–grain interaction, infrared emission, and electric dipole damping from HDL10. Our notations are summarized in Table 1.

2.2. Grain Electric Dipole Moment

The electric dipole moment of a grain arises from the intrinsic dipole moment of molecules within the grain and from the asymmetric distribution of the grain charge. The former is shown to be dominant (see DL98b).

The grain dipole moment $\mu$ can be written as

$$\mu = \mu_i + \epsilon Z e a_s,$$

where $\mu_i$ is the intrinsic dipole moment of an uncharged grain, $Ze$ is the grain charge, $a_s$ is the excitation-equivalent radius of the grain, and the vector $\epsilon a_s$ is the displacement between the grain center of mass and the charge centroid.

Following DL98b, the magnitude of the dipole moment is given by

$$\mu^2 = 23 \left[ \left( \frac{a_s}{a} \right)^2 \langle Z^2 \rangle + 3.8 \left( \frac{\beta}{0.4 D} \right)^2 a_{-7} \right] a_{-7}^2 D^2,$$

where $\langle Z^2 \rangle$ is the mean square grain charge, $\beta$ is the dipole moment per atom of the grain, and $a_{-7} = a / 10^{-7}$ cm. Above, $\epsilon \sim 0.1$ is assumed.

The electric dipole moment, assumed to be fixed in the grain body system, can be decomposed into three components along the grain principal axes:

$$\mu = \mu_1 a_1 + \mu_2 a_2 + \mu_3 a_3,$$

3 Denote $V$ to be the volume of the grain, then $a$ is defined as $V = 4\pi a^3/3$. 

2
Table 1  
Notations and Meanings

| Symbol | Meaning |
|--------|---------|
| a      | Grain size |
| ν      | Frequency |
| n_H    | H nucleus density |
| x_H    | H ionization fraction |
| x_M    | Metal ionization fraction |
| T_gas  | Gas temperature |
| T_vib  | Dust vibrational temperature |
| T_d    | Decoupling temperature for vibrational–rotational energy exchange |
| τ_H    | Gas damping time |
| τ_ed   | Electric dipole damping time |
| μ      | Electric dipole moment |
| ω_T    | Thermal angular velocity |
| J      | Angular momentum |
| a_1, a_2, a_3 | Basis vectors of grain principal axes |
| I_1, I_2, I_3 | Eigenvalues of moment of inertia tensor |
| x, y, z | Coordinate systems associated to J, I |
| e_1, e_2, e_3 | Inertial coordinate system fixed to the lab |
| θ, φ, ψ | Euler angles of grain axes in external system |
| q      | Electric dipole moment |
| P_rot  | Emission power |
| ν       | Emissivity at frequency ν |
| case 1, case 2 | μ oriented so that μ_1^2 = μ_2^2 = μ_3^2 |
| model 1, model 2 | 50% of grains having μ = μ_0/2, |
|        | 25% of grains having μ = μ_0 |
| y      | 2ν(H_2)/n_H |

where a_1, a_2, and a_3 are the basis vectors of principal axes of the grain.

Because the orientation of μ in the grain body is not well constrained, in the present paper, we study two limiting cases. In case 1, μ is fixed in the grain body such that μ_1^2 = μ_2^2 = μ_3^2 = μ^2/3. In case 2, μ is perpendicular to the grain axis of major inertia a_1, so that μ_1^2 = 0 and μ_2^2 = μ_3^2 = μ^2/2 = μ^2/2, where μ_1^2 = μ_2^2 + μ_3^2.

Table 2 presents typical physical parameters for various phases of the interstellar medium (ISM), including the cold neutral medium (CNM), warm neutral medium (WNM), and WIM.

3. ROTATIONAL DYNAMICS OF GRAIN OF IRREGULAR SHAPE

Very small dust grains (also polycyclic aromatic hydrocarbons (PAHs)) are expected to be planar, while larger grains are likely to be more-or-less spherical. Even though planar, small PAHs are not expected to be perfectly symmetric. In general, for both PAHs and larger particles, we expect the eigenvalues I_1 of the moment of inertia tensor to be nondegenerate: I_1 > I_2 > I_3.

![Figure 1](image-url)  
Torque-free motion of a grain having three principal axes a_1, a_2, and a_3 in an inertial coordinate system with x, y, z described by three Euler angles θ, φ, and ψ. (A color version of this figure is available in the online journal.)

We will refer to grains with nondegenerate eigenvalues as “irregular.”

3.1. Torque-free Rotation and Flip States

Let us consider an irregular grain characterized by a triaxial ellipsoid having moments of inertia I_1 > I_2 > I_3 along the principal axes a_1, a_2, and a_3.

The dynamics of the irregular grain is more complicated than that of a disk-like grain with I_2 = I_3. In addition to the precession of the axis of major inertia a_1 about J as in the disk-like grain, the axis a_1 wobbles rapidly, resulting in variations of the angle θ between a_1 and J at a rate θ. Therefore, we expect the wobbling of the irregular grain can produce more frequency modes than those observed in the disk-like grain (see HDL10).

To describe the torque-free motion of an irregular grain having a rotational energy E_rot, we use conserved quantities, including the angular momentum J, and a dimensionless parameter that characterizes the deviation of the grain rotational energy from its minimum value,

\[ q = \frac{2I_1E_{rot}}{J^2}. \]

Following Weingartner & Draine (2003), we define the total number of states s in phase space for q ranging from 1 to q as

\[ s = 1 - \frac{2}{\pi} \int_0^{\psi_1} d\psi \left[ \frac{I_3(I_1 - I_2) + I_2(I_2 - I_3)\cos^2\psi}{I_3(I_1 - I_2) + I_2(I_2 - I_3)\cos^2\psi} \right]^{1/2}, \]

where

\[ \psi_1 = \cos^{-1} \left( \frac{I_2(I_2q - I_3)}{I_3(I_2 - I_3)} \right)^{1/2}, \]

for q > q_sp and \( \psi_1 = \pi/2 \) for q ≤ q_sp, with q_sp ≡ I_1/I_2 being the separatrix between the two regimes.

The instantaneous orientation of the grain in an inertial coordinate system is given by three Euler angles ψ, φ, and θ (see Figure 1). The angular velocities are obtained by solving the Euler equations of motion. The torque-free motion of an irregular grain is treated in detail in Appendix A.

Briefly, the Euler equations give rise to two sets of solutions corresponding to “+” and “−” signs for \( \omega_i \) with i = 1, 2, and

Table 2  
Idealized Environments for Interstellar Matter

| Parameters | CNM | WNM | WIM |
|------------|-----|-----|-----|
| n_H (cm^{-3}) | 30  | 0.4 | 0.1 |
| T_gas (K) | 100 | 6000 | 8000 |
| x | 1   | 1   | 1   |
| x_H | 0.0012 | 0.1 | 0.99 |
| x_M | 0.0003 | 0.0003 | 0.001 |
| y = 2ν(H_2)/n_H | 0.0 | 0.0 | 0.0 |
3 (see Equations (A4)–(A6)). It can be seen that for \( q < q_{sp} \), two rotation states “±” correspond to \( \omega_1 > 0 \) and \( \omega_1 < 0 \), i.e., \( a_1 \cdot J > 0 \) and \( a_1 \cdot J < 0 \). Following Weingartner & Draine (2003), we refer to these rotation states as the **positive** flip state and **negative** flip state with respect to \( a_1 \) (see also Hoang & Lazarian 2009). For \( q > q_{sp} \), similarly, two rotation states correspond to \( \omega_3 > 0 \) and \( \omega_3 < 0 \), i.e., \( a_3 \cdot J < 0 \) and \( a_3 \cdot J > 0 \). These rotation states are referred to as the **positive** and **negative** flip states with respect to \( a_3 \).

### 3.2. Internal Relaxation, Thermal Fluctuations, and Thermal Flipping

#### 3.2.1. Internal Relaxation and Thermal Fluctuations

Internal relaxation (e.g., imperfect elasticity and Barnett relaxation; Purcell 1979; Lazarian & Efroimsky 1999) arises from the transfer of grain rotational energy to vibrational modes. For cold grains, this process tends to result in nearly perfect alignment of the grain axis of major inertia with the angular momentum. Naturally, if the grain has nonzero vibrational energy, energy can also be transferred from the vibrational modes into grain rotational energy (Jones & Spitzer 1967).

For an isolated grain, a small amount of energy gained from the vibrational modes results in fluctuations of the rotational energy \( E_{\text{rot}} \) when the grain angular momentum is conserved. Such fluctuations in \( E_{\text{rot}} \) result in fluctuations of \( q \) and of the angle \( \theta \) between \( a_1 \) and \( J \) for an axisymmetric grain. For an irregular grain, the fluctuations in \( E_{\text{rot}} \) are described by fluctuations in \( s(q) \) (see Equation (5)). Over time, the fluctuations in \( E_{\text{rot}} \) establish a local thermal equilibrium (LTE) at a rotational energy equilibrium temperature \( T_{\text{rot}} \).

#### 3.2.2. Exchange of Vibrational–Rotational Energy

The Intramolecular Vibrational–Rotational Energy Transfer (IVRET) process due to imperfect elasticity occurs on a timescale \( 10^{-5} \) s, for a grain of a few angstroms (Purcell 1979), which is shorter than the IR emission time. So, when the vibrational energy decreases due to IR emission, as long as the V-R energy exchange exists, interactions between vibrational and rotational systems maintain a thermal equilibrium, i.e., \( T_{\text{rot}} \approx T_{\text{vib}} \). As a result, the LTE distribution function of rotational energy reads (hereafter VRE regime; see Lazarian & Roberge 1997)

\[
f_{\text{VRE}}(s, J) \propto \exp \left( -\frac{E_{\text{rot}}}{k_B T_{\text{rot}}} \right) \approx \exp \left( -\frac{E_{\text{rot}}}{k_B T_{\text{vib}}} \right).
\]

The existence of V-R energy exchange depends on the rotational modes. In principle, the rotational energy can change in increments of \( \hbar \omega \), with \( \omega \) being the angular frequency of rotational modes. However, at low vibrational energy \( E_{\text{vib}} \), the vibrational mode spectrum is sparse, and there may not be available transitions with \( \Delta E_{\text{vib}} = \hbar \omega_{\text{rot}} \). For the case \( a_1 \parallel J \), the V-R energy exchange occurs only when the grain is hot just after absorption of a UV photon, because the grain rotating with \( a_1 \parallel J \) has only one rotational mode \( \omega = \omega_{\text{rot}} \equiv J/\hbar \). As the grain cools down further, there is no available vibrational transition corresponding to an energy change \( \hbar \omega_{\text{rot}} \) and the V-R coupling ceases.

For a disk-like or irregular grain, multiple rotational frequency modes are observed and some modes correspond to energy \( \hbar \omega > \hbar \omega_{\text{rot}} \) (see Equation (14) or Figure 2). This may allow V-R energy exchange even when the vibrational energy is relatively low. Nevertheless, the energy separation between the vibrational ground state and the first vibrationally excited state is large enough that V-R energy exchange is unlikely to take place after the PAH cools to the vibrational ground state. The key, then, is to know the vibrational “temperature” of a cooling PAH at the time when V-R energy exchange ceases to be effective. Sironi & Draine (2009) estimated a decoupling temperature \( T_d = 65 \) K for a PAH with 200 C atoms.

In regions with the average starlight background, the mean time interval between absorptions of starlight photon will be \( \sim 10^6 \) s, for a PAH containing 200 C atoms. Because the PAH will cool below 65 K in \( \sim 10^6 \) s (see, e.g., Figure 9 of Draine & Li 2001), V-R energy exchange will be suppressed most of the time, taking place only during \( \sim 10^3 \) s intervals following absorption of starlight photons. However, the \( 10^6 \) s interval between photon absorptions is short compared to the timescale over which \( J \) will change appreciably, and we will therefore approximate the V-R energy exchange process as continuous, even though it is episodic.

Substituting \( E_{\text{rot}} \) as a function of \( J \) and \( q \) from Equation (4) into Equation (7), the distribution function for the rotational energy becomes

\[
f_{\text{VRE}}(s, J) = A \exp \left( -\frac{q(s) J^2}{2 I k_B T_{\text{vib}}} \right),
\]

where \( A \) is a normalization constant such that \( \int_0^1 f_{\text{VRE}}(s, J) \, ds = 1 \).

