Gastrointestinal hormones are currently used to treat type 2 diabetes mellitus (T2D). Incretin preparations with gastric inhibitory polypeptide (GIP) activity or glucagon-like peptide-1 (GLP-1) provide new means for controlling blood glucose levels, body weight, and lipid metabolism. GIP, an incretin, has not been used due to lack of promising action against diabetes. However, recent studies have shown that GIP has an important effect on glucagon and insulin secretion under normoglycaemic conditions. Co-existence of GIP with GLP-1 and glucagon signalling leads to a stronger effect than that of GLP-1 stimulation alone. The development of a GIP/GLP-1R unimolecular dual agonist with affinity for both GIP and GLP-1 receptors is under investigation, and the drug is expected to be clinically available in the near future. Tirzepatide, a GIP/GLP-1R unimolecular dual agonist, regulates metabolism via both peripheral organs and the central nervous system. The SURPASS phase III clinical trials conducted for tirzepatide comprise 10 clinical trials, including five global trials and the global SURPASS-CVOT trial, with >13,000 patients with T2D (ClinicalTrials.gov Identifier: NCT04255433). The clinical application of tirzepatide as a therapy for T2D may provide new insights into diabetic conditions and help clarify the role of GIP in its pathogenesis.

For the past 10 years, GLP-1 receptor agonists, which are mimetic of incretins, have been used for the treatment of type 2 diabetes mellitus (T2D). GIP as a drug has not been developed due to lack of promising action against diabetes. After the discovery of its amino acid sequence in 1971, GIP was found to promote insulin secretion in a glucose-dependent manner. By cloning the GIP cDNA, the structure of prepro-GIP was successfully revealed. GIP mRNA expression in the upper segment of the small intestine and localization of its gene in the chromosome was demonstrated. GIP is shown to be related to high-fat diet-induced obesity.

Functional analysis of GIP reports its potential effect on glucagon and insulin secretion under normoglycaemic conditions. It also has positive effects on lipid metabolism, bone metabolism and the central nervous system (CNS). Moreover, the effect of GIP, GLP-1 and glucagon signalling together is stronger compared to GLP-1 alone. Succeeding this work, a unimolecular dual agonist of GIP and GLP-1 is under development and will be available in the near future as anticipated. Treatments that regulate metabolism, particularly gastrointestinal hormones, are becoming increasingly common; for example, GIP plus glucagon or a triagonist comprising GIP, GLP-1 and glucagon is also being developed for patients with obesity, diabetes or dyslipidaemia. Herein, we review GIP activation based on in vivo studies, focusing on the physiological role of cooperative GIP and SURPASS, which include 10 clinical studies of tirzepatide–GIP/GLP-1 dual agonist.

Based on the treatment outcomes with GIP/GLP-1 dual agonist, we might explore other combinations, such as a triagonist–GLP/GIP/glucagon or other dual agonists involving glucagon, which are currently under development.

Gastrointestinal hormones, incretin, GIP and GLP-1

Nutrients in the digestive tract stimulate the secretion of gastrointestinal hormones and activate metabolic function. Subsequently, this influences immunity and is involved in communication among organs.

Gastrointestinal hormones - especially GIP and GLP-1 - both gut-induced incretins, are secreted in response to nutrient ingestion, which stimulates the pancreatic β-cells to increase insulin secretion in a glucose-dependent manner; thus, exhibiting insulinogetic effects.
GIP and GLP-1 are occasionally secreted by the same cell, also referred to as K/L or L/K cells (Figure 1). The influence of GIP and GLP-1 on the pancreatic α-cell function is inverse. GIP stimulates the α-cells to promote glucagon secretion, while GLP-1 reduces it. Elevation of glucagon is associated with T2D. Therefore, suppression of glucagon activity using a GLP-1 receptor (GLP-1R) agonist has been developed for treatment of T2D. The use of gastrointestinal hormones, particularly GLP-1 and GIP, includes incretin preparations such as a novel GLP-1R agonist or a GIP/GLP-1 dual agonist, which is anticipated to provide new means for controlling T2D and body weight.

**GLP-1R activity**

GLP-1R, a member of the class B family of G protein-coupled receptors, is found in various organs. It is expressed mainly in pancreatic β-cells, various gut-cells, and also in the peripheral nervous system and CNS cells (Figure 1). Signal transduction occurs after GLP-1R agonists bind to GLP-1Rs, mirroring a GLP-1 bioactivity effect favourable for patients with T2D, where this incretin therapy lowers blood glucose levels by stimulating insulin secretion from β-cells. This therapy is effective when there is no complete loss of β-cell function. Additionally, there is suppression of appetite induced through the CNS, leading to body weight reduction. Since GLP-1R is expressed in the cells of various organs including pancreatic β-cells, GLP-1R agonists manifest favourable effects during its circulation.

