Abstract
Wounding is a severe impairment of function, especially for an exposed organism like the network-forming true slime mould *Physarum polycephalum*. The tubular network making up the organism’s body plan is entirely interconnected and shares a common cytoplasm. Oscillatory contractions of the enclosing tube walls drive the shuttle streaming of the cytoplasm. Cytoplasmic flows underlie the reorganization of the network for example by movement toward attractive stimuli or away from repellants. Here, we follow the reorganization of *P. polycephalum* networks after severe wounding. Spatial mapping of the contraction changes in response to wounding reveal a multi-step pattern. Phases of increased activity alternate with cessation of contractions and stalling of flows, giving rise to coordinated transport and growth at the severing site. Overall, severing surprisingly acts like an attractive stimulus enabling healing of severed tubes. The reproducible cessation of contractions arising during this wound-healing response may open up new venues to investigate the biochemical wiring underlying *P. polycephalum*’s complex behaviours.

1. Introduction
Simple organisms like fungi and slime moulds are able to display complex behaviours. This is surprising given that their network-like body plan lacks any central organizing centre. The slime mould *Physarum polycephalum* has emerged as a model system to study the complex dynamics these organisms use to adapt to their environment. The organism has been shown to find the shortest path through a maze [1] and connect food sources in an efficient and at the same time robust network comparable to man-made transport networks [2]. Furthermore, the slime mould distributes its body mass among several resources to obtain an optimal diet [3] and is able to anticipate recurring stimuli [4].

*P. polycephalum* is a true slime mould that forms a plasmodial network. Nuclei keep on dividing without forming cell walls, which results in a syncytial web-like network. The cytoplasm within this tubular network flows back and forth in a shuttle flow [5]. These cytoplasmic flows are driven by cross-sectional contractions of the actin-myosin meshwork lining the gel-like tube walls [6]. Flows are organized across the entire network in a peristaltic wave of contractions that matches organism size [7]. Flows generated in the organism are optimized for transport as contractions increase the effective dispersion of particles way beyond molecular diffusivity by a mechanism called Taylor dispersion [8].

*P. polycephalum* adapts its network-like morphology to its environment by chemotaxis [9–11]. Here, stimulants are classified by being an attractant or a repellant depending on the organism’s response to migrate toward or away from the stimulant. Stimulants have also been shown to affect

\(^1\) Authors contributed equally to this work
cross-sectional contractions organism-wide by an increase in their frequency and amplitude for an attractant or a decrease for a repellant [12, 13]. A variety of chemical stimuli have been discussed for \textit{P. polycephalum}, with glucose being a prominent attractant and salts like NaCl being effective repellents [14–16]. Temperature [17, 18] and light [19, 20] have also been found to act as stimulants that trigger organism-wide restructuring of the transport networks’ morphology. In fact, the cytoplasmic flows themselves serve as the medium by which stimuli pervade the organism [21].

A lot less is known about the impact of mechanical perturbations on the organism. In its natural habitat the slime mould suffers predation from grazing invertebrates causing severing that disrupts the transport network and its cytoplasmic flows. In experiments it has been found that quickly stretching a strand to 10–20% of its length while keeping it intact increases the amplitude of oscillations [22]. Excising a single strand from a plasmodial network has been observed to lead to a roughly 20 minute cessation of contractions in the strand until recovery [23]. This phenomenon was not observed for strands excised from the growing fan region of the slime mould resulting in speculations about the motive force being limited to the fan only. Yet, the cessation of contractions turned out to be hard to reproduce, see [24] and references therein. Among these discordant observations what remains established is local gelation of cytoplasmic flows upon touch without severing the organism [25]. Despite the limited knowledge, wounding the organism by severing the network is part of daily laboratory routines and an eminent perturbation in natural habitat.