Define a rotational temperature \( T_J = J^2/2 I k_B \). Thus, the distribution for \( q \) becomes \( f_{\text{VRE}} \propto \exp (q - q(t) T_{\text{vib}}) \). When \( T_J \gg T_{\text{vib}} \), the grain is suprathermally rotating and \( a_1 \) is aligned with \( J \). In contrast, when \( T_J \ll T_{\text{vib}} \), the grain rotates subthermally and thermal fluctuations randomize the grain axes with respect to \( J \). For fixed angular momentum, the thermal fluctuations increase with \( T_{\text{vib}} \).

#### 3.2.3. Thermal Flipping

Transfer of energy between the vibrational and rotational modes due to dissipation or thermal fluctuations will cause \( E_{\text{rot}} \), and therefore \( q \), to vary with time. If \( q \) crosses the separatrix state \( q = q_{sp} \), the new flip state is effectively chosen randomly. Changes in \( q \) can also result from external forcing (e.g., collisions with gas atoms or absorption/emission of radiation) that may change both \( J \) and \( E_{\text{rot}} \). If the external torques are not “chiral,” then the changes in \( q \) over time will result in equal probabilities of the two flip states. However, the chirality of the grain may lead to \( q \)-changing processes that depend not only on \( q \), but also on which flip state the grain is in. The present treatment neglects any grain chirality.

### 4. ELECTRIC DIPOLE EMISSION FROM GRAINS OF IRREGULAR SHAPE

Below we investigate electric dipole emission arising from irregular grains. We first calculate the emission power spectrum arising from a torque-free rotating irregular grain. Then, we compute the spinning dust emissivity and compare the results with those from disk-like grains.

#### 4.1. Power Spectrum

A torque-free rotating irregular grain can rotate either in the positive or negative flip state, and the treatment in this section...
is applicable to a general flip state. To find the electric dipole emission spectrum from such an isolated irregular grain, we follow the approach in HDL10. We first represent the dipole moment \( \mu \) in an inertial coordinate system and then compute its second derivative. We obtain

\[
\ddot{\mu} = \sum_{i=1}^{3} \mu_i \ddot{a}_i,
\]

where \( \mu_i \) are components of \( \mu \) along principal axes \( a_i, \ddot{a}_i \) are second derivative of \( a_i \) with respect to time, and \( i = 1, 2, \) and \( 3 \).

The instantaneous emission power of the dipole moment is defined by

\[
P_{\text{ed}}(J, q, t) = 2 \frac{3c^2}{I} \ddot{\mu}^2.
\]

The power spectrum is then obtained from the Fourier transform (FT) for the components of \( \ddot{\mu} \). For example, the amplitude of \( \ddot{\mu}, \ddot{\mu}_y, \ddot{\mu}_z \) at the frequency \( \nu_k \) is defined as

\[
\ddot{\mu},,k = \int_{-\infty}^{+\infty} \ddot{\mu}(t) \exp(-i2\pi\nu_k t) dt,
\]

where \( k \) denotes the frequency mode. The emission power at the positive frequency \( \nu_k \) is given by

\[
P_{\text{ed},k}(J, q) = \frac{4}{3c^3} \left( \ddot{\mu}^2 + \ddot{\mu}_y^2 + \ddot{\mu}_z^2 \right),
\]

where the factor 2 arises from the positive/negative frequency symmetry of the Fourier spectrum. To reduce the spectral leakage in the FT, we convolve the time \( \ddot{\mu} \) with a Blackman–Harris window function (Harris 1978). The power spectrum needs to be corrected for the power loss due to the window function.

The total emission power from all frequency modes for a given \( J \) and \( q \) is then

\[
P_{\text{ed}}(J, q) = \sum_k P_{\text{ed},k}(J, q) \equiv \frac{1}{T} \int_0^T dt \left( 2 \frac{3c^2}{I} \ddot{\mu}^2 \right),
\]

where \( T \) is the integration time.\(^5\)

Here we compute power spectra for case 1 (\( \mu_1 = \mu/\sqrt{3} \)) of the \( \mu \) orientation, but our approach can be used straightforward for any orientation of \( \mu \).

\(^5\) This is the result of Parseval’s Theorem.
Schawlow (1955). In the large $J$ limit, these selection rules will correspond to the modes of Equations (14) and (15).

For $q > I_1/I_2$, only the mode $m = 0$ has angular frequency given by Equation (14).

In the following, the emission modes induced by the oscillation of $\mu_x$ or $\mu_y$, which lie in the $\hat{x}\hat{y}$ plane, perpendicular to $\mathbf{J}$, are called in-plane modes, and those induced by the oscillation of $\mu_z$, in the direction perpendicular to the $\hat{x}\hat{y}$ plane are called out-of-plane modes. The order of mode is denoted by $m$ and $n$, respectively.

Figure 2 also shows that the emission power for out-of-plane modes $\omega_n$ is negligible compared to the power emitted by in-plane modes $\omega_m$.

The upper panel in Figure 3 shows the variation of the angular frequency of the dominant modes $m = 0, \pm 1, \pm 2$ with $q$. The kink at $q = q_{sp} = I_1/I_2$ in $\omega_m$ arises from the change of grain rotation state. For $q < q_{sp}$, the frequency $\omega_{m=0} = (\phi)$ is almost constant, whereas it increases with $q$ to $\omega_{m=0} = J/I_3$ at $q = I_1/I_3$. The frequency of the mode $m = 1$ also increases with $q$ for $q > q_{sp}$. The increase of frequency for the two dominant modes $m = 0$ and $1$ for $q > q_{sp}$ can result in an increase of the peak frequency of spinning dust spectrum. This issue will be addressed in the next section.

The middle panel in Figure 3 shows the emission power at the dominant frequency modes $|m| \leq 2$. For $q \sim 1$, most of the emission comes from the mode $m = -1$. As $q$ increases, the mode $m = 0$ becomes dominant.

The total emission power from all modes for irregular grains of different $I_2:I_3$ and $I_1:I_2 = 1:0.6$ is shown in the right panel.

We compute emission power spectra to infer $\omega_k$ and $P_{eik,k}$, as functions of $J$ and $q$, for various ratio of moments of inertia $I_1:I_2:I_3$. The obtained data will be used later to compute spinning dust emissivity.

### 4.2. Spinning Dust Emissivity

To calculate the spinning dust emissivity, the first step is to find the distribution function for grain angular momentum.

#### 4.2.1. Angular Momentum Distribution Function

Following HDL10, to find the distribution function for the grain angular momentum $\mathbf{J}$, we solve LEs describing the evolution of $\mathbf{J}$ in time in an inertial coordinate system. They read

$$dJ_i = A_i dt + \sqrt{B_{ii}} dq_i, \quad \text{for } i = x, y, z, \tag{17}$$

where $dq_i$ are random Gaussian variables with $\langle dq_i^2 \rangle = dt$, $A_i = \langle \Delta J_i/\Delta t \rangle$ and $B_{ii} = \langle (\Delta J_i)^2/\Delta t \rangle$ are damping and diffusion coefficients defined in the inertial coordinate system.

For an irregular grain, to simplify calculations, we adopt the $A_i$ and $B_{ii}$ for a disk-like grain obtained in HDL10. Following DL98b and HDL10, the disk-like grain has radius $R$ and thickness $H = 3.35\,\AA$, and the ratio of moments of inertia along and perpendicular to the grain symmetry axis $h = I_{11}/I_{22}$. Thereby, the effect of nonaxisymmetry on $A_i$ and $B_{ii}$ is ignored, and we examine only the effect the wobbling resulting from the irregular shape has on the spinning dust emissivity.

In dimensionless units, $J' = J/I_{14}\omega_{T,\parallel}$ with $\omega_{T,\parallel} = (2k_B T_{gas}/I_1)^{1/2}$ being the thermal angular velocity of the grain along the grain symmetry axis and $t' = t/\tau_{H,\parallel}$, Equation (17) becomes

$$dJ'_i = A'_i dt' + \sqrt{B'_{ii}} dq'_i, \tag{18}$$

where $\langle dq'_i^2 \rangle = dt'$ and

$$A'_i = -J'_i I_{14}\omega_{T,\parallel} - 2 J' I_{14}^3 3 \tau_{gas,\parallel}, \tag{19}$$

$$B'_{ii} = 2 I_{14} I_{11}^2 k_B T_{gas} \tau_{H,\parallel}, \tag{20}$$

where

$$\tau_{gas,\parallel} = \frac{\tau_{gas}}{\tau_{H,\parallel}} = \frac{F_{tot,\parallel}^{-1}}{\cos^2 \theta + \gamma_H \sin^2 \theta}, \tag{21}$$

$$\gamma_H = \frac{F_{tot,\parallel} \tau_{H,\parallel}}{F_{tot,\parallel} \tau_{H,\parallel}}, \tag{22}$$

$$\tau_{ed,\parallel} = \frac{\tau_{ed,\parallel}}{\tau_{H,\parallel}}, \tag{23}$$

where $\tau_{H,\parallel}$ and $\tau_{H,\perp}$ are the rotational damping times due to gas of purely hydrogen atom for rotation along the parallel and perpendicular directions to the grain symmetry axis $\mathbf{a}_1$, $\tau_{ed,\parallel}$ is the effective damping time due to electric dipole emission (see Appendix B), $\theta$ is the angle between $\mathbf{a}_1$ and $\mathbf{J}$, and $F_{tot,\parallel}$ and $F_{tot,\perp}$ are the total damping coefficients parallel and perpendicular to $\mathbf{a}_1$ (see HDL10).

At each time step, the angular momentum $J_i$ obtained from LEs is recorded and later used to find the distribution function $f_j$ with normalization $\int_0^\infty f_j dJ = 1$. 

---

6 The rotational levels of a particular asymmetric rotor, H$_2$O, are shown in Draine (2011).
4.2.2. Emissivity from Irregular Grains

As discussed in Section 4.1, an irregular grain rotating with a given angular momentum \( J \) radiates at frequency modes \( \omega_k \equiv \omega_m \) with \( m = 0, \pm 1, \pm 2, \ldots \) and \( \omega_k \equiv \omega_n \) with \( n = 1, 2, 3, \ldots \) (see Equations (14) and (15)). For simplicity, we define the former as \( \omega_m \) and the latter as \( \omega_n \), where \( i \) indicates the value for \( m \) and \( n \). These frequency modes depend on the parameter \( q(s) \), which is determined by the internal thermal fluctuations within the grain.

To find the emissivity at an observation frequency \( \nu = \omega / 2\pi \), we need to know how much emission each mode \( \omega_k \) contributes to the observation frequency \( \nu \). Consider an irregular grain rotating with the angular momentum \( J \); the probability of finding the emission at the angular frequency \( \omega \) depends on the probability of finding the value \( \omega \) such that

\[
\operatorname{pdf}(\omega | J) d\omega = f_{\text{VRE}}(s, J) ds = A \exp \left( -\frac{q(s) J^2}{2 I_1 k_B T_{\text{vib}}} \right) ds,
\]

where we assumed the VRE regime with \( f_{\text{VRE}} \) given by Equation (8).

For the mode \( \omega \equiv \omega_k(s) \), from Equation (24) we can derive

\[
\operatorname{pdf}_k(\omega | J) = \left( \frac{\partial \omega_k}{\partial s} \right)^{-1} f_{\text{VRE}}(s, J).
\]

The emissivity from the mode \( k \) is calculated as

\[
j_v^a = \frac{1}{4\pi} \int_{J_1}^{J_0} P_{\text{ed}}(k, \nu, \nu') \nu' f_j(J) \operatorname{pdf}_k(\omega | J) 2\pi dJ
\]

\[
+ \frac{1}{4\pi} \int_{J_1}^{J_0} P_{\text{ed}}(k, \nu, \nu') \nu' f_j(J) \operatorname{pdf}_k(\omega | J) 2\pi dJ,
\]

where \( q_\ll \) and \( q_\gg \) denote \( q \ll q_{sp} \) and \( q \gg q_{sp} \), respectively, \( J_1 \) and \( J_0 \) are lower and upper limits for \( J \) corresponding to a given angular frequency \( \omega_k(J, q) = \omega \), and \( 2\pi \) appears due to the change of variable from \( v \) to \( \omega \).

