Abstract

The NOvA long-baseline neutrino oscillation experiment is currently under construction and will use an upgraded NuMI neutrino source at Fermilab and a 14-kton detector at Ash River, Minnesota to explore the neutrino sector. NOvA uses a highly active, finely segmented detector design that offers superb event identification capability, allowing precision measurements of $\nu_e/\overline{\nu}_e$ appearance and $\nu_\mu/\overline{\nu}_\mu$ disappearance, through which NOvA will provide constraints on $\theta_{13}$, $\theta_{23}$, $|\Delta m^2_{\text{atm}}|$, the neutrino mass hierarchy, and the CP-violating phase $\delta$. In this article, we review NOvA’s uniquely broad physics scope, including sensitivity updates in light of the latest knowledge of $\theta_{13}$, and we discuss the experiment’s construction and operation timeline.

Keywords: NOvA, neutrino, long-baseline, mixing, mass hierarchy, CP violation

1. Introduction

The NuMI Off-axis $\nu_e$ Appearance (NOvA) experiment is a two-detector, long-baseline, atmospheric-regime neutrino oscillation experiment designed to address a broad range of open questions in the neutrino sector through precision measurements of $\nu_\mu \rightarrow \nu_e$, $\overline{\nu}_\mu \rightarrow \overline{\nu}_e$, $\nu_\mu \rightarrow \nu_\mu$, and $\overline{\nu}_\mu \rightarrow \overline{\nu}_\mu$ oscillations. As the name implies, much of NOvA’s physics scope comes from the appearance channels, as the observed rates of $\nu_e$ and $\overline{\nu}_e$ interactions provide information on (1) the ordering of the neutrino masses (i.e., whether the $\nu_3$ state is more or less massive than the other two), (2) the amount of CP violation present in the neutrino sector, (3) the size of the PMNS mixing angle $\theta_{13}$, and (4) whether the $\nu_3$ state has more $\nu_\mu$ or $\nu_\tau$ admixture (that is, whether $\theta_{23} > \frac{\pi}{4}$ or $< \frac{\pi}{4}$, respectively). Recent results by short-baseline $\overline{\nu}_e$ disappearance experiments demonstrating $\theta_{13} \approx 9^\circ$\cite{1,2,3} ensures that NOvA will have substantial event rates in the appearance channels. Through $\nu_\mu$ and $\overline{\nu}_\mu$ disappearance, NOvA will provide improved precision on the dominant atmospheric oscillation parameters $\theta_{23}$ and $|\Delta m^2_{\text{atm}}|$.

Outside of these primary goals, NOvA will also look for evidence of new physics through comparisons of $\nu_\mu \rightarrow \nu_\mu$ and $\nu_\mu \rightarrow \nu_\mu$, provide constraints on sterile neutrino models by measuring the total flux of active neutrinos at its downstream detector, monitor for supernova neutrino activity, perform neutrino-nucleus cross section measurements with a narrow-band beam, and pursue a variety of non-neutrino topics including searches for magnetic monopoles and hidden sector particles.

For all of the oscillation measurements, NOvA takes advantage of a two-detector configuration to mitigate uncertainties in neutrino flux, neutrino cross sections, and event selection efficiencies. The 14-kton Far Detector (FD) is currently under construction in Ash River, Minnesota, 810 km downstream of the neutrino source at Fermilab. The 0.3-kton Near Detector (ND) will be located on the Fermilab site in a new cavern to be excavated near the existing MINOS Near Detector Hall.

2. Neutrino source

NOvA uses Fermilab’s NuMI beamline as its neutrino source\cite{4}. The NOvA detectors are situated 14 mrad off the NuMI beam axis, so they are exposed to a relatively narrow band of neutrino energies centered at 2 GeV.\hfill\footnote{On behalf of the NOvA collaboration.}
Figure 1 shows how the energy spectrum for $\nu_\mu$ charged current (CC) events varies with detector position. The suppressed high-energy tail at NOvA’s off-axis location reduces neutral current backgrounds in the visible energy range of 1 to 3 GeV where the appearance of $\nu_\mu$ CC events should occur.

