ABSTRACT

In this paper, we use the current and future cosmic microwave background (CMB) experiments to test the Charge–Parity–Time Reversal (CPT) symmetry. We consider a CPT-violating interaction in the photon sector $L_{cs} \sim p_\mu A_\nu \tilde{F}^{\mu\nu}$, which gives rise to a rotation of the polarization vectors of the propagating CMB photons. By combining the 9 yr WMAP, BOOMERanG 2003, and BICEP1 observations, we obtain the current constraint on the isotropic rotation angle $\tilde{\alpha} = -2.12 \pm 1.14$ (1σ), indicating that the significance of the CPT violation is about 2σ. Here, we particularly take the systematic errors of CMB measurements into account. Then, we study the effects of the anisotropies of the rotation angle $|\Delta \alpha(\hat{n})|$ on the CMB polarization power spectra in detail. Due to the small observed CMB polarization data, the current CMB polarization data cannot constrain the related parameters very well. We obtain the 95% C.L. upper limit of the variance of the anisotropies of the rotation angle $C_{\alpha}^\alpha(0) < 0.035$ from all of the CMB data sets. More interestingly, including the anisotropies of rotation angle could lower the best-fit value of $r$ and the tension on the constraints of $r$ between BICEP2 and Planck. Finally, we investigate the capabilities of future Planck polarization measurements on $\tilde{\alpha}$ and $\Delta \alpha(\hat{n})$. Benefited from the high precision of Planck data, the constraints of the rotation angle can be significantly improved.

Key words: cosmic background radiation – cosmological parameters – cosmology: theory

1. INTRODUCTION

In the standard model of particle physics and some of its extensions, the Charge–Parity–Time Reversal (CPT) symmetry has a fundamental status. Probing its violation is an important way to search for the new physics beyond the standard model. Up to now, CPT symmetry has passed a number of high-precision experimental tests and no definite signal of its violation has been observed in the laboratory. So, the present CPT violating effects, if they exist, should be very small to be amenable to the laboratory experimental limits.

However, the CPT symmetry could be dynamically violated in the expanding universe. This has many interesting applications. For instances, in the literature (Li et al. 2002, 2004, 2007; Li & Zhang 2003; Feng et al. 2005; Davoudiasl et al. 2004), the cosmological CPT violation has been used to generate the matter–antimatter asymmetry in the early universe based on the mechanism proposed in Cohen & Kaplan (1988). The salient feature of these models is that the CPT violating effects at present are too small to be detected by the laboratory experiments, but large enough in the early universe to account for matter–antimatter asymmetry. More importantly, these types of CPT violating effects could be accumulated to be observable for the cosmological probes (Feng et al. 2005, 2006; Li et al. 2007). With the accumulation of high-quality observational data, especially those from the cosmic microwave background (CMB) experiments, cosmological observation becomes a powerful way to test the CPT symmetry.

Simply the cosmological CPT violation in the photon sector can be modeled by the coupling between photons and an external field $p_\mu$ through the Chern–Simons (CS) term $L_{CS} \sim p_\mu A_\nu \tilde{F}^{\mu\nu}$. Here, $\tilde{F}^{\mu\nu} = (1/2)\varepsilon^{\mu\nu\rho\sigma} F_{\rho\sigma}$ is the dual of the electromagnetic tensor. This coupling is gauge invariant if $\partial_\nu p_\mu = \partial_\mu p_\nu$. This is possible if $p_\mu$ is a constant field over the spacetime or arises from the derivative of a cosmic scalar field $\phi$. The scalar field $\phi$ is identified as the dark energy in the quintessential baryo/leptogenesis (Li et al. 2002; Li & Zhang 2003) and as the Ricci scalar $R$ in the gravitational baryo/leptogenesis (Li et al. 2004; Davoudiasl et al. 2004). The CS term violates the Lorentz and CPT symmetries spontaneously at the background in which $p_\mu$ is nonzero. One of its physical consequences is that the polarization vector of the photon is no longer transported parallel along the light ray:

$$k^\mu \nabla_\mu Q + \nabla_\mu k^\mu Q = 2 p_\mu k^\mu U,$$

$$k^\mu \nabla_\mu U + \nabla_\mu k^\mu U = -2 p_\mu k^\mu Q.$$  (1)

Here, $Q$ and $U$ are Stokes parameters describing the linear polarizations of the radiation field. They are not conserved due to the CS term. The vector $k^\mu$ is the four-vector of the photon. The rotation of the polarization direction of electromagnetic waves propagating over large distances

$$(Q' \pm iU') = \exp(\pm 2i\alpha)(Q \pm iU).$$  (2)

The rotation angle is the integral of $p_\mu$ along the photon’s trajectory from the source of light (s) to the observing point (o) (Li & Zhang 2008)

$$\alpha = \int_s^o p_\mu dx^\mu.$$  (3)