Emissivity by a grain of size \( a \) at the observation frequency \( v \) arising from all emission modes is then

\[
j_v^a = \sum_k j_v^a(k),
\]

Consider, for example, the emission mode \( k \equiv m_0 \). For the case \( I_2 \) slightly larger than \( I_3 \), this mode has the angular frequency \( \omega_{m_0} = (\phi) = (J/I_1)q_0 \) with \( q_0 \) obtained from calculation of \( \omega_{m_0} \), and is independent of \( q \) for \( q < q_{sp} \). As a result,

\[
\operatorname{pdf}_{m_0}(\omega | J) = \delta(\omega - (J/I_1)q_0).
\]

Thus, the first term of Equation (26), denoted by \( j_v^a(m_0, \ll) \), is rewritten as

\[
j_v^a(m_0, \ll) = \frac{1}{2} \int_{J_1}^{J_0} P_{\text{ed}}(m_0, J, \nu, \nu') \nu' f_j(J) \delta(\omega - (J/I_1)q_0) dJ,
\]

\[
= \frac{1}{2} \frac{I_1 f_j(J_0)}{q_0} \int_{J_1}^{J_0} P_{\text{ed}}(m_0, J_0, q(s)) dJ,
\]

where \( J_0 = I_1 \omega / q_0 \) and the value of \( q(s) \) remains to be determined.

For \( q > q_{sp} \), \( \langle \phi \rangle \) is a function of \( q \). Hence, the emissivity (26) for the mode \( k \equiv m_0 \) becomes

\[
j_v^a = \frac{1}{2} \frac{I_1 f_j(J_0)}{q_0} \int_{J_1}^{J_0} dJ P_{\text{ed}}(m_0, J_0, q(s)) f_{\text{VRE}}(J_0, s) + \frac{1}{2} \frac{I_1 f_j(J_0)}{q_0} \int_{J_1}^{J_0} dJ P_{\text{ed}}(m_0, J, q, \nu) f_{\text{VRE}}(J, \nu) \operatorname{pdf}(\omega | J) dJ,
\]

where \( s_{sp} \) is the value of \( s \) corresponding to \( q = q_{sp} \) and the term \( P_{\text{ed}}(m_0, J_0, q(s)) \) in Equation (29) has been replaced by its average value over the internal thermal distribution \( f_{\text{VRE}} \).

The emissivity per H is obtained by integrating \( j_v^a \) over the grain size distribution

\[
j_v^a = \frac{1}{n_H} \int_{J_{\text{min}}}^{J_{\text{max}}} \frac{d\nu}{dn} \frac{dn}{d\nu} j_v^a, \quad (31)
\]

where \( j_v^a \) is given by Equation (27).

4.2.3. Emissivity from Disk-like Grains

HDL10 showed that a disk-like grain with an angular momentum \( J \) radiates at frequency modes

\[
\omega_{m_1} = \phi + i \psi = \frac{J}{I_1} [h + i(1 - h) \cos \theta],
\]

\[
\omega_{n_1} = \dot{\phi} = \frac{J}{I_1} (1 - h) \cos \theta,
\]

where \( i = 0 \) and \( \pm 1 \). The emission power of these modes are given by following analytical forms (HDL10; Silsbee et al. 2011):

\[
P_{m_0} = \frac{2 \mu^2}{3 \epsilon^3} \omega_{m_0}^4 \sin^2 \theta,
\]

\[
P_{n_1} = \frac{2 \mu^2}{3 \epsilon^3} \omega_{n_1}^4 (1 + \cos \theta)^2,
\]

\[
P_{n_1} = \frac{2 \mu^2}{3 \epsilon^3} \omega_{n_1}^4 \sin^2 \theta.
\]

For the disk-like grain, from Equation (5), we obtain the number of states in phase space \( s \) for \( q \) spanning from \( 1 - q \):

\[
s = 1 - \left( \frac{h - q}{h - 1} \right)^{1/2} = 1 - \cos \theta,
\]

where \( q = 1 + (h - 1) \sin^2 \theta \) has been used. Thus, for an arbitrary mode with frequency \( \omega_k \), we obtain

\[
\operatorname{pdf}_k(\omega | J) d\omega = f_{\text{VRE}}(s, J) ds = f_{\text{VRE}}(\theta, J) \sin \theta d\theta.
\]

Taking use of \( \omega = \omega_k(J, \theta) \), we derive

\[
\operatorname{pdf}_k(\omega | J) = f_{\text{VRE}}(\theta, J) \left( \frac{\partial \omega_k}{\partial \theta} \right)^{-1} \sin \theta.
\]

Therefore, by substituting Equations (34)–(36) in Equation (26), the emissivity at the observation frequency
\[ v = \omega / (2\pi) \] from a disk-like grain of size \( a \) is now given by

\[
j^\omega_a = \frac{1}{2} \frac{f_J(I_k \omega / h)}{h} 2\mu_b^2 \frac{3\omega^4}{3} (\sin^2 \theta)
+ \frac{1}{2} \frac{\mu_b^2}{6c^3} \omega^4 \int_{J_1}^{J_2} \text{pdf}_{m_v}(\omega | J) f_J(J) dJ
+ \frac{1}{2} \frac{\mu_b^2}{6c^3} \omega^4 \int_{J_1}^{J_2} \text{pdf}_{m_v}(\omega | J) f_J(J) dJ
+ \frac{1}{2} \frac{\mu_b^2}{6c^3} \omega^4 \int_{J_1}^{J_2} \text{pdf}_{n_v}(\omega | J) f_J(J) dJ,
\]

(40)

where pdf \(_{m_v}\) and pdf \(_{n_v}\) are easily derived by using Equation (39) for \( \omega_{m_v} \) and \( \omega_{n_v} \), \( J_1 = I_k \omega / (2h - 1) \) and \( J_2 = I_k \omega \) for \( m \pm 1 \) mode, and \( J_1 = I_k \omega / (h - 1) \) and \( J_2 = \infty \) for \( n_1 \) mode (see Equations (32) and (33)).

As in HDL10, we also consider the regime without internal relaxation. Then, the distribution function \( f_{\text{RE}}(\theta, J) \) is replaced by a Maxwellian distribution (hereafter Mw regime):

\[
f_{\text{Mw}}(\theta) = \frac{1}{4\pi} \frac{h}{(\cos^2 \theta + h \sin^2 \theta)^{3/2}}.
\]

(41)

For symmetric rotors \((h = 1)\), the distribution function for \( \theta \) is isotropic:

\[
f_{\text{iso}}(\theta) = \frac{1}{4\pi},
\]

(42)

satisfying the normalization condition \( \int_0^\pi f_{\text{iso}}(\theta) 2\pi \sin \theta d\theta = 1 \).

### 4.3. Results

In this section, we present results for spinning dust emissivity from grains of irregular shape obtained using the method in Section 4.2.

#### 4.3.1. A Simple Model of Irregular Grain

We assume that the smallest grains of size \( a \leq a_2 = 6 \) Å, have irregular shape, and larger grains are spherical. To compare with emission from the disk-like grains, we consider the simplest case of the irregular shape in which the circular cross section of the disk-like grain is changed to an elliptical cross section. We are interested in the emission of two PAHs with the same mass \( M \) and thickness \( L \), therefore, the length of the semi-axes of elliptical disk is constrained by

\[
M = \pi R^2 L = \pi b_2 b_3 L,
\]

(43)

where \( R = (4a^3 / 3L)^{1/2} \) is the radius of the disk-like grain, \( b_2 \) and \( b_3 \) are the length of semi-axes \( a_2 \) and \( a_3 \), and \( b_1 = L \) is kept constant. Assuming that the circular disk is compressed by a factor \( \alpha \leq 1 \) along \( a_2 \), then Equation (43) yields

\[
b_2 = \alpha R, \ b_3 = \alpha^{-1} R.
\]

(44)

Denote the parameter \( \eta \equiv b_1 / b_2 = \alpha^{-2} \), then the degree of grain shape irregularity is completely characterized by \( \eta \).

The moments of inertia along the principal axes for the irregular grain are

\[
I_1 = \frac{M}{4} (b_2^2 + b_3^2) = \frac{I_2}{2} (\eta + \eta^{-1}),
\]

(45)

where \( I_2 \) is the moment of inertia for the disk-like grain. The ratios of moments of inertia read

\[
\begin{align*}
I_1 &= \frac{3(\eta + \eta^{-1})}{(L/R)^2 + 3\eta}, \\
I_2 &= \frac{(L/R)^2 + 3\eta}{(L/R)^2 + 3\eta^{-1}}.
\end{align*}
\]

(46)

(47)

For each grain size \( a \), the parameter \( \eta \) is increased from \( \eta = 1 \) to \( \eta = \eta_{\text{max}} \). However, \( \eta_{\text{max}} \) is constrained by the fact that the shortest axis \( a_2 \) should not be shorter than the grain thickness \( L \). Below we assume conservatively \( \eta_{\text{max}} \sim 3/2 \).

#### 4.3.2. Rotational Emission Spectrum

Although irregular grains radiate in a large number of frequency modes, we take into account only the dominant modes with order \( |m| \leq 2 \) and disregard the modes that contribute less than \( \sim 0.5\% \) to the total emission. We also assume that grains smaller than \( a_2 \) have a fixed vibrational temperature \( T_{\text{vib}} \), and that for the instantaneous value of \( J \) the rotational energy has a probability distribution \( f_{\text{RE}} \) (i.e., VRE regime).

We adopt the grain size distribution \( dn/da \) from Draine & Li (2007) with the total to selective extinction \( R_V = 3.1 \) and the total carbon abundance per hydrogen nucleus \( f_C = 5.5 \times 10^{-5} \) in carbonaceous grains with \( a_{\text{min}} = 3.55 \) Å and \( a_{\text{max}} = 100 \) Å.

The spinning dust emissivity is calculated for a so-called model A (similar to DL98b; HDL10), in which 25% of grains have the electric dipole moment parameter \( \beta = 2\hbar \), 50% have \( \beta = \hbar_0 \), and 25% have \( \beta = 0.5\hbar_0 \) with \( \hbar_0 = 0.4 \) D. In the rest of the paper, the notation model A is omitted, unless stated otherwise.

Figure 4 shows the spinning dust spectra for different degree of irregularity \( \eta \) and various dust temperature \( T_{\text{vib}} \) in the WIM. The emission spectrum for a given \( T_{\text{vib}} \) shifts to higher frequency as \( \eta \) decreases (i.e., the degree of grain irregularity increases), but their spectral profiles remain similar.

To see more clearly the effect of grain shape irregularity, in Figure 5 we show the variation of peak frequency \( \nu_{\text{peak}} \) and peak emissivity \( \nu_{\text{peak}} \) as a function of \( \eta \) for different \( T_{\text{vib}} \) and for case 1 \((\mu_1 = \mu / \sqrt{3})\) of \( \mu \) orientation for the WIM.

For low \( T_{\text{vib}} \) (i.e., \( T_{\text{vib}} = 20 \) K), \( \nu_{\text{peak}} \) increases slowly with \( \eta \), while \( \nu_{\text{peak}} \) varies slightly. As \( T_{\text{vib}} \) increases, both \( \nu_{\text{peak}} \) and \( \nu_{\text{peak}} \) increase rapidly with \( \eta \), but the former increases faster.

Figure 6 shows the results for case 2 \((\mu_1 = 0)\) of \( \mu \) orientation. Similar to case 1, \( \nu_{\text{peak}} \) increases with \( \eta \) for \( T_{\text{vib}} \geq 60 \) K, but changes rather little for \( T_{\text{vib}} = 20 \) K. The variation of \( \nu_{\text{peak}} \) with \( \eta \) is more complicated. For \( T_{\text{vib}} \leq 60 \) K, it increases first to \( \nu_{\text{peak}} \sim 1.23 \) and then drops as \( \eta \) increases.