Some low molecular weight GLP-1R agonists can act on GLP-1R in the arcuate nucleus of the hypothalamus, crossing the blood-brain barrier, thereby regulating nerve cells. In patients prescribed with a GLP-1R agonist as a personalized medicine (that could also reduce the body weight), longer adherence to such therapy with improved satisfaction is anticipated as the patient has chosen a therapy more suitable to their needs.

**GIP-R activity**

GIP is an incretin secreted by the K cells in the upper segment of the small intestine in response to nutrient ingestion (Figure 1). Following GIP release from the gut endocrine K cells, rapid inactivation occurs by dipeptidyl peptidase-4 (DPP-4) through cleavage into non-insulinotropic truncated forms. The postprandial level of GIP under normal physiological conditions is approximately four times that of GLP-1. GIP receptors (GIPRs) are present in gastrointestinal (GI), brain, heart, kidney, skeletal muscle, and fat. The GIP-R activity is illustrated in Figure 2.
in the β-cells. Additionally, GIPRs are abundantly expressed in adipocytes, the CNS and bones, causing an effect on the adipose tissue, the CNS, and bones (Figure 1).

In healthy people, GIP induces nutrient-stimulated insulin and glucagon secretion in a glucose-dependent manner. The stimuli that induce insulin secretion in response to a 50 g oral glucose load are glucose alone (33%), GIP (44%) and GLP-1 (22%) GIP has an augmented effect on insulin secretion, unlike GLP-1, and plays an important role in glucose metabolism in humans. Moreover, GIP accompanied with insulin or GLP-1 signalling, leads to a reduction in blood glucose levels and body weight. Thus, GIP promotes insulin secretion in healthy individuals, however this effect is not observed in patients with T2D (Figure 2).

Unlike GLP-1, GIP failed to stimulate glucagon secretion during hyperglycaemia. Alternatively, stimulated glucagon secretion via GIP does occur during hypoglycaemic conditions accompanied by glucagonotropic enhanced activity.

The physiological significance of GIP-stimulated glucagon secretion remains unexplored. In contrast, in patients with T2D, glucose-dependency of GIP-stimulated glucagon secretion, such as in healthy people, does not remain (Figure 2). Elimination of GIPR activity in β-cells demonstrated a characteristic of T2D, associated with reduced postprandial insulin secretion and hyperglycaemia (Figure 2).

Glucagon secretion by stimulation of GIP, even occurring during hyperglycaemia (Figure 2), suggests unfortunate GIPR activity in α-cells, which contributes to the pathogenesis of T2D. GIP is potentially responsible for the facilitation of glucose-induced β-cell proliferation, in addition to a reduction in α-cell expansion.

GIP positively impacts energy storage by controlling fat metabolism and lipid storage through increased blood flow in adipose tissue and triglyceride uptake; it also accumulates fat via the CNS in humans (Figure 1). GIP plays an important role in the regulation of food intake, lipoprotein lipase activity and fat decomposition during carbohydrate/fat degradation in adipose tissue; it produces a direct lipolytic effect during hyperglycaemia and low levels of insulin.

Elimination of GIPR activity by various mechanisms, including genetic ablation blockage, GIPR antagonist or neutralization of GIP, has a favourable effect on glucose tolerance and obesity. GIPR antagonists have been developed as treatments for T2D and obesity. Additionally, enhancement of GIP activity, using agonists of GIPR or chronic elevation of GIP levels causing weight loss when coexisting with GLP-1 receptor activation, are useful treating obesity and T2D, leading to improved insulin secretion, glycaemic control, and an accompanying amelioration of β-cell function. Further studies on clinical use of tirzepatide associated with GIPR activity will provide a platform for unravelling the pathogenesis and understanding GIPR activity in α-cells and regulation of glucagon secretion.

GIP-based pharmacotherapy, which relies on CNS-GIPR signalling, is of importance, particularly in systemic metabolic control. Apoptosis inhibition and osteoblast proliferation are also stimulated by GIP, resulting in bone formation and remodelling.