The related phenomena called “cosmological birefringence” has the effect of changing the polarization of the radiation from radio galaxies and quasars (Carroll et al. 1990; Carroll 1998). For CMB, it has the effect of coverting part of the E-mode polarization to B-mode polarization, and it especially has the ability to produce TB and EB correlations even though these are absent before recombination in the traditional CMB theory. In the case of the isotropic rotation angle, denoted as $\tilde{\alpha}$, the full
set of the rotated CMB spectra (denoted by primes) was first obtained in Feng et al. (2006)

\[
C_{\ell}^{TB} = C_{\ell}^{TE} \sin(2\bar{\alpha}),
\]

\[
C_{\ell}^{EB} = \frac{1}{2} (C_{\ell}^{EE} - C_{\ell}^{BB}) \sin(4\bar{\alpha}),
\]

\[
C_{\ell}^{TE} = C_{\ell}^{TE} \cos(2\bar{\alpha}),
\]

\[
C_{\ell}^{EE} = C_{\ell}^{EE} \cos^2(2\bar{\alpha}) + C_{\ell}^{BB} \sin^2(2\bar{\alpha}),
\]

\[
C_{\ell}^{BB} = C_{\ell}^{BB} \cos^2(2\bar{\alpha}) + C_{\ell}^{EE} \sin^2(2\bar{\alpha}),
\]

while the CMB temperature power spectrum remains unchanged. These formulae combined with CMB data can be used to detect or constrain the rotation angle, i.e., the signal of CPT violation. For instance, one may detect \( \bar{\alpha} \) by searching for the distinctive TB correlation (Lue et al. 1999). However, as was first pointed out by Feng et al. (2005), in the CMB polarization experiments, the EB spectrum will be the most sensitive for probing the signal of CPT violation. Another important feature of this model is that it provides a new mechanism to produce the CMB B-modes polarization, an alternative to the primordial gravitational waves and weak lensing. This can be seen from the last equation in Equation (4), even the primordial B-mode is absent, a sizable CMB BB power spectrum can be obtained from the EE power spectrum through the rotation. Based on Equation (4), the first evidence of the rotation angle in terms of the full CMB data set was done in Feng et al. (2006) and stimulated a lot of interest in this field (see Li et al. 2007; Xia et al. 2008a, 2008b, 2008c, 2010; Komatsu et al. 2009; Wu et al. 2009; Brown et al. 2009; Komatsu et al. 2011; Liu et al. 2006; Xia 2012; Hinshaw et al. 2013; Geng et al. 2007; Cabella et al. 2007; Kostelecky & Mewes 2007; Kahniashvili et al. 2008; Finelli & Galaverni 2009; Li et al. 2009; Gruppuso et al. 2013; Zhao & Li 2014a and references within). These studies showed there is a possibility that current CMB experiments may detect the rotation angle at the level of \( O(1^\circ) \), providing a powerful method to test the fundamental Lorentz and CPT symmetries.

Recently, the Background Imaging of Cosmic Extragalactic Polarization (BICEP1; Kaufman et al. 2014) collaboration released their high precision three-year data of the CMB temperature and polarization including the TB and EB power spectra. Another CMB experiment, the Q/U Imaging Experiment (QUIET; Araujo et al. 2012), also published the CMB polarization power spectra at 95 GHz with the EB power spectrum. Furthermore, the nine-year WMAP (WMAP9; Hinshaw et al. 2013), BOOMERanG 2003 (Bo03; Montory et al. 2006; Jones et al. 2006; Piacentini et al. 2006), and QU Extragalactic Survey Telescope at DASI (QUaD; Hinders et al. 2009) also provided the TB and EB polarization power spectra. Thus, it is important and necessary to combine these new data together to detect or constrain the rotation angle and test the CPT symmetry.

However, as first pointed out in Li & Zhang (2008), the rotation angle is generally direction dependent or anisotropic, denoted by \( \alpha(d) \). For instance, if the external field \( p_\mu \propto \delta_\mu \phi \) is arising from a cosmic scalar field \( \phi \), then the rotation angle is determined by the distribution of this field on the last scattering surface. Usually, this distribution is not homogeneous because \( \phi \) as a dynamical field must fluctuate around its uniform background. Hence the CMB photons coming from different directions would undergo different rotations. As first studied in Li & Zhang (2008), the anisotropies of the rotation angle will introduce corrections or distortions to the spectra (4) from isotropic rotation. At a later time, Kamionkowski (2009) and Gluscevic et al. (2009) also studied the direction dependence of the rotation angle and developed a different formalism to measure the anisotropies of the rotation angle and constructed the minimum-variance estimator (a similar method can also be found in Yadav et al. 2009). They considered the non-Gaussian signal and the correlation between different \( \ell \) and \( m \) of the rotated polarization angular momentum introduced by the rotation. Then, they applied the estimator to constraint the anisotropic rotation angle and found no evidence of the nonzero power spectrum of rotation angle within 3\( \sigma \) (Gluscevic et al. 2012). Recently, Li & Yu (2013) performed a non-perturbative calculation of the rotated power spectra and made constraints on the anisotropic rotation angle and the shape of its power spectrum in terms of the CMB data. According to these results, there was no significant evidence for a nonzero rotation angle up to now.