### 5. SPINNING DUST SPECTRUM: EXPLORING PARAMETER SPACE

Below we explore parameter space by varying dust temperature, the lower grain size cutoff, the grain dipole moment, and the gas density. Our results from the previous section indicate that the spinning dust spectrum from grains of irregular shape is shifted in general to higher frequency, relative to that from disk-like grains, but their spectral profile remains similar. Therefore, it is sufficient to explore parameter space of spinning dust for disk-like grains, extrapolating to irregular grains using our results from the previous section. Spinning dust emissivity is then calculated using Equation (31) in which \( j^\omega_a \) is given by Equation (40).
Similar to Figure 5, but for case 2 (case 1 (49)).

\[
\langle j^\mu_{\nu} \rangle_T = \int_{T_{\nu} - T}^{T_{\nu}} \frac{dP}{dT_{\nu}} dT_{\nu} + \int_{T_{\nu} - T_{\nu}}^{T_{\nu}} \frac{dP}{dT_{\nu}} dT_{\nu} \tag{48}
\]

is the probability of the grain having \( T_{\nu} \approx T \) and \( dP/dT \) is the probability of the grain having temperature in \( T, T + dT \).

Figure 7 shows spinning dust spectra averaged over temperature distribution, \( \langle j^\mu(T_{\nu})_T \rangle \), for various decoupling temperatures \( T_{\nu} \) compared to spectra for grains having a single vibrational temperature \( T_{\nu} = T_{\nu} \). For low \( T_{\nu} \approx 70 \), the averaged emissivity \( \langle j^\mu(T_{\nu})_T \rangle \) is smaller than \( j^\mu(T_{\nu} = T_{\nu}) \), but the difference between \( j^\mu(T_{\nu} = T_{\nu}) \) and \( j^\mu(T_{\nu} = T_{\nu} = T_{\nu}) \) decreases as \( T_{\nu} \) increases.

For \( T_{\nu} = 60 \), Figure 7 shows that \( j^\mu(T_{\nu} = T_{\nu}) \) is approximately equal to \( j^\mu(T_{\nu} = T_{\nu} = T_{\nu}) \) with the difference less than a few percent.
In the rest of the paper, we adopt a conservative value $T_D = 60$ K and calculate the spinning dust emissivity assuming that all grains have a single temperature $T_d$.

5.2. Minimum Size $a_{\text{min}}$

The spinning dust emission spectrum is sensitive to the population of the smallest dust grains and its peak frequency is mostly determined by the smallest grains. When $a_{\text{min}}$ is increased, the peak frequency $v_{\text{peak}}$ decreases accordingly.

Figure 8 shows the variation of $v_{\text{peak}}$ as a function of $a_{\text{min}}$ for various environments, and case 2 ($\mu_1 = 0$) of $\mu$ orientation and for the CNM and WIM. Solid and dotted lines are emissivity spectra averaged over temperature distribution, $(j_\nu(T_d)\nu$, and spectra for grains having $T_{\text{vib}} = T_d$, $j_\nu(T_{\text{vib}} = T_d)$, respectively. Two values $T_d = 20$ and 60 K are chosen for illustration.

(A color version of this figure is available in the online journal.)

and VRE regime ($T_d = 60$ K). As expected, $v_{\text{peak}}$ decreases generically with $a_{\text{min}}$ increasing.

5.3. Effect of Electric Dipole Moment

5.3.1. Variation of Orientation of Electric Dipole Moment

Siltsbee et al. (2011) found that the total emission power $P_{\text{ed}}$ and the peak frequency are rather insensitive to the orientation of the electric dipole moment. That stems from their calculations assuming no internal relaxation (i.e., $T_{\text{vib}} \rightarrow \infty$), so that the angle $\theta$ is drawn from a isotropic distribution function $f_{\text{iso}}$. Below we study the variation of emissivity $j_\nu$ with the orientation of the dipole accounting for the internal relaxation.

To investigate the variation of $j_\nu$, with the orientation of $\mu$, in addition to case 1 ($\mu_1 = \mu/\sqrt{3}$) and case 2 ($\mu_1 = 0$) of $\mu$ orientation, we consider values of $\mu_1^2/\mu^2$ between 2/3 (case 1) and 1 (case 2). We also consider the regime of fast internal relaxation (VRE) and without internal relaxation (Mw and iso). Model A for the distribution of electric dipole moment is adopted.

Figure 9 shows the variation of $v_{\text{peak}}$ (upper panel) and $j_{\text{peak}}$ (lower panel) of spinning dust spectrum with $\mu_1^2/\mu^2$. It can be seen that for Mw and iso $f(\theta)$, $v_{\text{peak}}$ changes rather slowly with $\mu_1^2/\mu^2$, with somewhat larger variation found in the VRE regime. The peak emissivity for all regimes exhibits similar trend that decreases with increasing $\mu_1^2/\mu^2$, though such a decrease
is only \(\sim 10\%\) when the \(\mu\) orientation changes from case 1 \((\mu_1 = \mu / \sqrt{3})\) to case 2 \((\mu_1 = 0)\).

### 5.3.2. Variation of Distribution of Electric Dipole Moment

Our standard model (model A; see Table 1) assumed grains of a given size \(a\) to have three values of dipole moment, \(\beta = \beta_0, \beta_0/2,\) and \(2\beta_0\) with \(\beta_0 = 0.4\, \text{D}\), appearing in Equation (2).

Here we examine the possibility of considerable variation in the dipole moment per grain, by considering a model (model B) in which 40% of grains have dipole moment parameter \(\beta = \beta_0\); 15% have \(\beta = 2\beta_0\) and \(\beta_0/2\); 10% have \(\beta = 4\beta_0\) and \(\beta_0/4\); and 5% have \(\beta = 8\beta_0\) and \(\beta_0/8\). Emissivity per H for this model is compared with the typical model A in Figure 10.

Figure 10 shows emission spectra for model A and 2 in cases 1 \((\mu_1 = \mu / \sqrt{3})\) and 2 \((\mu_1 = 0)\) of the \(\mu\) orientation, for the CNM and WIM. Results for the VRE \((T_\text{d} = 60\, \text{K})\) regime are presented. The peak frequency from model B is lower than for model A, but model B has a higher peak emissivity. The larger value of \(\langle \beta^2 \rangle = 3.12\beta_0^2\) in model B leads to stronger electric dipole emission but also stronger rotational damping.

### 5.4. Variation of Values of Dipole Moment and Gas Density

Here we assume that all physical parameters are constant, including gas temperature and dust temperature. Only the value of characteristic dipole moment \(\beta_0\) and gas density \(n_\text{H}\) are varied in calculations. We run LE simulations for 16 values of \(\beta_0\) from 0.05 to 3.2 D, and 32 values of \(n_\text{H}\) from \(10^{-2}\) to \(1\, \text{cm}^{-3}\) for the WIM and from 1 to \(100\, \text{cm}^{-3}\) for the CNM. For a given value of \(\beta_0\), the gaseous rotational damping time and the damping and excitation coefficient from infrared emission vary with the gas density \(n_\text{H}\) as

\[
\tau_\text{H} = \tau_\text{H}(n_\text{H})^{-1/\mu}, \quad (50)
\]

\[
F_\text{IR} = F_\text{IR}(n_\text{H})^{-1}, \quad G_\text{IR} = G_\text{IR}(n_\text{H})^{-1}, \quad (51)
\]

where \(n_\text{H}\) is the typical gas density given in Table 2. Other rotational damping and excitation coefficients are independent of gas density.

The obtained distribution function for grain angular momentum is used to calculate spinning dust emissivity as functions of \(\beta_0\) and \(n_\text{H}\) (see Section 4.2.3).

Figure 11 shows the contour of peak frequency \(v_{\text{peak}}\) and peak emissivity \(j_{\text{peak}}\) in the plane of \(n_\text{H}, \beta_0\) for case 2 \((\mu_1 = 0)\) of the \(\mu\) orientation in the CNM and WIM and for the VRE regime with \(T_\text{d} = 60\, \text{K}\). For a given \(\beta_0\), both \(v_{\text{peak}}\) and \(j_{\text{peak}}\) increase with \(n_\text{H}\) due to the increase of collisional excitation with \(n_\text{H}\). For a given \(n_\text{H}\), as \(\beta_0\) increases, \(v_{\text{peak}}\) decreases, but \(j_{\text{peak}}\) increases. That is because as \(\beta_0\) increases, electric dipole damping rate increases, which results in a lower rotational rate of grains. Meanwhile, the emissivity increases with \(\beta_0\) as \(\beta_0^2\).

The results \((v_{\text{peak}}\) and \(j_{\text{peak}}\) for the Mw regime are slightly larger than those for the former case due to the lack of internal relaxation.

From Figure 11, it can be seen that the amplitude of variation of \(v_{\text{peak}}\) and \(j_{\text{peak}}\) as functions of \(n_\text{H}\) and \(\beta_0\) is very large. Thus, for a fixed grain size distribution, \(n_\text{H}\) and \(\beta_0\) are the most important parameters in characterizing the spinning dust emission.

### 6. EFFECT OF TURBULENCE ON SPINNING DUST SPECTRUM

Turbulence is present at all scales of astrophysical systems (see Armstrong et al. 1995; Chepurnov & Lazarian 2010). The effects of turbulence on many astrophysical phenomena, e.g., star formation, cosmic ray transport, and acceleration, have been widely studied. In the context of electric dipole emission from spinning dust, compressible turbulence will produce density variations that can affect grain charging, rotational excitation, and damping. We expect enhancement of spinning dust emissivity per particle from denser clumps, with an increase in the emission integrated along a line of sight. This issue is quantified in the following. For simplicity, we disregard the effect of turbulence on the grain charging.

#### 6.1. Numerical Simulations of MHD Turbulence

Gas density fluctuations in a turbulent medium are generated from magnetohydrodynamic (MHD) simulations. The sonic and Alfvenic Mach numbers are defined as usual \(M_s = (\delta V/c_s)\), \(M_A = (\delta V/v_A)\) with \(\delta V\) the amplitude for injection velocity, \(c_s\), and \(v_A = B_0/\sqrt{4\pi\rho}\) the sound speed and Alfvenic speed.

The simulations are performed by solving the set of non-ideal MHD equations, in conservative form:

\[
\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \quad (52)
\]

\[
\frac{\partial \rho \mathbf{v}}{\partial t} + \nabla \cdot \left[ \rho \mathbf{v} \mathbf{v} + \left( p + \frac{B^2}{8\pi} \right) I - \frac{1}{4\pi} \mathbf{BB} \right] = \rho \mathbf{f}, \quad (53)
\]

**Figure 11.** Contour of peak frequency and peak emissivity in the plane of $n_H$ and $\beta_0$ for the CNM (upper) and the WIM (lower), for the VRE ($T_0 = 60$ K) regime. Case 2 ($\mu_1 = 0$) of the $\mu$ orientation is considered. Peak frequency increases with $n_H$ but decreases with $\beta_0$. Emissivity increases with both $n_H$ and $\beta_0$.

Figure 12. Spinning dust emissivity per H in the presence of compressible turbulence with sonic Mach number $M_s = 2$ and 7, compared to that from a uniform medium with gas density $n_H = n_{H0}$ for the CNM (red) and WIM (green). The peak emissivity is increased, and the spectrum is shifted to higher frequency due to compressible turbulence. Case 2 ($\mu_1 = 0$) of the $\mu$ orientation is considered.