**Protective effect of incretin on various organs**

Any long-acting GLP-1 agonist exhibits the same anti-inflammatory effects as natural GLP-1, and is therefore demonstrated to protect organs such as the heart, kidneys and others (Figure 1). GLP-1 and other intestinal hormones are known to drive natriuresis via the gut-kidney axis. Onset of apparent albuminuria in high-risk patients with T2D having cerebro-cardiovascular disease complications was significantly reduced by long-acting GLP-1 agonist administration. The reduction in cerebrovascular events was significantly noted among Asian patients. GIP has also been shown to reduce pro-inflammatory cytokine expression, thereby reducing the inflammatory response in the

Tirzepatide: A Novel, Once-weekly Dual GIP and GLP-1 Receptor Agonist for the Treatment of Type 2 Diabetes

The beneficial effects of GIP on neurodegenerative diseases are well documented. Pharmacological concentrations of GIP agonists are more likely to provide protective effects against atherosclerosis in both patients with diabetic and non-diabetic conditions.

In patients with T2D, the incidence of heart failure significantly increases due to ischaemic heart disease and also separately due to the diabetic condition itself. Obesity, which is closely linked to T2D, is also often associated with heart failure. It is expected that anti-diabetic drugs cause weight reduction, better glycaemic control and improvement in macrovascular outcomes such as cerebral cardiovascular risk factors, in addition to microvascular outcomes.

Since evidence suggests that GLP-1R agonists have a protective effect on various organs (Figure 1), the use of a GIP/GLP-1R dual agonist is under clinical investigation to prevent the aggravation of diabetic complications.

GIP and GLP-1 synergistic activation

In patients with T2D, GIP-stimulated glucagon secretion observed in healthy participants is not maintained. However, the coexistence of GIP and GLP-1 in patients with T2D produces glucagon concentrations akin to control conditions. DPP-4 inhibitors enhance GIP and GLP-1, which are physiologically derived in the gut in response to oral nutrient intake, thus acting similarly to the coexistence of GIP and GLP-1 (Figure 3).

In patients with T2D, physiological secretion of GIP or GLP-1 decreases, thus reducing insulin secretion, compared to that in healthy participants. Notably, DPP-4 inhibitors enhance GLP-1 or GIP level in patients with T2D. However, in patients with T2D, GIP/GLP-1R dual agonists provide pharmacological concentration levels of GLP-1 and GIP, adding a synergistic effect and producing robust stimulation of insulin secretion.

Pharmacological activation of GIPRs is anticipated to produce therapeutic effects regarding energy metabolism in peripheral tissues, whereas the chronic use of long-acting GIPR agonists did not reduce body weight. Synergistic activation of GIP/GLP-1R produced higher therapeutic efficacy for T2D, leading to a greater body weight reduction, compared with GIP or GLP-1 alone. Reinforced suppression of calorie intake, accompanied by a gradual increase in energy consumption, produces a reduction in body weight. Evidence suggests that GIP/GLP-1 synergism occurs in the CNS and reduces body weight, independent of insulin sensitivity and fat metabolism. Compared to a GLP-1R agonist alone, a GIPR/GLP-1R unimolecular dual agonist has also shown restorative and neuroprotective properties.

Regarding the effects of increased antidiabetic action and decreased body weight by dual stimulation of GIP and GLP-1R, more than either GIP or GLP-1 alone, one of the reasons that might be postulated for this synergism is that GIP signals mediate insulinoergic and glucagonotropic effects through the brain or fat. Nevertheless, further research is needed concerning the links between the gut, brain and blood glucose levels which employ gastrointestinal hormones including dual, tri or more synergistic stimulations. Therefore, tirzepatide has the potential to be a key that unlocks the door to this conundrum. While many people have suggested that in vitro research has such potential, in fact the direct administration of tirzepatide in humans lends itself to a more timely revealing of the facts behind the system of blood glucose maintenance.

GIP/GLP-1R unimolecular dual agonist, tirzepatide

The GIP/GLP-1R unimolecular dual agonist, tirzepatide, is a multifunctional peptide based on the native GIP peptide sequence, designed to bind both the receptors. The synergistic effect of GIP and GLP-1 on food intake and increasing energy expenditure results in body weight reduction. Tirzepatide structurally comprises a peptide of 39 amino acids (molecular weight: 4810.52 Dalton) with the bioactive moiety enabling it to bind to albumen and prolong its half-life of 5 days.

Tirzepatide has exhibited robust results in glycaemic control and body weight reduction compared to other alternatives. In my opinion, early stage T2D results from the misalignment of the metabolic orbits of insulin, glucagon, intestinal hormones such as representative incretins, and other factors in the CNS. Since conventional treatment of T2D is not aimed at restoring original pancreatic β-cell function, but instead ‘exogenously replenishing’ the declining function, tirzepatide robust effectiveness is due to the improvement of the misalignment of the metabolic orbits as it might act as a critical factor of metabolic orbit. This improvement in misalignment may be also possibly due to intervention in GIP signalling with GLP-1 signalling.