Following the previous works, in this paper, we will revisit this problem by attaching more importance to the effects of direction-dependent rotations on the CMB power spectra. We will perform a global analysis on them using the latest CMB polarization data, as well as the future simulated CMB data. The structure of the paper is as follows. In Section 2, we describe the current and future simulated data sets that we use. Section 3 contains our main results from the current observations and future measurements, while Section 4 is dedicated to the conclusions and discussions.

2. CMB DATA SETS

2.1. Current Data Sets

In our calculations, we mainly use the full data of WMAP9 temperature and polarization power spectra (Komatsu et al. 2011). The WMAP9 polarization data are composed of TE/TB/EE/BB/EB power spectra on large scales (2 \( \leq \ell \leq 23 \)) and TE/TB power spectra on small scales (24 \( \leq \ell \leq 800 \)), while the WMAP9 temperature data are only used to set the underlying cosmology. For the systematic error, the Wilkinson Microwave Anisotropy Probe (WMAP) instrument can measure the polarization angle to within \( \pm 1.5 \) of the design orientation (Page et al. 2003, 2007). In the computation, we use the routines for computing the likelihood supplied by the WMAP team. Besides the WMAP9 information, we also use some small-scale CMB observations.

The BOOMERanG dated 2003 January Antarctic flight (Montory et al. 2006) measures the small-scale CMB polarization power spectra in the range of 150 \( \leq \ell \leq 1000 \). Recently, the BOOMERanG collaboration reanalyzed the CMB power spectra and took into account the effect of systematic errors rotating the polarization angle by \(-0.9 \pm 0.7 \) (Pugno 2009).

The BICEP1 (Kaufman et al. 2014) and QUaD (Hinders et al. 2009) collaborations released their high precision data of the CMB temperature and polarization including the TB and EB power spectra. These two experiments, located at the South Pole, are the bolometric polarimeters designed to capture the CMB information at two different frequency bands of 100 GHz and 150 GHz, and on small scales—the released three-year BICEP1 data are in the range of 21 \( \leq \ell \leq 335 \) (Kaufman et al. 2014); whereas the QUaD team measures the polarization spectra at 164 \( \leq \ell \leq 2026 \), based on an analysis of the observation in the second and third seasons (Wu et al. 2009; Brown et al. 2009). They also provide the systematic errors of measuring the polarization angle, \( \pm 1.3 \) and \( \pm 0.5 \), for BICEP1 and QUaD observations, respectively.
Table 1

| Experiment | $f_{sky}$ | $\ell_{\text{max}}$ (GHz) | $\Delta f_{\text{WHM}}$ | $\Delta \ell$ | $\Delta \varphi$ |
|------------|-----------|----------------|-------------------|--------------|-------------|
| Planck     | 0.80      | 2500           | 100               | 6.8          | 10.9        |
|            | 143       | 7.1            | 6.0               | 11.4         |             |
|            | 217       | 5.0            | 13.1              | 26.7         |             |

Notes. We use the CMB power spectra only at $\ell \leq 2500$. The noise parameters $\Delta \varphi$ and $\Delta \ell$ are given in units of $\mu$Karcmin.

Very recently, the BICEP2 collaboration announced the detection of CMB $B$-mode polarization and released the data in the 150GHz frequency band (Ade et al. 2014). However, they claimed that the EB power spectra are only used for the self-calibration of the detector polarization orientations (Keating et al. 2013). Any polarization rotation has been removed from the results. Therefore, in our calculations, we only use the BICEP2 data to constrain the anisotropies of the rotation angle.

Finally, we have the CMB polarization power spectra at 95 GHz from the second season QUIET observation. Using two pipelines to analyze the data, they characterized the EB power spectrum between $\ell = 25$ and 975 and gave the total systematic error in the EB power spectrum (Araujo et al. 2012).

2.2. Future Data Sets

The Planck collaboration has released the first cosmological papers providing the high resolution, full sky, CMB maps. Due to the improved precision, this new Planck data have constrained several cosmological parameters at the few percent level. However, these Planck data do not include the CMB polarization information and the rotation angle has nothing to do with the CMB temperature power spectrum. Therefore, current CMB measurements are still not accurate enough to verify the possible CPT violation. In order to improve the constraints on the rotation angle, we follow the method given in Xia et al. (2008a, 2008c) and simulate the CMB polarization power spectra with the assumed experimental specifications of the Planck (Ade et al. 2013a) polarization measurements. We choose the best-fit model from the Planck data (Ade et al. 2013b) as the fiducial model.