(A color version of this figure is available in the online journal.)

| Model | $M_s$ | $M_A$ | $v_A/c_s$ | $(\rho^2)/(\bar{\rho}^2)$ |
|-------|-------|-------|-----------|------------------|
| 1     | 2.0   | 0.7   | 2.9       | 1.7              |
| 2     | 4.4   | 0.7   | 6.3       | 2.1              |
| 3     | 7.0   | 0.7   | 10        | 3.0              |

6.2. Results: Influence of Gas Density Fluctuations

In a medium with density fluctuations, the effective emissivity is

$$\langle j_\nu \rangle = \int_0^1 f(x) j_\nu(x)dx,$$

where $f(x)dx$ is the fraction of the mass with $\rho/\langle \rho \rangle \in (x, x + dx)$. We use compression distributions $f(x)$ obtained from MHD simulations for $M_s = 2$ and 7 to evaluate $\langle j_\nu \rangle$ for the WIM and CNM, respectively. We assume case 2 ($\mu_1 = 0$) of the $\mu$ orientation. The resulting effective emissivity is compared with the emissivity from the uniform medium in Figure 12. It can

$$\frac{\partial \mathbf{B}}{\partial t} - \nabla \times (\mathbf{v} \times \mathbf{B}) = 0,$$  \hspace{1cm} (54)

with $\nabla \cdot \mathbf{B} = 0$, where $\rho$, $\mathbf{v}$, and $p$ are the plasma density, velocity, and pressure, respectively, $I$ is the diagonal unit tensor, $\mathbf{B}$ is the magnetic field, and $f$ represents the external acceleration source, responsible for the turbulence injection. Under this assumption, the set of equations is closed by an isothermal equation of state $p = c_s^2 \rho$. The equations are solved using a second-order-accurate and non-oscillatory MHD code described in detail in Cho & Lazarian (2003). Parameters for the models of MHD simulations are shown in Table 3, including the sonic Mach number $M_s$ and Alfvenic Mach number $M_A$. 

12
be seen that the turbulent compression increases the emissivity and shifts the peak to higher $v_{\text{peak}}$.

The increase of peak frequency and peak emission intensity, as a function of $M_s$ are shown in Figure 13. $\nu_{\text{peak}}$ and $j_{\text{peak}}$ are emissivity for the turbulent and uniform media, respectively. $(\nu_{\text{peak}})$ and $v_{\text{peak}}$ are peak frequency for the former and latter. Results for $M_s = 2$ and $7$ are obtained from the spinning dust spectra for the WIM and CNM, respectively. For $M_s = 4.4$, results for the CNM are chosen. It is shown that the emission intensity can be increased by factors from $\sim 1.2$ to $1.4$, and peak frequency is increased by factors from $1.1$ to $1.2$ as $M_s$ increases from $2$ to $7$.

6.3. Observational Constraining Turbulence Effects

The discussion of interstellar conditions adopted in DL98 was limited by idealized interstellar phases. It is now recognized that turbulence plays an important role in shaping the ISM.

The distribution of phases, for instance, CNM and WNM of the ISM at high latitudes can be obtained from absorption lines. Similarly, studying fluctuations of emission it is possible to constrain parameters of turbulence. In an idealized case of a single phase medium with fluctuations of density with a given characteristic size one can estimate the value of the three-dimensional fluctuation by studying the two-dimensional fluctuations of column density. A more sophisticated technique of obtaining sonic Mach numbers have been developed recently (see Kowal et al. 2007; Esquivel & Lazarian 2010; Burkhart et al. 2009, 2010). In particular, Burkhart et al. (2010), using just column density fluctuations of the Small Magellanic Cloud, obtained a distribution of Mach numbers corresponding to the independent measurements obtained using Doppler shifts and absorption data. With such an input, it is feasible to quantify the effect of turbulence in actual observational studies of spinning dust emission.

7. GALACTIC CMB FOREGROUND COMPONENTS

7.1. Galactic CMB Foreground Components

The Galactic CMB foreground consists of four components: synchrotron emission ($I_{\nu}^{\text{syn}}$), free–free emission ($I_{\nu}^{\text{ff}}$), thermal dust emission ($I_{\nu}^{\text{td}}$), and spinning dust emission ($I_{\nu}^{\text{sdd}}$):

$$I_{\nu} = I_{\nu}^{\text{syn}} + I_{\nu}^{\text{ff}} + I_{\nu}^{\text{td}} + I_{\nu}^{\text{sdd}}. \tag{56}$$

The synchrotron emission consists of soft and hard components. The soft component has the spectrum $I_{\nu}^{\text{syn}} \sim \nu^{-\beta}$ with $\beta = 0.7$–$1.2$ and is dominant below 1 GHz. The soft synchrotron is produced from electrons accelerated by supernova shocks that spiral about the Galactic magnetic field (Davies et al., 1996).

The hard component, also named “Haze,” is present around the Galactic center, and its origin is still unknown (Finkbeiner et al., 2004). The free–free emission arising from ion–electron scattering has a flatter spectral index $I_{\nu}^{\text{ff}} \sim \nu^{-\beta}$ with $\beta \approx 0.1$. It is an important CMB foreground in the range 10–100 GHz. The third component due to thermal dust emission (vibrational emission of dust grains) dominates above 100 GHz. Finally, the spinning dust component dominates the range 20–60 GHz.

Dobler et al. (2009) subtracted the synchrotron contribution using the Haslam et al. (1982) 408 MHz map plus a model for the “haze” component. The remaining emission was decomposed into two components: (1) a “thermal-dust-correlated” spectrum correlated with the Schlegel et al. (1998, hereafter SFD) dust map (basically, 100 $\mu$m) and (2) an Hα-correlated spectrum correlated with observed (reddening-corrected) Hα. Both components included an “anomalous emission” component, peaking around 30–40 GHz, that is attributable to spinning dust.

The spinning dust intensity is given by

$$I_{\nu}^{\text{sdd}} = \int j_{\nu} dl, \tag{57}$$

where $j_{\nu}$ is the spinning dust emissivity and the integral is taken along a line of sight. Below, we constrain the physical parameters of spinning dust by fitting the model of foreground emissions to Hα-correlated and thermal-dust-correlated emission spectra.

PAHs are likely to be irregular, but we do not attempt to determine the degree of irregularity in the present paper. Instead, we calculate spinning dust spectra for disk-like grains, and account for the effect of the grain shape irregularity by scaling the emission to account for irregularity. Consider a simple model of the grain’s irregular shape, with the ratio of semi-axes $\eta = b_3/b_2 = 1.2$ (see Section 4.3). Then, the model peak frequency and peak emissivity are scaled with those from disk-like grains as follows:

$$v_{\text{peak}}^{\text{mod}} = v_{\text{peak}}(\text{disk}) \times \frac{v_{\text{peak}}(\eta)}{v_{\text{peak}}(\text{disk})}, \tag{58}$$

$$j_{\text{peak}}^{\text{mod}} = j_{\text{peak}}(\text{disk}) \times \frac{j_{\text{peak}}(\eta)}{j_{\text{peak}}(\text{disk})}, \tag{59}$$

where we take $v_{\text{peak}}(\eta)/v_{\text{peak}}(\text{disk})$ and $j_{\text{peak}}(\eta)/j_{\text{peak}}(\text{disk})$ from Figures 5 and 6.

7.2. Fitting to Hα-correlated Emission

The Hα intensity is approximately given by (Draine, 2011)

$$I_{\text{H\alpha}} = 0.361 T_\epsilon^{-0.942-0.031 \ln T_\epsilon} \frac{\text{EM}}{R}, \tag{60}$$

where $T_\epsilon = T_e/(10^4 \, K)$, $T_e$ is the electron temperature, and EM is the emission measure.

---

8 It may be seen that Alfven Mach numbers have a subdominant effect on the distribution of densities (see Kowal et al. 2007). Thus, in our study (see Table 3) we did not vary the Alfven Mach number.
Dobler et al. (2009) have determined the spectrum \( I_{\nu}^{\text{obs}} \) of the H\(_{\alpha}\)-correlated emission in the WMAP five-year data. The thermal dust contribution has been almost completely removed as part of the SFD-correlated component, and synchrotron emission has similarly been removed by its correlation with the Haslam et al. (1982) 408 MHz map. Within the frequency range considered here, the residual thermal dust emission and synchrotron emission are assumed negligible.

Thus, as in Dobler et al. (2009), we fit the H\(_{\alpha}\)-correlated spectrum with three components: free–free emission, spinning dust emission, and CMB cross-correlation bias. We present the ratio of intensity to H\(_{\alpha}\) intensities. The free–free emission is given by (Draine 2011)

\[
\frac{I_{\nu}^{\text{ff}}}{I_{H\alpha}} = F_0 \left( \frac{\nu}{23 \text{ GHz}} \right)^{-0.12} \text{kJy sr}\text{^{-1} R}\text{^{-1}},
\]

where

\[
F_0 = 0.197T_4^{0.614+0.942\ln T_4}.
\]

The CMB bias is defined as \( \partial B_\nu(T)/\partial T \big|_{T=2.7K} \propto \nu^2 \), and we obtain

\[
\frac{I_{\nu}^{\text{cmb}}}{I_{H\alpha}} = C_0 \left( \frac{\nu}{23 \text{ GHz}} \right)^2 \frac{1}{\text{plc}(\nu)} \text{kJy sr}\text{^{-1} R}\text{^{-1}},
\]

where \( C_0 \) is a free parameter and plc is the Planck correction factor to convert thermodynamic temperature \( \Delta T \) to antenna temperature at frequency \( \nu \).

The spinning dust component is taken as the emission from the WIM. We obtain

\[
\frac{I_{\nu}^{\text{sd}}}{I_{H\alpha}} = S_{d0} \times \left( \frac{I_{\nu}^{\text{sd}}}{I_{H\alpha}} \right)_{\text{WIM}},
\]

where \( \left( I_{\nu}^{\text{sd}}/I_{H\alpha} \right)_{\text{WIM}} \) is calculated for our model for the WIM with a standard PAH abundance, and the fitting parameter \( S_{d0} \) allows for the possibility that the PAH abundance in the WIM may differ from our standard value.

Using Equation (60) for the above equation, we obtain the spinning dust intensity per H\(_{\alpha}\),

\[
\left( \frac{I_{\nu}^{\text{sd}}}{I_{H\alpha}} \right)_{\text{WIM}} = \left( \frac{j_v}{n_{\text{H}}} \right)_{\text{WIM}} \times \left( \frac{n_{\text{H}}}{F_0} \right)_{\text{WIM}} \times \left( \frac{\nu}{23 \text{ GHz}} \right)^2 \frac{1}{\text{plc} (\nu)} \times \frac{8.55 \times 10^{18} \mu_0}{\beta_0} \times 0.942 + 0.031 \ln T_4 \times 10^{18} \text{ cm}^{-3} / \text{cm}^{-2} / n_{\text{H}}^2 \times \left( \frac{\nu}{23 \text{ GHz}} \right)^{-0.12} \text{ kJy sr}\text{^{-1} R}\text{^{-1}},
\]

where \( j_v/n_{\text{H}} \) is the measured H\(_{\alpha}\) correlated emission intensity and \( \sigma_\nu \) is the mean noise per observation at the frequency band \( \nu \) (see Hinshaw et al. 2007; Dobler et al. 2009).

In general, \( \chi^2 \) is a function of three amplitude parameters \( F_0, C_0, S_{d0} \), and two physical parameters \( n_{\text{H}} \) and \( \beta_0 \). Therefore, the fitting proceeds by minimizing \( \chi^2 \) over five parameters.

Figure 14 shows \( \chi^2 \) contours as functions of \( \beta_0 \) and \( n_{\text{H}} \) for case 2 (\( \mu_1 = 0 \)) and for VRE (\( T_4 = 60 \) K), for the values of \( S_{d0} \) and \( F_0 \) for which \( \chi^2 \) is minimized. We can see that the distribution of \( \chi^2 \) is localized and centered around the standard values in the plane \( n_{\text{H}} - \beta_0 \).

Figure 15 shows the fit of the three-component model to the H\(_{\alpha}\)-correlated foreground spectrum for VRE and Mw regimes for case 2 of \( \mu \). Both regimes provide a good fit to the data.