SURPASS clinical trials

In the original phase II trial (A phase 2 study of once-weekly LY3298176 compared with placebo and dulaglutide in patients with type 2 diabetes mellitus; ClinicalTrials.gov identifier: NCT03131687), patients with T2D with diet and exercise therapy alone or those undergoing metformin therapy, and a BMI of 23–50 kg/m², were randomly assigned to receive either once-weekly tiazepatide (1 mg, 5 mg, 10 mg or 15 mg), dulaglutide (1.5 mg), or placebo for 26 weeks. Based on the primary efficacy outcome from this study - that is, change in glycated haemoglobin A1C (HbA1c) from baseline to 26 weeks - the SURPASS clinical phase III trials (A phase of tirzepatide [LY3298176] in participants with type 2 diabetes mellitus; ClinicalTrials.gov identifier: NCT03954834; A study of tirzepatide [LY3298176] versus semaglutide once weekly as add-on therapy to metformin therapy in patients with type 2 diabetes [SURPASS-2]; ClinicalTrials.gov identifier: NCT03987919; A study of tirzepatide [LY3298176] versus insulin degludec in participants with type 2 diabetes [SURPASS-3]; ClinicalTrials.gov identifier: NCT03882970; A study of tirzepatide [LY3298176] once a week versus insulin glargine once a day in participants with type 2 diabetes and increased cardiovascular risk [SURPASS-4]) employed 3 dosages.

Global phase III clinical trials conducted to evaluate the efficacy and safety of weekly tirzepatide included anti-hyperglycaemic therapy-naive patients and patients on various oral anti-hyperglycaemic drugs, including metformin, sulfonylurea, pioglitazone, SGLT2 inhibitor and/or insulin compared with placebo, basal insulins, or the conventional GLP-1R agonist (Tables 1 and 2; Figure 4). Tirzepatide demonstrated robust glycaemic control (Figure 4) and body weight reduction compared to the controls, which included the conventional GLP-1R agonist semaglutide. In particular, in the SURPASS-1 trial, tirzepatide was reported to be a curative drug in patients with early stage T2D. In all studies, over 90% of the patients taking tirzepatide achieved HbA1c levels <7%; between 40% and 52% of patients achieved HbA1c levels <5.7% (Figure 4). Weight reduction ranged from 6.2–12.9 kg (6.6–13.9%) depending on
the dose (Figure 5); in addition, this weight reduction did not bottom out at 40 weeks.21,70–74,81–84 Weight loss of 15% or more was observed in 13–27% of patients.70–74

It has been reported that post-bariatric surgery decreases in body weight were -45.0 kg at 2 years, -36.3 kg at 6 years and -35.0 kg at 12 years, while the decreases in those not undergoing the surgery were -2.9 kg at 2 years and 0 kg at 12 years. However, surgery for severe obesity generally brings a high level of risk. Firstly, two-step treatment, such as GIP/GLP-1R agonist treatment following bariatric surgery would provide a more effective outcome than each therapy undertaken alone. Tirzepatide treatment has also been studied in clinical trials for cardiovascular (CV) outcomes (Tables 1 and 2). The full list of SURPASS trials is as follows:

- SURPASS-1 (ClinicalTrials.gov identifier: NCT03954834): assesses efficacy, safety, and tolerability of tirzepatide monotherapy versus placebo in patients with T2D with diet and exercise alone.20–24
- SURPASS-2 (ClinicalTrials.gov identifier: NCT03987919): assesses efficacy and safety of tirzepatide versus semaglutide (1 mg) weekly as add-on therapy to metformin in patients with T2D.21
- SURPASS-3 (ClinicalTrials.gov identifier: NCT03987919): assesses efficacy and safety of tirzepatide versus insulin degludec in patients prescribed metformin with or without SGLT2 inhibitors.72
- SURPASS-4 (ClinicalTrials.gov identifier: NCT03730662): assesses the efficacy and safety of tirzepatide versus insulin glargine in patients with T2D with high CV risk (87% of participants had previous events) on oral anti-hyperglycaemic medications.73
- SURPASS-5 (A study of tirzepatide (LY3298176) versus placebo in participants with type 2 diabetes inadequately controlled on insulin glargine with or without metformin; ClinicalTrials.gov identifier: NCT04039503): assesses the efficacy and safety of the addition of tirzepatide versus placebo in patients with T2D prescribed insulin glargine with or without metformin.74
- SURPASS-6 (A study of tirzepatide (LY3298176) versus insulin lispro (U100) in participants with type 2 diabetes inadequately controlled on insulin glargine (U100) with or without metformin; ClinicalTrials.gov identifier: NCT04537923): assesses the effect of the addition of tirzepatide weekly versus insulin lispro (U100) three times daily in patients with T2D prescribed insulin glargine.