In Table 1, we list the assumed experimental specifications of the future Planck polarization measurement. The likelihood function is $\mathcal{L} \propto \exp(-\chi^2_{\text{eff}}/2)$ and

$$\chi^2_{\text{eff}} = \sum_{\ell}(2\ell + 1)f_{\text{sky}} \left( \frac{A}{|\mathcal{C}|} + \ln \frac{\bar{C}}{|\mathcal{C}|} + 3 \right),$$

where $f_{\text{sky}}$ denotes the observed fraction of the sky in the real experiments, $A$ is defined as

$$A = \hat{C}_{\ell}^{TT} (\hat{C}_{\ell}^{EE} \hat{C}_{\ell}^{BB} - \hat{C}_{\ell}^{EB} \hat{C}_{\ell}^{EB}) + \hat{C}_{\ell}^{TT} (\hat{C}_{\ell}^{BB} \hat{C}_{\ell}^{BB} - \hat{C}_{\ell}^{EB} \hat{C}_{\ell}^{EB}) + \hat{C}_{\ell}^{EB} (\hat{C}_{\ell}^{TT} \hat{C}_{\ell}^{BB} - \hat{C}_{\ell}^{EB} \hat{C}_{\ell}^{EB}) + \hat{C}_{\ell}^{EB} (\hat{C}_{\ell}^{TT} \hat{C}_{\ell}^{BB} - \hat{C}_{\ell}^{EB} \hat{C}_{\ell}^{EB}) + \hat{C}_{\ell}^{EB} (\hat{C}_{\ell}^{TT} \hat{C}_{\ell}^{BB} - \hat{C}_{\ell}^{EB} \hat{C}_{\ell}^{EB}),$$

and $|\mathcal{C}|$ and $|\hat{C}|$ denote the determinants of the theoretical and observed data covariance matrices, respectively.

The likelihood has been normalized with respect to the maximum likelihood $\chi^2_{\text{eff}} = 0$, where $\bar{C}_N^Y = \bar{C}_N^X$.

3. NUMERICAL RESULTS

In our study, we make a global analysis of all the power spectra of the CMB data that we have mentioned above with the public available Markov Chain Monte Carlo package CosmoMC (Lewis & Bridle 2002), which has been modified to compute the nonzero TB and EB power spectra discussed above. We assume the purely adiabatic initial conditions and impose the flatness condition motivated by inflation. Our basic parameter space is $\mathbf{P} \equiv (\omega_b, \omega_c, \Omega_b h^2, \Omega_c h^2, n_s, A_s, r)$, where $\omega_b \equiv \Omega_b h^2$ and $\omega_c \equiv \Omega_c h^2$ are the dark baryonic and cold dark matter densities relative to the critical density, $\Omega_b$ is the dark energy density relative to the critical density, $r$ is the optical depth to reionization, $A_s$ and $n_s$ characterize the primordial scalar power spectrum, $s$ is the tensor to scalar ratio of the primordial spectrum. For the pivot of the primordial spectrum, we set $k_{\text{pivot}} = 0.002 \text{Mpc}^{-1}$. Furthermore, in our analysis, we include the CMB lensing effect, which also produces $B$-modes from $E$-modes (Zaldarriaga & Seljak 1998), when we calculate the theoretical CMB power spectra.

3.1. Isotropic Rotation

First, we consider the constraint on the direction-independent rotation angle $\bar{\alpha}$, induced by the CS term, from the current CMB measurements. As we know, this rotation angle is accumulated along the journey of CMB photons, and the constraints on the rotation angle depend on the multipole $\ell$ (Liu et al. 2006), Komatsu et al. (2009, 2011) found that the rotation angle is mainly constrained from the high-$\ell$ polarization data, and the polarization data at low multipoles do not significantly affect the result. Therefore, in our analysis, we assume a constant rotation angle $\bar{\alpha}$ at all multipoles. Furthermore, we impose a conservative flat prior on $\bar{\alpha}$ as $-\pi/2 \leq \bar{\alpha} \leq \pi/2$.

Following previous works (Pagano 2009; Xia 2012), in this paper, we consider the possible systematic errors of CMB measurements by including two rotation angles, $\bar{\alpha}$ and $\beta$, in order to take into account the real rotation signal and the systematic errors. Therefore, in the analyses of this section, we have five free parameters: the direction-independent rotation angle $\bar{\alpha}$ and four systematic errors, $\beta_{\text{WMAP9}}, \beta_{B03}, \beta_{\text{BICEP1}},$ and $\beta_{\text{QUaD}}$, for four CMB observations, respectively. Plus, we impose priors on these four systematic errors,

$$\beta_{\text{WMAP9}} = 0.0 \pm 1.5, \quad \beta_{B03} = -0.9 \pm 0.7, \quad \beta_{\text{BICEP1}} = 0.0 \pm 1.3, \quad \beta_{\text{QUaD}} = 0.0 \pm 0.5,$$

and marginalize over them to constrain the rotation angle. For the QUIET experiment, since they already provided the systematic errors of EB power spectrum, we directly include this information into our analysis (Araujo et al. 2012). In Figure 1, we present current constraints on $\bar{\alpha}$ from the WMAP9, B03, BICEP1, QUaD, and QUIET CMB polarization power spectra with CMB systematic errors.
Using the latest WMAP9 power spectra data at all multipoles $\ell$ and the prior of $\beta_{\text{WMAP9}}$, we obtain the constraint on the rotation angle: $\tilde{\alpha} = -1.06 \pm 1.39$ at 68\% confidence level, which is quite consistent with that obtained from the WMAP team (Hinshaw et al. 2013) and is a significant improvement over the WMAP3 (Xia et al. 2008a) and WMAP5 (Komatsu et al. 2009; Xia et al. 2008b) results. Similarly, we obtain the constraint on $\alpha$ from the B03 polarization data: $\tilde{\alpha} = -4.63 \pm 4.16$, with the CMB systematic effect included. The results are in good agreement with previous results (Feng et al. 2006; Pagano 2009).