Table 4 shows the best-fit parameters and \( \chi^2 \) for H\(_{\alpha}\)-correlated Emission

| \( \mu \) | \( f_{\text{int}}(\theta) \) | \( n_{\text{H}} \) (cm\(^{-3}\)) | \( \beta_0(D) \) | \( S_{d0} \) | \( F_0 \) | \( C_0 \) | \( \chi^2 \) |
|---|---|---|---|---|---|---|---|
| Case 1 | VRE | 0.15 | 0.76 | 0.04 | 0.09 | 0.0012 | 1.9 |
| Mw | 0.08 | 1.0 | 0.06 | 0.1 | 0.001 | 4.5 |
| Case 2 | VRE | 0.11 | 0.65 | 0.06 | 0.09 | 0.0012 | 1.1 |
| Mw | 0.14 | 0.84 | 0.04 | 0.09 | 0.0012 | 1.6 |

For the spinning dust model, we consider a range of gas densities \( n_{\text{H}} \in [0.01, 1] \) cm\(^{-3}\) and the value of dipole moments \( \beta_0 \in [0.1, 1] \) D. For each \( (n_{\text{H}}, \beta_0) \), we compute \( (j_v/n_{\text{H}})_{\text{WIM}} \). We then vary the values of \( F_0, S_{d0}, \) and \( C_0 \). From a given value \( F_0 \), we derive the gas temperature \( T_4 \) using Equation (62). When
From Table 4, it can be seen that the best-fit value \( S_{d0} \sim 0.04-0.06 \) is significantly lower than the value \( S_{d0} = 0.3 \) in Dobler et al. (2009). Our lower \( S_{d0} \) stems from the higher value of \( \beta_0 \) required from the increase of emissivity in the HDL10 model compared to the DL98 model used in Dobler et al. (2009), and the further (modest) increase in emissivity for irregular grains. As a result, a higher depletion of small PAHs is required to obtain a good fit.

In addition, from best-fit values \( F_0 \) in Table 4 we derive the gas temperature \( T_g \sim 2700-3500 \text{ K} \) as found by Dobler et al. (2009). This is lower than the typical temperature \( T_g = 8000 \text{ K} \) usually assumed for the WIM. Dong & Draine (2011) proposed a model of three components that can explain the low gas temperature in the WIM.

### 7.3. Fitting to Thermal Dust-correlated Emission

In addition to the H\(\alpha\)-correlated emission, the foreground induces a dust-correlated emission spectrum with a usual thermal dust emission component falling from 94 to 40 GHz, and another component rising from 40 to 23 GHz (see Bennett et al. 2003). The latter component is consistent with the spinning dust emission (DL98ab; de Oliveira-Costa et al. 2004; HDL10). Although this peak frequency around 22 GHz is consistent with prediction by the DL98 model, it is lower than the prediction by the improved model of HDL10, using the same parameters for the CNM as in DL98b.

- Three-component fit model (solid line) to the H\(\alpha\)-correlated spectrum using CMB5 data (diamonds) from Dobler et al. (2009) for VRE (upper) and Mw (lower) regimes using case 2 (\( \mu_1 = 0 \)) of \( \mu \). Three components of free–free emission, spinning dust emission, and CMB bias are shown separately. Shown are the best-fit parameters and \( \chi^2 \).

(A color version of this figure is available in the online journal.)

As in Dobler et al. (2009), we fit the thermal-dust-correlated emission spectrum with a three-component model including spinning dust, thermal dust, and CMB bias.\(^9\)

Dobler et al. (2009) determined the spectrum \( I_v/T_{94 \text{ GHz}}(\text{FDS}) \) for the contribution \( I_v \) to the intensity from the thermal-dust-correlated emission, where \( T_{94 \text{ GHz}}(\text{FDS}) \) is the antenna temperature at 94 GHz predicted for the FDS dust model (Finkbeiner et al. 1999).

The Planck collaboration (2011c) showed that the thermal dust emission can be approximated by

\[
I_v^{\text{th}} = \epsilon(v) B_v(T_{\text{d}}) N_{\text{H}},
\]

where \( T_{\text{d}} = 17.6 \text{ K} \) and \( \epsilon(v) = 0.92 \times 10^{-25} (\lambda/250 \mu\text{m})^{-1.8} \text{ cm}^{-2} \text{ H}^{-1} \).

We model the spinning dust contribution as

\[
I_v^{\text{sd}} = S_{d0} \left( \frac{j_v}{R_{\text{H}}} \right)_{\text{CNM}}.
\]

Thus, we seek to fit the Dobler et al. (2009) spectrum by

\[
\frac{I_v}{T_{94 \text{ GHz}}(\text{FDS})} = \left\{ \left( \frac{v}{94 \text{ GHz}} \right)^{3.8} + S_{d0} \left[ \frac{j_v}{n_{\text{H}} \epsilon_{\text{CNM}}} \right]_{94 \text{ GHz}} \right\} \epsilon(v) B_v(T_{\text{d}})_{94 \text{ GHz}} + C_0 \left( \frac{v}{94 \text{ GHz}} \right)^2 \text{ kJy sr}^{-1} \text{ m K}^{-1},
\]

where \( A, S_{d0}, \) and \( C_0 \) are adjustable parameters. For each trial \( n_{\text{H}} \) and \( \beta_0 \), we adjust \( A, S_{d0}, \) and \( C_0 \) to minimize \( \chi^2 \). We consider different possible values of \( n_{\text{H}} \) and \( \beta_0 \).

Best-fit parameters and \( \chi^2 \) for different situations are shown in Table 5. In case 1 (\( \mu_1 = \mu/\sqrt{3} \)), the best fit corresponds to \( n_{\text{H}} = 6.0-6.5 \text{ cm}^{-3} \) and \( \beta_0 \sim 0.94-0.97 \text{ D} \) for the VRE and Mw regimes. In case 2 (\( \mu_1 = 0 \)), the best fit corresponds to \( n_{\text{H}} = 7.0-7.5 \text{ cm}^{-3} \) and \( \beta_0 \sim 0.95 \text{ D} \) for VRE and Mw regimes. The significance of fitting is low in both cases 1 and 2. Case 2 fits slightly better (\( \chi^2 = 30-35 \)) than case 1 (\( \chi^2 = 54-56 \)).

Figure 16 shows the best fit to the thermal-dust-correlated spectrum obtained using case 2 models, for both VRE and Mw regimes.

We see that the fitting to thermal-dust-correlated emission has large \( \chi^2 \). The reason is that the curvature of the model spectrum is larger than that of the observed spectrum for frequencies 22–44 GHz.

### 7.4. Classical versus Quantum Treatment

Ysard & Verstraete (2010, hereafter YV10) questioned the validity of classical mechanics in the DL98 model for spinning
dust emission. YV10 put forward a quantum-mechanical formalism for treating the rotational emission. However, they only calculated spinning dust emission for the rotational transition $\Delta J = -1$ and $\Delta K = 0$, which is induced by the oscillation of the dipole component along the grain symmetry axis.

In our view, a quantum description of spinning dust is unnecessary, because, as shown in DL98b for spherical grain, the angular quantum number

$$ J \equiv I_{1\omega} / h \approx 7 \left( \frac{N_C}{20} \right)^{5/6} \left( \frac{T_{\text{rot}}}{100 \text{ K}} \right)^{1/2}, $$

which shows that even the smallest PAHs have angular quantum number $J \gg 1$, and therefore, the classical treatment should be valid.

Miville-Deschênes et al. (2008) made an attempt to separate the spinning dust component from the Galactic foreground components (mostly synchrotron and anomalous emission) using both the WMAP intensity and polarization data. The inferred spinning dust spectrum is presented in Figure 17 (diamond symbols).

Ysard et al. (2010) presented a fit to observation data for spinning dust, which is extracted from WMAP data for regions with latitude $b = 22\degree:4$ (the spinning dust spectrum extracted from WMAP data using the quantum mechanical approach from YV10). They assumed a lower cutoff of the grain size corresponding to the number of carbon atoms $N_{\text{min}} = 24$ and 48 for the CNM and WNM, and dipole moment $\mu_0 = 0.3$ D. Converting to the grain size using the usual relationship $a = 10(N_C/410)^{1/3}$ Å, we obtain $a_{\text{min}} \sim 3.88$ and 4.89 Å, respectively. However, since the $a_{\text{min}}$ chosen for the WNM is much larger than that for the CNM, the peak frequency of its emission spectrum is expected to be much lower than that for the CNM, because the peak frequency decreases with increasing $a_{\text{min}}$ (see Section 5.2). This disagrees with results shown in Figure 5 of Ysard et al. (2010), where the peak frequency of the WNM ($\nu_{\text{peak}} \sim 45$ GHz) is much larger than that for the CNM ($\nu_{\text{peak}} \sim 22$ GHz).

To see how well the improved model of spinning dust in HDL10 fits to observation data for selected regions in Ysard et al. (2010), we assume the same spinning dust parameters as in Ysard et al. (i.e., gas density, dipole moment $\mu_0$, and $a_{\text{min}}$).

The total emission intensity from the CNM and WNM with column density $N_H(CNM)$ and $N_H(WNM)$ is given by

$$ I_{\nu}^{\text{mod}} = N_H(CNM) \left( \frac{j_{\nu}^{sd}}{n_H} \right)_{\text{CNM}} + N_H(WNM) \left( \frac{j_{\nu}^{sd}}{n_H} \right)_{\text{WNM}}, $$

where $[j_{\nu}^{sd}/n_H]$ is the spinning dust emissivity per H calculated for the CNM and WNM, respectively (see Table 2). The fitting proceeds by minimizing $\chi^2$ (Equation (67)) with $N_H(CNM)$ and $N_H(WNM)$ as free parameters. We found that the best fit is achieved at $N_H(CNM) = 3.5 \times 10^{20}$ cm$^{-2}$ and $N_H(WNM) = 1.4 \times 10^{21}$ cm$^{-2}$. The best fit is shown in Figure 17 and $\chi^2$ is also shown. We can see that our improved model can reproduce the observational data for high latitude regions.

8. DISCUSSION

8.1. Relative Importance of Effects

The present paper extends further the improved model of spinning dust emission in HDL10 by including the following effects: irregular grain shape, dust temperature fluctuations due to transient heating, orientation of dipole moment, and fluctuations of gas density due to compressible turbulence.

8.1.1. Power Spectrum of Grains of Irregular Shape

First of all, we find that a torque-free rotating irregular grain radiates at multiple frequency modes with angular frequency $\omega_{\text{min}}$ and $\omega_{\text{max}}$, depending on a dimensionless parameter $q$, the ratio of the rotational energy to the rotational energy along the axis of major inertia.
In case 1 \((\mu_1 = \mu/\sqrt{3})\) of \(\mu\) orientation, the mode \(\omega_{m=1}\) dominates the dipole emission for \(q\) close to 1 (when \(a_1\) makes a small angle with \(J\)). As \(q\) increases, the mode \(\omega_{m=0}\) increases accordingly, and becomes dominant. Physically, the mode \(\omega_{m=0}\) arises from the precession of the dipole moment component parallel to \(a_1\) axis about the angular momentum. Its emission power increases with the angle \(\theta\) between \(a_1\) and \(J\), i.e., \(\theta = \pi/2\) or \(q = q_{sp}\).

In case 2 \((\mu_1 = 0, \text{i.e., no dipole component along } a_1\), the mode \(m \neq 0\) does not exist when the grain rotates about \(a_1\) for \(q < q_{sp}\). For \(q > q_{sp}\), the irregular grain rotates about \(a_3\), therefore, the dipole moment component along \(a_3\) induces the frequency mode \(m = 0\).

In both case 1 and case 2, the modes \(m = \pm 1\), which result from the oscillation of dipole moments along \(a_1\) and \(a_3\), always exist, and have power increasing with \(q\) up to \(q = q_{sp}\), then decrease in importance as \(q\) increases further.

8.1.2. Increase of Spinning Dust Emission with the Degree of Grain Shape Irregularity

For both cases 1 \((\mu_1 = \mu/\sqrt{3})\) and 2 \((\mu_1 = 0)\) of the \(\mu\) orientation, we find that the peak frequency increases rapidly with increasing degree of grain shape irregularity \(\eta\) (see Section 4.3). The underlying reason is that the deformation of the grain from the disk-like shape allows the grain to rotate along the axis of minimum moment of inertia \(a_1\), in addition to rotation about \(a_1\) and \(a_3\) axes. For a given angular momentum, the angular velocity along \(a_3\) is largest, so that the emission frequency of the irregular grain is in general higher than that of the disk-like grain with the same mass.

Peak emissivity also increases with the grain shape irregularity for case 1. But for case 2, \(j_{\text{peak}}\) decreases with \(\eta\) for \(T_{\text{vib}} \lesssim 60\) K, and starts to increase with \(\eta\) as \(T_{\text{vib}}\) increases. When the internal thermal fluctuations are rather weak \((T_J > T_{\text{vib}})\) so that the grain tends to rotate with the minimum rotational energy, \(\theta\) and \(q\) deviate slightly from \(\theta = 0\) and \(q = 1\), and the rotational emission spectrum of irregular grains differs only slightly from that of disk-like grains. In contrast, for strong thermal fluctuations \((T_J \ll T_{\text{vib}})\), the thermal fluctuations enable grains to spend an important fraction of time rotating with large \(q\). Because the total power emission increases with \(q\), the higher probability of rotating with larger \(q\) results in larger emissivity and peak frequency than disk-like grains.