| Study acronym | Study type | Number of enrolments | Eligibility | Comparator | Study duration (weeks) | Primary outcome | Estimated completion |
|---------------|------------|----------------------|-------------|------------|------------------------|-----------------|---------------------|
| SUMMIT (NCT04847557) | Phase III randomized double-blind | Estimated 700 | ≥40 years old, stable heart failure (NYHA class II-IV) and LVEF ≥50% | Placebo | 52 | Efficacy and safety | November 2023 |
| SURMOUNT-1 (NCT04184622) | Phase III randomized double-blind | 2,539 | BMI ≥30 kg/m², or BMI ≥27 kg/m² with related comorbidities | Placebo | 72 | Weight decrease in people with diabetes and obesity | May 2024 |
| SYNERGY-NASH (NCT04166773) | Phase II randomized double-blind | Estimated 196 | BMI ≥27 kg/m² and NASH stage 2 or 3 fibrosis | Placebo | 52 | Absence of NASH, with no worsening of fibrosis on liver histology | December 2023 |

BMI = body mass index; LVEF = left ventricular ejection fraction; NASH = non-alcoholic steatohepatitis; NYHA = New York Heart Association.

**Other tirzepatide trials**

The other trials into tirzepatide are as follows (Table 3):
- **SUMMIT** (ClinicalTrials.gov Identifier: NCT04847557): a phase III trial comparing the efficacy and safety of tirzepatide versus placebo in patients with heart failure with preserved ejection fraction, as described above.
- **SURMOUNT-1** (A study of tirzepatide (LY3298176) in participants with obesity; ClinicalTrials.gov identifier: NCT04184622): a phase III trial evaluating the efficacy and safety of tirzepatide in reducing weight in obese subjects without T2D at 72 weeks. Eligible participants were those with either a BMI ≥30 kg/m², or ≥27 kg/m² plus one or more of the following: hypertension, dyslipidemia, obstructive sleep apnea or cardiovascular disease.
- **SYNERGY-NASH** (ClinicalTrials.gov Identifier: NCT04166773): a phase II trial for the efficacy and safety of tirzepatide in participants with non-alcoholic steatohepatitis (NASH). The primary outcome is the proportion of the participants with an absence of NASH at 52 weeks with no worsening of fibrosis in liver pathology. Eligible participants were those with a BMI ≥27 kg/m² and ≤50 kg/m², with or without T2D and having a histologic diagnosis of NASH with stage 2 or 3 fibrosis following liver biopsy.

**Safety profile**

There are no specific signs in a serious adverse event. Mild-to-moderate adverse effects (including nausea, vomiting and diarrhoea) occurred frequently during the dose-escalation period...
When tirzepatide was not combined with sulfonylurea or insulin, the reductions in glycaemic control and body weight for the patients in the SURPASS studies (Figure 6) were more frequent with tirzepatide than with semaglutide. This was transient, as the trial drug was discontinued in 3–11% of the patients. When tirzepatide was not combined with sulfonylurea or insulin, the conclusions of SURPASS studies, without causing hypoglycaemia. The current focus areas for research are preventative factors to combat accelerated β-cell deterioration - a critical cause of diabetes - and exploring the benefits of GIPR. The novel drugs represented by tirzepatide seem promising in revealing new pathogenic insights. It is also believed that unexploited anti-diabetic drugs with GIP and GLP-1 signal activation will unravel undiscovered avenues of treatment for T2D and its complications. The clinical success of this dual GIP/GLP-1R agonist will inspire the development of multiple agonists, such as other dual agonists or triagonists consisting of multiple ligands, including hormones with wider applications.

Conclusion

Tirzepatide, a dual GIP/GLP-1R agonist, demonstrated robust reductions in glycaemic control and body weight for the patients in the SURPASS studies, without causing hypoglycaemia. The current focus areas for research are preventative factors to combat accelerated β-cell deterioration - a critical cause of diabetes - and exploring the benefits of GIPR. The novel drugs represented by tirzepatide seem promising in revealing new pathogenic insights. It is also believed that unexploited anti-diabetic drugs with GIP and GLP-1 signal activation will unravel undiscovered avenues of treatment for T2D and its complications. The clinical success of this dual GIP/GLP-1R agonist will inspire the development of multiple agonists, such as other dual agonists or triagonists consisting of multiple ligands, including hormones with wider applications.