The NuMI source is undergoing upgrades to increase its average beam power from 350 kW to 700 kW. Much of the increased power comes from a reduction in the Main Injector cycle time, which will drop from 2.2 seconds to 1.3 seconds. This cycle time reduction is in turn made possible by reconfiguring the antiproton Recycler as a proton injection ring, thereby allowing ramping in the Main Injector to occur concurrently with the next injection. The NuMI upgrades are scheduled to last 12 months, ending May 2013.

3. Detectors

The NOvA detectors are highly segmented, highly active tracking calorimeters. The segmentation and the overall mechanical structure of the detectors are provided by a lattice of PVC cells with cross sectional size (6 cm) x (4 cm). Each cell extends the full width or height of the detector – 15.6 m in the FD, 4.1 m in the ND – and is filled with liquid scintillator. Light produced by the scintillator is collected and transported to the end of the cell by a wavelength-shifting fiber that terminates on a pixel of a 32-channel avalanche photodiode. Figure 2 shows a sketch of the FD and ND along with a cut-away view of the PVC lattice. Each of the 928 layers of the FD has 384 cells, for ~360,000 total channels of readout. The ND has 206 layers each with 96 cells plus a muon range stack at the downstream end (not shown in the figure) made by interleaving steel plates with standard detector layers.

Figure 3 shows three simulated events in the NOvA ND. Muons are clearly identifiable as long, straight tracks with appropriate energy deposition per unit path-length ($\frac{dE}{dx}$). Proton tracks can be separated from other hadron tracks by their $\frac{dE}{dx}$ profiles. The NOvA detector technology is particularly well-suited for electromagnetic shower identification, as the radiation length in the detector (38 cm) is many times larger than the relevant PVC cell dimensions. This level of granularity helps $\pi^0$ decays stand out, as the decay photons leave telltale gaps in detector activity between the neutrino interaction location and the photon conversion point, as in the bottom panel of Figure 3.

Since November 2010, NOvA has operated a prototype detector, dubbed the Near Detector on the Surface (NDOS), that has allowed full-scale detector assembly and integration tests, electronics and data acquisition development, calibration R&D, Monte Carlo simulation tuning, and early analysis R&D. The NDOS sits 110 mrad off the NuMI beam axis and approximately on the Booster beam axis and is identical in size to the ND except in its width, with 64 cells spanning it horizontally rather than 96. With the NDOS, NOvA has recorded hundreds of neutrino interactions from both the NuMI and Booster sources and has collected millions of cosmic ray interactions. Figure 4 shows two distributions...
using NuMI neutrino events: the reconstructed primary track direction and the total visible energy. The data and simulation are in excellent agreement.

The NDOS continues to operate. FD construction has begun and will proceed over a two-year period ending Summer 2014. Neutrino data taking will commence with a partial detector (∼5 kton) when the NuMI beam returns in May 2013. After a six-month beam commissioning period, the NuMI line will be ready for its full 700-kW operation. Figure 5 shows the expected NOvA exposure during early running.

4. \(\nu_e/\bar{\nu}_e\) appearance

NOvA will begin its oscillation data run in \(\nu\) mode, that is with the NuMI horn configured to focus positive secondary hadrons. While FD construction and NuMI commissioning will still be underway during the first year of data taking, NOvA can nonetheless reach a 5\(\sigma\) C.L. observation of \(\theta_{13}\)-driven \(\nu_\mu \rightarrow \nu_e\) oscillations after one year, assuming the normal mass hierarchy. Figure 6 shows how this sensitivity changes with time.

The baseline NOvA exposure is \(3.6 \times 10^{21}\) protons-on-target (p.o.t.), which can be accumulated in six years at design intensities, with a 14-kton FD. For the sensitivities shown below, this exposure is assumed divided evenly between \(\nu\) and \(\bar{\nu}\) running, a split that works well for many parameter scenarios but is nonetheless adjustable. The analysis techniques used here are those described in the NOvA Technical Design Report [5]. Updated analyses for use in the first NOvA results are under active development.