8.1.3. Orientation of Dipole Moment

We investigated the effects of changing the orientation of the electric dipole moment \(\mu\). We found (see Figure 9) that as the orientation is varied from having a component parallel to \(a_1\) (case 1, \(\mu_1 = \mu/\sqrt{3}\)) to being entirely perpendicular to \(a_1\) (case 2, \(\mu_1 = 0\)), the peak frequency \(v_{\text{peak}}\) and the peak emissivity both decrease by \(\sim 10\%\). Given the sensitivity of the spectrum to other variables (mass distribution, \(|\mu|\), grain shape, gas density, and gas temperature), it does not seem possible to infer the orientation of \(\mu\) from observations of the spectrum.

8.1.4. Density Fluctuation Due to Compressible Turbulence

We identified interstellar turbulence as another factor that influences emission spectrum. The spinning dust emissivity is determined by two principal processes: collisional and radiative damping and excitation. Local compression due to turbulence increases the collisional excitation, which results in increased spinning dust emissivity. We found that the emission is increased by a factor from 1.2 to 1.4 as the sonic Mach number increases from \(M_s = 2–7\).

8.2. Constraints from Spinning Dust Emission

Recent studies showed that the correspondence of the DL98 model to observations can be improved by adjusting the parameters of the model. For instance, the five-year (WMAP) data showed a broad bump with frequency at \(\sim 40\) GHz in the Ha-correlated emission (Dobler & Finkbeiner 2008; Dobler et al. 2009). Using Ha as a tracer of the WIM, they showed that this bump can be explained using the DL98 model by varying either dipole moment or gas density of the WIM.

By fitting the three components of synchrotron, free–free emission, and spinning dust emission to Ha-correlated spectrum, Dobler et al. (2009) found that the spinning dust model with \(\beta_0 = 0.15\) D and density \(n_{\text{H}} = 0.15\) cm\(^{-3}\) could reproduce the observed spectrum, with \(v_{\text{peak}} = 37\) GHz. Our best-fit values from the improved model correspond to \(n_{\text{H}} = 0.08–1.15\) cm\(^{-3}\) and \(\beta_0\) in the range of 0.6–1.0 D.

In addition to the Ha-correlated emission, WMAP data show a thermal-dust-correlated spectrum that declines from 23 GHz to 40 GHz. This peak at low frequency is lower than the HDL10 model prediction using the standard parameters for the CNM.

Our results show that the thermal-dust-correlated data can be fitted with spinning dust emission from the CNM of density \(n_{\text{H}} \sim 6–8\) cm\(^{-3}\) and \(\beta_0 \sim 0.95–1.0\) D. Similar to Dobler et al. (2009), we also found that the best-fit model did not provide a very good fit (high \(\chi^2\)). The reason for that is the rotational spectrum is steeper than the observation data in frequency range 20–50 GHz. Dobler et al. (2009) suggested that the superposition of spinning dust spectra from different ISM phases along a sight line would produce a flatter spectral slope. With our results for irregular grains, one can see that by averaging the rotational spectrum over various degrees of irregularity \(\eta\) with the fraction of irregular grains decreasing with \(\eta\) (see Section 4), the obtained spectrum becomes shallower, which can improve the fit.

8.3. Range of Applicability of the Model of Spinning Dust Emission

The model of spinning dust emission has been used to interpret the anomalous microwave emission in the general ISM (e.g., Finkbeiner et al. 2004; Dobler & Finkbeiner 2008; Gold et al. 2009, 2011; Planck Collaboration 2011c), in star-forming regions in the nearby galaxy NGC 6946 (Scaife et al. 2010; Murphy et al. 2010) and in the Persus and Ophiuchus clouds (Casassus et al. 2008; Tibbs et al. 2010; Planck Collaboration 2011a). Early Planck results have been interpreted as showing an emission excess from spinning dust in the Magellanic Clouds (Bot et al. 2010; Planck Collaboration 2011b).

This paper together with HDL10 presents a comprehensive model of spinning dust, accounting for non-disk-like (“irregular”) grains and new electric dipole emission modes from torque-free rotation of irregular grains, and investigating the effects of variation in grain dipole moment, gas density, and different regimes of V-R mode coupling. We believe that apart from being an important tracer of the WIM, the spinning dust spectrum can become an important diagnostic tool to constrain physical properties of astrophysical dust (e.g., size distribution, shape, electric dipole moment, and gas density) in various environments.
9. SUMMARY

The model of spinning dust emission is further extended by accounting for effects of irregular grain shape, fluctuations of dust temperature, and effects of ISM turbulence. We consider both regimes of fast internal relaxation and without internal relaxation. Our main results are as follows.

1. Small grains of irregular shape radiate in general at multiple harmonic frequency modes. The rotational emission shifts to higher frequency as the degree of grain shape irregularity increases, but the spectral profile remains similar. The effect of the grain shape irregularity is more important for higher dust temperature or stronger internal thermal fluctuations. Depending on the irregularity parameter $\eta$, peak frequency and peak emissivity can be increased by a factor of up to 1.4, relative to disk-like grains of the same mass (see Figures 5 and 6) for case 1 ($\mu_1 = \mu/\sqrt{3}$).

2. Fluctuations of dust temperature $T_{\text{vib}}$ also increase the rotational emissivity relative to the emissivity for grains of a steady low temperature.

3. Fluctuations of gas density and gas pressure due to compressible turbulence enhance both emission and peak frequency of spinning dust spectrum compared to that in uniform media. An increase in emission by a factor from 1.2 to 1.4 is expected as the sonic Mach number $M_s$ increases from 2 to 7.

4. Spinning dust parameters (e.g., gas density and dipole moment) are constrained by fitting the improved model to WMAP cross-correlation foreground spectra, including Hz and thermal-dust-correlated spectra. We find a reduced PAH abundance in the WIM ($d_0 \approx 0.05$) with dipole moment parameter $\beta_0 \approx 0.7$ D. For the thermal-dust-correlated emission, we find a normal PAH abundance ($d_0 \approx 0.9$) and $\beta_0 \approx 0.95$ D.

5. Our improved model also provides a good fit to WMAP data for selected regions at high latitude ($b = 22\degree$) obtained by Ysard et al. (2010).

APPENDIX A

ELECTRIC DIPOLE EMISSION FROM AN IRREGULAR GRAIN

A.1. Torque-free Motion

The effective size $a$ of an irregular grain with volume $V$ is defined as the radius of a sphere with the same volume $V$, i.e.,

$$a = (3V/4\pi)^{1/3}. \tag{A1}$$

In general, an irregular grain can be characterized by a triaxial ellipsoid with moments of inertia $I_1$, $I_2$, and $I_3$ around three principal axes $a_1$, $a_2$, and $a_3$, respectively. Define dimensionless parameters $\alpha_j$ so that the moments of inertia are written as

$$I_j = \alpha_j L_{\text{eqh}}, \tag{A2}$$

where $L_{\text{eqh}} = (8\pi/15) \rho a^5$ is the moment of inertia of the equivalent sphere of radius $a$ and $\rho$ is the mass density of the grain.

For a torque-free rotating grain, its angular momentum $\mathbf{J}$ is conserved, while the angular velocity $\boldsymbol{\Omega}$ nutates and wobbles with respect to $\mathbf{J}$. We can term the wobbling associated with the irregularity in the grain shape irregular wobbling, to avoid confusion with thermal wobbling (also thermal fluctuations) induced by the Barnett relaxation (Purcell 1979) and nuclear relaxation (Lazarov & Draine 1999b).

A detailed description of the torque-free motion for an asymmetric top in terms of Euler angles $\theta$, $\phi$, and $\psi$ (see Figure 1) can be found in classical textbooks (e.g., Landau & Lifshitz 1976; see also WD03), and a brief summary is given below.

Consider an ellipsoid with three principal axes $a_1$, $a_2$, $a_3$ and moments of inertia $I_1 > I_2 > I_3$.

Define a dimensionless quantity

$$k^2 = \frac{(I_2 - I_3)(q - 1)}{(I_1 - I_2)(1 - q/I_1)} \tag{A3}$$

where $q = 2I_r E_{\text{rot}}/J^2$ is the ratio of total kinetic energy to the rotational energy along the axis of major inertia $a_1$.

1. For $q < I_1/I_2$, $k^2 < 1$, the solution of Euler equations is

$$\omega_1 = \pm \frac{J}{I_1} \left( \frac{I_1 - I_3q}{I_1 - I_2} \right)^{1/2} \text{dn}(\tau), \tag{A4}$$

$$\omega_2 = \frac{J}{I_2} \left( \frac{I_2(q - 1)}{I_1 - I_2} \right)^{1/2} \text{sn}(\tau), \tag{A5}$$

$$\omega_3 = \frac{J}{I_3} \left( \frac{I_3(q - 1)}{I_1 - I_3} \right)^{1/2} \text{cn}(\tau), \tag{A6}$$

where $\text{cn}$, $\text{sn}$, and $\text{dn}$ are hyperbolic trigonometric functions, and $\tau$ is given by

$$\tau \equiv t \frac{1}{J} \left[ \frac{(I_1 - I_2)(1 - I_3q/I_1)}{I_1^2 I_2 I_3} \right]^{1/2}, \tag{A7}$$

and the sign “$+$” in $\omega_1$ and $\omega_3$ are taken the same. We denote the rotation with “$+$” and “$-$” signs as positive and negative rotation states. For $q < I_1/I_2$, the grain mostly rotates about the axis of major inertia $a_1$, while it rotates about $a_3$ for $q > I_1/I_2$.

The rotation period around the axis of major inertia $a_1$ is

$$P_\tau = 4F(\pi/2, k^2), \tag{A8}$$

where $F$ is the elliptic integral defined by

$$F(\epsilon, m) = \int_0^\pi \frac{d\theta}{(1 - m \sin^2 \theta)^{-1/2}}. \tag{A9}$$

(2) For $q > I_1/I_2$, angular velocities are given by

$$\omega_1 = \pm \frac{J}{I_1} \left( \frac{I_1 - I_3q}{I_1 - I_2} \right)^{1/2} \text{cn}(\tau), \tag{A10}$$

$$\omega_2 = \frac{J}{I_2} \left( \frac{I_2(q - 1)}{I_2 - I_3} \right)^{1/2} \text{sn}(\tau), \tag{A11}$$
we obtain
\[ \omega_3 = \pm \frac{J}{I_3} \left( \frac{I_3(q - 1)}{I_1 - I_3} \right)^{1/2} \, \text{d}n(t), \] (A12)
where
\[ \tau \equiv t J \left( \frac{(I_2 - I_3)(q - 1)}{I_1 I_2 I_3} \right)^{1/2}. \] (A13)

Rotation period for this case is given by
\[ P_r = 4F(\pi/2, k^{-2}). \] (A14)