In our previous work (Xia et al. 2010), we reported that the two-year BICEP1 data (Chiang et al. 2010) favored a nonzero $\tilde{\alpha}$ at about 2.4$\sigma$ confidence level, due to the clear bump structure in the BICEP1 TB and EB power spectra at $\ell \sim 150$. Even including the impact of systematic effect, the significance is still larger than 2$\sigma$ from the BICEP1 data alone (Xia 2012). Recently, the BICEP1 collaboration released the three-year data and paid particular attention to the constraint on the rotation angle (Kaufman et al. 2014). They carefully discussed the effects of systematic errors, the polarization angle calibration, and differential beam effects, on the constraint of the rotation angle and obtained the $\pm 1^{\circ}$ systematic uncertainty on the orientation calibration. Therefore, we revisit the limit on $\tilde{\alpha}$ from the new BICEP1 data and obtain the constraint at 68\% C.L.:

$$\tilde{\alpha} = -2.69 \pm 1.52 \, (68\% \text{ C.L.}),$$ (9)

The significance of the nonzero rotation angle reduces to 1.8$\sigma$, due to the large systematic uncertainty of BICEP1 data. When WMAP9 and B03 data are added to the BICEP1 data, the constraint on $\tilde{\alpha}$ gets tightened:

$$\tilde{\alpha} = -2.12 \pm 1.14 \, (68\% \text{ C.L.}),$$

$$-4.30 < \tilde{\alpha} < 0.15 \, (95\% \text{ C.L.}),$$ (10)

which implies $\tilde{\alpha} \neq 0$ at about a 2$\sigma$ confidence level, when considering the systematic effects of these three CMB measurements.

We also constrain the rotation angle from the QUaD and QUIET polarization data. Similarly to previous results, we use the QUaD and QUIET data and obtain the constraint at a 68\% confidence level: $\tilde{\alpha} = 0.59 \pm 0.64$ and $\tilde{\alpha} = 1^{\circ} 88 \pm 1^{\circ} 15$, respectively. When comparing with the result of WMAP9+B03+BICEP1 (Equation (10)), there is still a $\sim 2\sigma$ tension, which needs to be taken care of during further investigation. By combining all of these CMB polarization data together and including their systematic effects, we obtain the tightest constraint: $\tilde{\alpha} = 0.03 \pm 0.55 \, (68\% \text{ C.L.}).$

Finally, we use the new BICEP2 polarization data to constrain the isotropic rotation angle and obtain the constraint: $\tilde{\alpha} = 0.12 \pm 0.16 \, (68\% \text{ C.L.})$, due to the self-calibration of the detector polarization orientations (Li et al. 2014). This constraint is clearly expected and consistent with the use of the self-calibration method on the BICEP2 data.

### 3.2. Anisotropies of the Rotation Angle

In this section, we briefly review the basics of the effects of the direction dependent rotation angle on the CMB power spectra (Li & Yu 2013) and perform global analyses on the related parameters from the current CMB measurements.

First, we decompose the CMB temperature and polarization fields in terms of the spin-weighted spherical harmonics (Seljak 1996):

$$T(\hat{n}) = \sum_{\ell m} T_{\ell m} Y_{\ell m}(\hat{n}),$$

$$Q \pm i U(\hat{n}) = \sum_{\ell m} (E_{\ell m} \pm i B_{\ell m})_{\pm 2} Y_{\ell m}(\hat{n}).$$ (11)

Then, the two parity eigenstates $E_{\ell m}$ and $B_{\ell m}$ have the parities $(-1)^{\ell}$ and $(-1)^{\ell+1}$ respectively. In traditional CMB theory, the TB and EB cross-correlations vanish. As usual, in the linear perturbation theory, the rotation angle is decomposed into the isotropic part and the fluctuations $\alpha(\hat{n}) \equiv \tilde{\alpha} + \Delta \alpha(\hat{n})$.