Table 1 shows the number of \(\nu_e\) and \(\bar{\nu}_e\) CC event candidates expected after a six-year run. Since these counts
Table 1: Representative numbers of $\nu_\mu \rightarrow \nu_e$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ candidate events expected in the FD after three years each of $\nu$ and $\bar{\nu}$ running, assuming $\sin^2(2\theta_{23})=0.095$. The two columns are labeled by running mode, $\nu$ or $\bar{\nu}$. Each row includes both right- and wrong-sign components.

|          | $\nu$ | $\bar{\nu}$ |
|----------|-------|-------------|
| $\nu_\mu$ CC | 19    | 10          |
| $\nu_\mu$ CC | 5     | <1          |
| $\nu_\mu$ CC | 8     | 5           |
| total bg.    | 32    | 15          |
| $\nu_\mu$ CC | 68    | 32          |

Figure 5: Expected development of detector mass, beam power, instantaneous exposure, and integrated exposure in the first few years of NOvA running.

Figure 6: Sensitivity to $\nu_\mu \rightarrow \nu_e$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ oscillations in early running. The solid (dashed) lines assume the normal (inverted) hierarchy. The red curves that begin May 2014 assume a switch to $\bar{\nu}$ running after one year. This run plan is merely an example, and the time of switching to $\bar{\nu}$ running is flexible. The black curves labeled “combined” show the appearance significance for the combined $\nu_\mu \rightarrow \nu_e$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ samples.

Probabilities depend on both the mass hierarchy and the value of the CP-violating phase $\delta$, and it is instructive to see these dependencies graphically. Figure 7 shows the locus of possible values for these two probabilities for a given set of mixing angles. Overlayed on the figure are the expected $1\sigma$ and $2\sigma$ C.L. contours for a particular test point after six years of NOvA running. This representation of the appearance measurements, though approximate, makes plain the nature of NOvA’s hierarchy and CP violation sensitivity. For example, no possible inverted hierarchy scenarios are included in the $2\sigma$ intervals for the test point shown, so the inverted hierarchy would be excluded by at least $2\sigma$ in this scenario. Figure 7 also demonstrates that the significance with which NOvA can establish the hierarchy depends on $\delta$. This significance is shown explicitly as a function of $\delta$ in Figure 8.

By the end of the primary NOvA run, the T2K experiment will have a significant $\nu_\mu \rightarrow \nu_e$ oscillation data set of its own, and the appearance probabilities for T2K depend relatively little on the mass hierarchy. Thus, potential degeneracies in the NOvA measurement can be partially lifted by including T2K data. The combined sensitivity is shown in Figure 9.

The examples given so far have assumed $\sin^2(2\theta_{23})=1$. $\nu_\mu$ disappearance measurements in the coming years, including those from NOvA (see below), will provide increased precision on $\sin^2(2\theta_{23})$, and it is possible that non-maximal mixing will be established. Figure 10 shows how non-maximal mixing

---

R. B. Patterson / Nuclear Physics B Proceedings Supplement – Preprint

 depend strongly on the exact oscillation parameters, a sort of “average” is shown here by assuming no matter effects, no solar oscillations, and $\theta_{23}=\frac{\pi}{4}$. The signal efficiency is $\sim 45\%$ and the neutral current (NC) leakage rate is $\sim 1\%$. These rates are somewhat higher than those in the Technical Design Report as the analysis cuts have been reoptimized for a non-zero value of $\theta_{13}$.

Given its narrow-band beam, NOvA primarily measures oscillations of 2 GeV neutrinos. Thus, the appearance measurement approximately reduces to the extraction of two numbers from the data: the probabilities for $\nu_\mu \rightarrow \nu_e$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ oscillations at 2 GeV. These two
influences the NOvA appearance measurements. In particular, the set of \( P(\nu_e), P(\nu_A) \) values that NOvA can measure at 2 GeV is now described by four ellipses rather than two, with the higher (lower) probability cases corresponding to \( \theta_{23} > \frac{\pi}{4} \) \( \left( \theta_{23} < \frac{\pi}{4} \right) \). Equivalently, the higher probability cases are those where the \( \nu_A \) state has more \( \nu_e \) than \( \nu_e \) admixture, and vice versa.