(3) For \( q \approx I_1/I_3 \), Equation (A3) shows that \( k^2 \to \infty \), the rotation of the grain is about the axis near \( a_1 \). Thus, \( \omega_3 \approx J/I_3 \) and \( \omega_1 \approx \omega_2 \approx 0 \). From Euler equations, we obtain
\[ \frac{I_1 \, d\omega_1}{dt} = \omega_2 \omega_3 (I_2 - I_3), \] (A15)
\[ \frac{I_2 \, d\omega_2}{dt} = \omega_3 \omega_1 (I_3 - I_1). \] (A16)
Substituting \( \omega_3 = \Omega_0 = J/I_3 \), the equations are rewritten as
\[ \frac{dJ_1}{dt} = \Omega_0 J_2 \left( 1 - \frac{I_3}{I_2} \right), \] (A17)
\[ \frac{dJ_2}{dt} = -\Omega_0 J_1 \left( 1 - \frac{I_3}{I_1} \right), \] (A18)
where \( J_1 = I_4 \omega_3 \). Taking the first derivative of Equation (A17), and using (A18), we obtain solutions for \( J_1 \) and \( J_2 \):
\[ J_1 = A \cos \omega t, \] (A19)
\[ J_2 = \frac{A}{\omega} \left( 1 - \frac{I_3}{I_1} \right) \sin \omega t = \frac{A}{0 - I_3/I_2}^{1/2} \left( 1 - \frac{I_3}{I_1} \right)^{1/2} \sin \omega t, \] (A20)
where \( \omega^2 = \Omega_0^2 (1 - I_3/I_1)^2 (1 - I_1/I_3)\) and \( A \) is a constant of integration. Denote \( A/(1 - I_3/I_2)^{1/2} = \mu J \), with \( \alpha \) a small parameter, then
\[ J_1 = \alpha J \left( 1 - \frac{I_3}{I_2} \right)^{1/2} \cos \omega t, \] (A21)
\[ J_2 = \alpha J \left( 1 - \frac{I_3}{I_1} \right)^{1/2} \sin \omega t. \] (A22)
The value of \( \alpha \) is found by using the relation
\[ q = \frac{2I_1 E}{J^2}, \] (A23)
\[ E = \frac{J_1^2}{2I_1} + \frac{J_2^2}{2I_2}, \] (A24)
where we have used the fact that at \( t = 0 \), \( J_2 = 0 \). Substituting \( J_1 \) and \( J_2 \) into Equation (A24) and plugging it into Equation (A23), we obtain
\[ q = \alpha^2 \left( \frac{I_3}{I_2} - 1 \right) + \frac{I_1}{I_3}, \] (A25)
Hence,
\[ \alpha = \left( \frac{I_1/I_3 - q}{1 - I_3/I_2} \right)^{1/2}. \] (A26)
As \( q = I_1/I_3 \), then \( \alpha = 0 \), i.e., \( J_1 = J_2 = 0 \) and \( J_3 = J \).

When the angular velocity components are known, we can infer the orientation of the grain axes in the inertial coordinate system using Euler angles:
\[ \cos \theta = \frac{I_1 \omega_1}{J}, \] \[ \tan \psi = \frac{I_5 \omega_3}{I_5 \omega_3}. \] (A27)

A.2. Flip States

For a given \( J \), there are two sets of solution ("±" sign) for \( \omega_3 \) of the Euler motion equations (see Equations (A4)–(A6)). It can be seen that for \( q < q_{\text{dp}} \), two rotation states "±" correspond to \( \omega_3 > 0 \) and \( \omega_3 < 0 \), i.e., \( a_1, J > 0 \) and \( a_1, J < 0 \). We define these rotation states as positive flip state and negative flip state (also WD03; Hoang & Lazarian 2008). For \( q > q_{\text{dp}} \), the similar situation occurs with \( \omega_3 \), and there are positive and negative flip states with respect to \( a_3 \).

A.3. Electric Dipole Emission for Irregular Grain

Let us consider the general case where the dipole is fixed in the grain body and given by
\[ \mu = \mu_1 a_1 + \mu_2 a_2 + \mu_3 a_3, \] (A28)
where \( \mu_i \) are components of electric dipoles along three principal axes. In Paper I, we disregarded the third term in Equation (A28) because of grain’s axisymmetry.

In the inertial coordinate system \( \hat{x}\hat{y}\hat{z} \) (see Figure 1), \( a_1 \), \( a_2 \), and \( a_3 \) are described as
\[ a_1 = \sin \phi \sin \theta \hat{\alpha} - \cos \phi \sin \theta \hat{\beta} \hat{\gamma} + \cos \theta \hat{\gamma}, \] (A29)
\[ a_2 = \left( \cos \phi \cos \psi - \sin \phi \sin \psi \cos \theta \right) \hat{\gamma} + \left( \sin \phi \cos \psi + \cos \phi \sin \psi \cos \theta \right) \hat{\beta} \hat{\gamma} + \sin \psi \sin \theta \hat{\gamma}, \] (A30)
\[ a_3 = -\left( \cos \phi \sin \psi + \sin \phi \cos \psi \cos \theta \right) \hat{\gamma} + \left( -\sin \phi \sin \psi + \cos \phi \cos \psi \cos \theta \right) \hat{\beta} \hat{\gamma} + \cos \psi \sin \theta \hat{\gamma}, \] (A31)
where \( \phi, \psi, \) and \( \theta \) are Euler angles.

Complex motion of the grain principal axes with respect to \( J \) results in an acceleration for the dipole moment in the inertial coordinate system \( \hat{x}\hat{y}\hat{z} \):
\[ \ddot{\mu} = \mu_1 \ddot{a}_1 + \mu_2 \ddot{a}_2 + \mu_3 \ddot{a}_3, \] (A32)
where \( \ddot{a}_1 \) and \( \ddot{a}_2 \) are given by
\[ \ddot{a}_1 = \left[ -\left( \dot{\phi}^2 + \dot{\theta}^2 \right) \sin \phi \sin \theta + \dot{\theta} \dot{\phi} \cos \phi \cos \theta \right] \hat{\gamma} + \left[ \dot{\phi}^2 \sin \phi \cos \theta + \dot{\phi} \dot{\theta} \cos \phi \sin \theta \right] \hat{\beta} \hat{\gamma} \]
\[ - \dot{\theta} \dot{\psi} \sin \phi \cos \psi \sin \theta \hat{\gamma}, \] (A33)
\[ \ddot{a}_2 = \left[ -\left( \dot{\phi}^2 + \dot{\theta}^2 \right) \cos \phi \cos \psi - \sin \phi \sin \psi \cos \theta \right] \hat{\gamma} - 2 \dot{\phi} \dot{\theta} \left( \sin \phi \sin \psi + \cos \phi \cos \psi \cos \theta \right) \hat{\gamma} + \left[ \dot{\phi} \dot{\theta} \cos \phi \sin \theta + \dot{\theta} \dot{\phi} \sin \phi \cos \theta \right] \hat{\beta} \hat{\gamma} \]
\[ - \dot{\theta} \dot{\psi} \cos \phi \cos \psi \sin \theta \hat{\gamma} + \dot{\phi} \dot{\theta} \sin \phi \cos \psi \cos \theta \hat{\beta} \hat{\gamma}, \] (A34)
\[ \mathbf{a}_3 = (\phi^2 + \psi^2)(\cos \phi \sin \psi + \sin \phi \cos \psi \cos \theta) + 2\phi \psi (\sin \phi \cos \psi + \cos \phi \sin \psi \cos \theta) + [\dot{\theta}^2 \sin \phi \cos \psi \cos \theta + \dot{\theta} \dot{\phi} \cos \phi \cos \psi \sin \theta - \dot{\theta} \psi \sin \phi \cos \psi \sin \theta \mathbf{i} + [(\phi^2 + \psi^2)(\sin \phi \sin \psi - \cos \phi \cos \psi \cos \theta) - 2\phi \psi (\cos \phi \cos \psi - \sin \phi \sin \psi \cos \theta))] \mathbf{y} + [\dot{\theta}^2 \cos \phi \cos \psi \cos \theta + \dot{\theta} \dot{\phi} \sin \phi \cos \psi \sin \theta + \dot{\theta} \psi \cos \phi \sin \psi \sin \theta | \mathbf{y} + [-(\psi^2 + \phi^2) \cos \phi \sin \psi - \dot{\theta} \psi \sin \phi \cos \psi \sin \theta | \mathbf{z}. \] \tag{A35}

The precession and rotation rates \( \dot{\phi} \) and \( \dot{\psi} \) are related to the angular velocity components as follows (Landau & Lifshitz 1976):

\[ \omega_1 = \dot{\phi} \cos \theta + \dot{\psi}, \tag{A36} \]

\[ \omega_2 = \dot{\phi} \sin \theta \sin \psi + \dot{\theta} \cos \psi, \tag{A37} \]

\[ \omega_3 = \dot{\phi} \sin \theta \cos \psi - \dot{\theta} \sin \psi. \tag{A38} \]

By solving equations, we obtain

\[ \dot{\theta} = \omega_2 \cos \psi - \omega_3 \sin \psi, \tag{A39} \]

\[ \phi = \frac{\omega_2 \sin \psi + \omega_3 \cos \psi}{\sin \theta} = J \frac{I_2 \omega_2 + I_3 \omega_3}{I_2 \omega_2^2 + I_3 \omega_3^2}, \tag{A40} \]

\[ \dot{\psi} = \omega_1 - \dot{\phi} \cos \theta. \tag{A41} \]

Plugging into Equation (A32) with the use of Equations (A33) and (A34) we obtain the acceleration components as functions of time. Performing FT for these components gives us the spectrum of electric dipole emission (see Figure 2).

The dipole emission power of this torque-free rotating grain can be obtained by averaging the \( \mu^2 \) over time:

\[ P_{ed} = \frac{2}{3c^3} \langle \mu^2 \rangle \equiv \frac{1}{T} \int_0^T \frac{2}{3c^3} \mu^2 \, dt. \tag{A42} \]

APPENDIX B

ELECTRIC DIPOLE DAMPING FOR DISK-LIKE GRAIN

In the grain body system \( \mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3 \), the dipole moment is given by Equation (A28). The orientation of axes \( \mathbf{a}_i \) in an inertial system are determined by Euler angles (see Figure 1). The increase of grain’s angular momentum over time arising from the acceleration of dipole emission is then

\[ \frac{d\mathbf{J}}{dt} = -\frac{2}{3c^3} [\mathbf{\mu} \times \mathbf{\ddot{\mu}}]. \tag{B1} \]

Using Equations (A28) and (A32) for (B1) and averaging it over \( \phi \) and \( \psi \) from 0 to 2\( \pi \) due to torque-free motion, the non-vanishing component is given by

\[ \frac{dJ_z}{dt} = -\frac{2}{3c^3} J_3 \left[ \frac{\mu_1^2}{2} \cos^2 \theta (h^3 - 3h + 2) + \cos^2 \theta (3h - 2h^3) + h^3 \right] \tag{B2} \]

where we assumed \( \mu_2^2 = \mu_3^2 = \mu_2^2 / 2 \). The components \( dJ_x / dt \) and \( dJ_y / dt \) are averaged out to zero.

For case 1 with \( \mu_1 \mu_2 = 2:3 \), i.e., \( \mu_1^2 = \mu_2^2 = \mu_3^2 = \mu_2^2 / 3 \), (similar to HDL10):

\[ \frac{dJ_z}{dt} = -\frac{2}{9c^3} J_3 \cos^4 \theta (h^3 - 3h + 2) + \cos^2 \theta (-2h^3 + 3h) + h^3(1 + \sin^2 \theta). \tag{B3} \]

For case 2 with \( \mu_1 \mu_2 = 0:1 \), i.e., \( \mu_1 = 0 \) and \( \mu_2^2 = \mu_3^2 = \mu_2^2 / 2 \),

\[ \frac{dJ_z}{dt} = \frac{\mu_2^2 J_3^3}{3c^3 J_{l//}} [\cos^4 \theta (h^3 - 3h + 2) + \cos^2 \theta (-2h^3 + 3h) + h^3]. \tag{B4} \]

In dimensionless variables, we have

\[ \frac{dJ'_z}{dt'} = \frac{2}{3} \left( \frac{J'_3}{\tau_{ed,eff}} \right)^2 \]

where \( \tau'_{ed,eff} = \tau_{ed,eff} / \tau_{H//} \) with

\[ \tau_{ed,eff} = \tau_{ed,||} \times \frac{2}{\cos^2 \theta (3h - 2h^3) + \cos^2 \theta (h^3 - 3h + 2) + h^3}, \tag{B6} \]

\[ \tau_{ed,||} = \frac{3J'_3 c^3}{4k_B T g h^2}, \tag{B7} \]

for case 1, and

\[ \tau'_{ed,eff} = \tau_{ed,||} \times \frac{2}{\cos^2 \theta (-2h^3 + 3h) + \cos^2 \theta (h^3 - 3h + 2) + h^3}, \tag{B8} \]

\[ \tau_{ed,||} = \frac{J'_3 c^3}{2k_B T g h^2}, \tag{B9} \]

for case 2.

For \( \theta = 0 \), \( \tau_{ed,eff} = \tau_{ed,||} \).