The anisotropies $\Delta \alpha(\hat{n})$ considered as random fields can be decomposed in terms of (scalar) spherical harmonics on the full sky:

$$\Delta \alpha(\hat{n}) = \sum_{\ell m} b_{\ell m} Y_{\ell m}(\hat{n}),$$ (12)

and it is possible to define the angular power spectrum of rotation angle under the assumption of statistical isotropy of $b_{\ell m}$

$$\langle b_{\ell m} b_{\ell m}^* \rangle = C^{\alpha \alpha}(\ell) \delta_{\ell \ell} \delta_{mm}.\quad (13)$$

With the angular power spectrum, one can calculate the two-point correlation function using the following relation

$$C^{\alpha}(\beta) \equiv \langle \Delta \alpha(\hat{n}_1) \Delta \alpha(\hat{n}_2) \rangle = \sum_\ell \frac{2\ell+1}{4\pi} C^{\alpha \alpha}_\ell P_\ell(\cos \beta).$$ (14)

where $\beta$ is the angle between these two directions, $\cos(\beta) = \hat{n}_1 \cdot \hat{n}_2$.

Using the non-perturbative method, we calculate the rotated power spectrum $C_\ell^{\alpha \alpha}$ and express them in terms of the unrotated ones $C_\ell$, via the computations of the rotated correlation functions (Li & Yu 2013):

$$C_\ell^{\alpha \alpha} = C_\ell + \frac{1}{2} \left( C_\ell^{EE} + C_\ell^{BB} \right)$$

$$\times \int_{-1}^{1} d_2(\beta) d_2(\beta) e^{4C_\ell^{\alpha \alpha}(\beta)} \, d \cos \beta$$

$$C_\ell^{EE} - C_\ell^{BB} = \cos(4\tilde{\alpha}) \exp \left[ -4C_\ell(0) \right] \sum_\ell \frac{2\ell+1}{2}$$

$\times \int_{-1}^{1} d_2(\beta) d_2(\beta) e^{4C_\ell^{\alpha \alpha}(\beta)} \, d \cos \beta$.
\[
\times \left( C_{\ell}^{EE} - C_{\ell}^{BB} \right) \int_{-1}^{1} d_2^\ell(\beta) d_{-2}^\ell(\beta) e^{-4C(\beta)} d \cos(\beta)
\]
\[
C_{\ell}^{EB} = \sin(4\alpha) \exp \left[-4C(0)\right] \sum_{\ell'} \frac{2\ell' + 1}{4} \left( C_{\ell'}^{EE} - C_{\ell'}^{BB} \right)
\]
\[
\times \int_{-1}^{1} d_2^{\ell'}(\beta) d_{-2}^{\ell'}(\beta) e^{-4C(\beta)} d \cos(\beta)
\]
\[
C_{\ell}^{TE} = \cos(2\alpha) \exp \left[-2C(\alpha)\right] \sum_{\ell'} \frac{2\ell' + 1}{2} C_{\ell'}^{TE}
\]
\[
\times \int_{-1}^{1} d_2^{\ell'}(\beta) d_{-2}^{\ell'}(\beta) d \cos(\beta) = C_{\ell}^{TE} \cos(2\alpha) e^{-2C(\alpha)}
\]
\[
C_{\ell}^{TB} = \sin(2\alpha) \exp \left[-2C(\alpha)\right] \sum_{\ell'} \frac{2\ell' + 1}{2} C_{\ell'}^{TB}
\]
\[
\times \int_{-1}^{1} d_2^{\ell'}(\beta) d_{-2}^{\ell'}(\beta) d \cos(\beta) = C_{\ell}^{TB} \sin(2\alpha) e^{-2C(\alpha)}.
\]

Here, \(C(\alpha) \equiv \sum_{\ell} (2\ell + 1) C_{\ell}^{\alpha \alpha} / 4\pi\) is the variance of the anisotropies of the rotation angle. More detailed calculations are laid out in Li & Yu (2013). In these calculations, we assume that the unrotated CMB field and the direction-dependent rotation angle are Gaussian random fields and have the isotropic statistics. Consequently, the rotated polarizations of CMB are also statistically isotropic and their spectra have no off-diagonal terms. We have calculated the ensemble average of the rotation angle field, which is different from the formalism developed in Kamionkowski (2009). They considered a fixed rotation angle field that could break the statistical isotropy of the rotated CMB field. Therefore, some correlation functions between different \(\ell\) and \(m\) will be nonzero and the whole calculation become complicated. We leave them for future work (S. Y. Li et al. 2015, in preparation).

Based on the equations above, we show the distortions to the CMB BB, TB, and EB power spectra from the nonzero direction-dependent rotation angle in Figure 2. Due to the nonzero variance \(C(\alpha)\), the amplitude of BB, TB, and EB power spectra are slightly suppressed when including the direction dependence of rotation angle, which means this fluctuation can be safely treated as a small effect if the isotropic rotation angle is sizeable.