This bifurcation in the set of possible outcomes allows NOvA to make a measurement of this flavor balance \( \left( i.e., \text{of the } \theta_{23} \text{ octant} \right) \). If \( \sin^2(2\theta_{23}) < 1 \), then the NOvA appearance data will provide information on the mass hierarchy, \( \delta \), and the \( \theta_{23} \) octant simultaneously.
Figure 11 shows NOvA’s sensitivity to these three unknowns under two example scenarios, one in the degenerate regime and one not. Several features in the figure deserve mention. (1) The absence of any inverted hierarchy contours in the top panel indicates the >2σ significance of hierarchy determination expected in this scenario. (2) The bottom panel shows a “degenerate” scenario, in which CP violation and long-baseline matter effects introduce cancelling perturbations in the oscillation probabilities. In such scenarios, NOvA provides only correlated information on the mass hierarchy and δ. (3) NOvA’s θ23 octant sensitivity is largely independent of the hierarchy and δ. This is seen qualitatively in Figure 10 by the separation of the two octants’ probabilities, and it is visible in the bottom panel here, where the correct octant is strongly preferred despite the presence of ambiguities in determining the mass hierarchy and δ.

4.1. Disappearance

While electron identification capability was key in the design of NOvA, the detectors also have excellent energy resolution for νµ charged current events, particularly for quasi-elastic interactions, and NOvA will make precision measurements of the atmospheric oscillation parameters sin2(2θ23) and |Δm2<sub>atm</sub>| through νµ disappearance. Like the appearance analyses, the disappearance analyses are under active development, and the sensitivities shown here come from earlier estimates updated to include the latest knowledge of beam and detector performance.

NOvA’s narrow-band 2-GeV spectrum and matching 810-km baseline mean that the νµ flux is largely oscillated away at the FD. Figure 12 shows the expected reconstructed energy spectrum for νµ and νµ CC quasi-elastic events after three years each of ν and ν running at design exposures. Both a maximal and a non-maximal mixing scenario are shown, and these are readily distinguished given the expected event counts and the energy resolution of 4% assumed for this quasi-elastic sample.

Figure 13 shows the sensitivity to sin2(2θ23) and |Δm2<sub>atm</sub>| for three test cases. If sin2(2θ23) is near the current global best-fit value of 0.95 [7], NOvA can establish non-maximal mixing at >2σ.

5. Closing

NOvA FD construction is underway at Ash River, and ND cavern excavation is now beginning at Fermilab. The ND-sized prototype detector, NDOS, has operated for two years at Fermilab and has allowed rapid development of assembly procedures and analysis tools.

The NuMI beam will return May 2013, and NOvA will begin collecting neutrino data immediately with a partial detector. Full instantaneous exposure will be reached in summer 2014 when the 14-kton FD is complete. With a six-year run, NOvA can unambiguously resolve the neutrino mass hierarchy at >95% C.L. for over a third of possible values of δ. NOvA will otherwise provide δ-dependent hierarchy determination plus measurements of θ13, θ23, |Δm2<sub>atm</sub>]|, and δ itself.

NOvA will begin its FD neutrino run in ν mode, with a future switch to ν running yet to be scheduled. For the normal mass hierarchy, NOvA can achieve 5σ C.L. observation of atmospheric-regime νµ → νe oscillations with its first year of data, even with the exposure limita-
tions of on-going detector construction and NuMI beam commissioning.

$$\sin^2(2\theta_{23}) = 0.94$$

Figure 12: Reconstructed neutrino energy spectrum expected at the FD in two scenarios after a 3+3 year ($\nu+\bar{\nu}$) run. The solid black (dashed red) histogram is for $\sin^2(2\theta_{23}) = 1$ ($\sin^2(2\theta_{23}) = 0.94$).

$$|\Delta m^2| \quad (10^{-3} \text{eV}^2)$$

Figure 13: NOvA 1$\sigma$ and 2$\sigma$ sensitivity to $\sin^2(2\theta_{23})$ and $|\Delta m^2_{\text{atm}}|$ after a 3+3 year ($\nu+\bar{\nu}$) run.