In this case, we need seven more parameters to describe the effect of the direction-dependent rotation angle on CMB polarization power spectra: the variance of the two point correlation functions \(C(0)\) and the six parameters for the binned power spectrum of the rotation angle: \(C_{\ell^i}^{\alpha \alpha} (i \in [1, 6])\), which are the average values of \(C_{\ell^i}^{\alpha \alpha}\) in the multipole regions \([2, 100], [101, 200], [201, 300], [301, 400], [401, 500], [501, 2500]\), respectively. We use the binned power spectrum \(C_{\ell^i}^{\alpha \alpha}\) to calculate the CMB polarization power spectra to fit the CMB data sets, based on Equation (15). In the calculations, we only impose physical priors on these parameters: \(C(0) > 0\) and \(C_{\ell^i}^{\alpha \alpha} (i) > 0\).

We use the WMAP9, B03, and BICEP1 data combination to constrain the rotation angle and obtain the limits, shown as black dashed lines in Figure 4:

\[
\hat{\alpha} = -2.16 \pm 1.15 \text{ (68\% C.L.)},
\]
\[
C(0) < 0.035 \text{ (95\% C.L.)},
\]
\[
C_{\ell^1}^{\alpha \alpha} < 3.3 \times 10^{-6} \text{ (95\% C.L.)},
\]
\[
C_{\ell^2}^{\alpha \alpha} < 1.3 \times 10^{-6} \text{ (95\% C.L.)}.
\]

We find that including the direction dependence of rotation angle does not significantly affect the constraint on \(\hat{\alpha}\). The
The best-fit value of $\hat{\alpha}$ is slightly smaller, since the nonzero $C_0^\alpha$ suppresses the rotated CMB power spectra and partly cancels the effect from the nonzero $\alpha$. This result also proves that this direction dependence of the rotation angle is a small effect, comparing with the effect from the obvious nonzero $\hat{\alpha}$. The constraints on $C_0^\alpha$ and $C_\ell^\alpha(i)$ are consistent with previous works (Li & Yu 2013).

We also include the QUaD and QUIET polarization power spectra into the analysis. Due to the high precision of the high-$\ell$ data from the QUaD experiment, the constraint on the last bin of the rotation angle power spectrum becomes tighter: $C_\ell^\alpha(6) < 6.6 \times 10^{-8}$ (95% C.L.). We do not find the signal of the direction-dependent rotation angle from the current CMB polarization power spectra.

Finally, we replace the BICEP1 data as the new BICEP2 data in the calculation. When combining with the WMAP9 and B03 polarization data, the 95% upper limits of the parameters of direction dependence of rotation angle are shrunk by a factor of $\sim 2$ (blue dash–dotted lines in Figure 4), due to the high precision of the new BICEP2 data:

$$
C_0^\alpha < 0.023 \ (95\% \ C.L.),
C_\ell^\alpha(1) < 1.5 \times 10^{-6} \ (95\% \ C.L.),
C_\ell^\alpha(2) < 0.6 \times 10^{-6} \ (95\% \ C.L.),
C_\ell^\alpha(3) < 0.5 \times 10^{-6} \ (95\% \ C.L.),
C_\ell^\alpha(4) < 0.6 \times 10^{-6} \ (95\% \ C.L.),
C_\ell^\alpha(5) < 0.5 \times 10^{-6} \ (95\% \ C.L.),
C_\ell^\alpha(6) < 0.5 \times 10^{-7} \ (95\% \ C.L.).
$$

Furthermore, we obtain the constraint on the tensor-to-scalar ratio: $r = 0.12 \pm 0.04$ (68% C.L.), which implies the nonzero detection of the primordial CMB B-modes power spectrum. More interestingly, the median value of $r$ here is slightly lower than that reported by the BICEP2 collaboration $r = 0.2$ (Ade et al. 2014), since the direction dependence of the rotation angle would also contribute to the CMB BB power spectrum (Li & Zhang 2008; Zhao & Li 2014b) and partly explain the CMB B-modes data of BICEP2 (Lee et al. 2014). As we know, the Planck data could also be used to study the very early universe and give the tight constraint on the tensor-to-scalar ratio: $r < 0.11$ (95% C.L.) (Ade et al. 2013b). Therefore, considering the direction dependence of rotation angle could lower the best-fit value of $r$ and make it more consistent with the constraint from Planck data. Consequently, the tension on the constraints of $r$ between Planck and BICEP2 data has been relaxed. Note that, in this case the constraint on the isotropic rotation angle becomes $\alpha = -0.34 \pm 1.10$ (68% C.L.). The best-fit value of $\alpha$ is quite close to zero, which means that the isotropic rotation angle cannot contribute extra information to the CMB BB power spectrum. Therefore, the greatest contribution to the explanation of the discrepancy between BICEP2 and Planck’s constraints comes from the anisotropic rotation angle. In Figure 3, we show the CMB BB power spectrum of the best-fit model obtained from the WMAP9+B03+BICEP2 data combination. The effect of the nonzero anisotropic rotation angle does contribute to the BB power spectrum to suppress the value of $r$. If increasing the contribution of tensor perturbations from $r = 0.12$ to $r = 0.2$, then the theoretical prediction of the CMB BB power spectrum (black thin line) is obviously higher than the BICEP2 data at $80 < \ell < 150$.

### 3.3. Future Planck Constraints

Since the current CMB polarization measurements cannot determine the rotation angle, especially its dependence on direction, conclusively, it is worth discussing whether future CMB polarization data could give more stringent constraints on the rotation angle. Therefore, we simulate the future CMB power spectra with Planck to constrain the rotation angle. The fiducial model we choose is the best-fit Planck model (Ade et al. 2013b): $\Omega_r h^2 = 0.022161$, $\Omega_b h^2 = 0.11889$, $\Omega_\Lambda = 0.6914$, $\tau = 0.0952$, $n_s = 0.9611$, $\log[10^{10} A_s] = 3.0973$ at $k_0 = 0.05 \text{Mpc}^{-1}$, and $r = 0$. Here, we neglect the systematic error of future CMB measurement and the CMB lensing effect.

For the direction-independent rotation angle $\alpha$, the future Planck polarization measurement could shrink the standard deviation of the rotation angle by a factor of 10, namely $\sigma(\hat{\alpha}) \simeq 0.06$, which is consistent with our previous results (Xia et al. 2008a, 2008c). On the other hand, the future Planck mock data can also provide tighter constraints on the parameters related to $\Delta r(\hat{\phi})$. The 95% C.L. upper limit of the variance becomes $C_0^\alpha < 0.0036$, which improves the constraint by a factor of 10. In Figure 4, we show the constraints on these parameters from the future Planck data (red solid lines). The high precision Planck polarization data improve the constraints on the binned rotation angle power spectrum significantly:

$$
C_\ell^\alpha(1) < 9.2 \times 10^{-7} \ (95\% \ C.L.),
C_\ell^\alpha(2) < 3.7 \times 10^{-7} \ (95\% \ C.L.),
C_\ell^\alpha(3) < 2.5 \times 10^{-7} \ (95\% \ C.L.),
C_\ell^\alpha(4) < 1.9 \times 10^{-7} \ (95\% \ C.L.),
C_\ell^\alpha(5) < 1.8 \times 10^{-7} \ (95\% \ C.L.),
C_\ell^\alpha(6) < 1.4 \times 10^{-8} \ (95\% \ C.L.).
$$

The future Planck data could verify the nonzero rotation angle and its direction dependence, as well as the possible cosmological CPT violation.

---

**Figure 3.** Theoretical CMB power spectra (thick lines) for the best-fit model obtained from the WMAP9+B03+BICEP2 data combination. The red thin line denotes the contribution of tensor perturbations with $r = 0.2$, and the black thin line is the total CMB BB power spectrum, correspondingly. For comparison, we also show the BICEP2 observational data.
4. CONCLUSIONS AND DISCUSSIONS

Probing the signals of fundamental symmetry breakings is an important way to search for new physics beyond the standard model. Currently, detecting the rotation of the CMB polarization, induced by the CS coupling, is considered to be an effective and important method for testing Lorentz and CPT symmetries in the physics and cosmology communities. In this paper, we present constraints on the rotation angle and its anisotropies using the latest CMB polarization data, as well as future simulated Planck data.

Following previous works, we include the systematic effects of CMB polarization data in the analysis. Due to the larger systematic error of new BICEP1 three-year data, the significance of the nonzero rotation angle reduces to around 2σ, namely $\hat{\alpha} = -2.12 \pm 1.14$ from the WMAP9+B03+BICEP1 data combination. We still find a $\sim 2\sigma$ tension between QUaD and WMAP9+B03+BICEP1 observations. When combining all CMB polarization data together, we obtain the tightest constraint on the rotation angle at a 68% confidence level: $\hat{\alpha} = 0.03 \pm 0.55$. Furthermore, we investigated the impact of the direction dependence of the rotation angle on the CMB polarization power spectra in detail and perform a global analysis to constrain the related parameters using CosmoMC. We found that the anisotropies of the rotation angle are just weak disturbances, namely the variance $C^\alpha(0) < 0.035$ at a 95% confidence level. Due to small effects, the current CMB polarization data cannot constrain these parameters very well. The obtained results are consistent with zero.

We also consider the new BICEP2 polarization data. Since the BICEP2 collaboration uses the “self-calibration” for the detector polarization orientations, any polarization rotation has been removed from their data. Therefore, we mainly use this data to study the anisotropies of the rotation angle. When combining with WMAP9 and B03 data, we obtain tighter constraints, which, however, are still consistent with zero, on the parameters of the anisotropies of the rotation angle. Interestingly, since the direction dependence of the rotation angle would also contribute to the CMB BB power spectrum, considering this direction dependence could lower the best-fit value of $r$ and relax the tension on the constraints of $r$ between from BICEP2 and from Planck data.

Since the current constraints on the rotation angle are not conclusive, we simulate the future Planck polarization data. We find that the future CMB data could significantly improve the constraint of $\hat{\alpha}$ by a factor of 10, as well as the parameters related to the direction dependence of the rotation angle. The future Planck data could constrain the nonzero rotation angle and its anisotropies and test the CPT symmetry more stringently.