Here, we investigate \textit{P. polycephalum}’s dynamics during wound healing following the quick and complete severing of a tube within the organism’s network. We follow the process of wound healing across the individual’s entire body, over the course of one hour after severing. The exemplary quantitative analysis of organism-wide contractions reveals a stepwise response spanning four different states. Briefly after severing, the contractions are often marked by an increase in amplitude and frequency, followed by a several minutes long cessation of contractions and stalling of cytoplasmic flows. This resting state is terminated by a sudden restart of vigorous contractions as the severed tube re-fuses. The vigorous state then transitions into a state of network-spanning contractions and continuous fan growth at the wounding site until the organism reverts back to pre-stimulus dynamics. Timing and significance of individual steps varies with the severity of cutting and cutting site location within the network. For example, stalling is found to be less pronounced when the network is cut in fan-like region. Overall, quick and complete severing triggers a response pattern with characteristics of the response to an attractive stimulus, including an increase in amplitude and frequency and net movement to stimulus site, see figure 1. The reproducibility of stalling clarifies earlier contradictions and at the same time opens new avenues to investigate the biochemical dynamics behind the highly coordinated actomyosin contractions underlying \textit{P. polycephalum}’s arguably fascinating dynamics.

2. Methods

2.1. Culturing and data acquisition

The plasmodium is prepared from microplasmodia grown in liquid medium. The recipe for the medium is inspired by [26], see section S1. The advantage of this method over growing the plasmodium on oat flakes or bacteria is the ability to precisely control the nutritional state and amount of the organism. Also, plasmodia grown this way are free from oat flake residues or vacuoles containing food, which provides a cleaner sample for imaging. To prepare the plate for imaging, 0.2–0.5 ml of the microplasmodia grown in a shaking culture at 30 °C are transferred to an 1.5% agar plate and stored in a closed, but not sealed, dish in the dark. After 12–24 h, the microplasmodia fuse into a single plasmodium. The plasmodium is ready for imaging when there are no visible traces of liquid medium and the organism assumed its characteristic network shape, which usually occurs up to 36 h after plating.

The imaging is performed with a Zeiss Axio Zoom V.16 microscope, equipped with a Zeiss PlanNeoFluar 1x/0.25 objective and a Hamamatsu ORCA-Flash 4.0 digital camera. A green filter (550/50 nm) is placed over the transmission light source of the microscope to diminish \textit{P. polycephalum}’s response to the light, and a humidity chamber prevents the sample from drying out. The acquisition of the images is done in Zeiss ZEN 2 (Blue Edition) software with bright-field setting. During the acquisition, the illumination of the sample is kept constant, and an image is taken every 3 s. The plasmodium is imaged for \(~1\) h before the application of the mechanical stimulus to allow for the accommodation to the light [10]. The stimulus is applied manually, using a microinjection needle with a blunt tip. The needle tip is held above the
surface of the agar at a small angle and quickly dragged across the chosen plasmodial tube. The cut is severe and complete non-severed networks, where the size and nutritional state are reproducible. However, there are challenges during the imaging that decrease the reproducibility of the experiment. In particular, plasmodia are highly motile and change their behaviour to escape the imaging region. These challenges combined make the reproducibility and required input for the presented comprehensive data analysis as they develop very large foraging fronts, which are not a suitable input for the presented comprehensive data analysis as they act as stimulus.

2.2. Comprehensive network-based contraction analysis

To quantify contraction dynamics we analyse bright field recordings in two different ways: for two morphologically static networks (see E2 and E3 in the experiment list) we perform an exhaustive network-based analysis as outlined in the following (see figures 5 and S4, available online at stacks.iop.org/JPhysD/50/434005/mmedia). For the additional 19 specimen, which alter their network morphology dramatically over the course of the experiment, we analyse kymographs along static parts of the network as described in details in section S3 (see exemplary E1 and mov. S5).

Images recorded as a time series are processed as 8-bit uncompressed TIFs. At first every image is processed separately, then the results are stitched together, largely following [7], and lastly the collective is analysed. On every single image, background is removed with the rolling-ball method.
The trend $d(t)$ is obtained with a moving-average filter with a kernel width of 200 s on each time trace (see figure 3). The dataset is detrended using the calculated trend and smoothed with a Gaussian using a kernel width of 39 s. The kernel widths were chosen to extract the characteristic contraction pattern which usually has a frequency of ~90 s. The values at every data point are stored as a complex valued time array, with the detrended and smoothed intensity representing the real part and the corresponding Hilbert transform representing the complex part, see S2 for more details. This time array, denoted analytic signal, serves as a basis to get instantaneous phase, frequency and amplitude by computing the angle or absolute value of the complex time series. Finally, the results are mapped back onto the network structure for each time point. In this fashion one can follow oscillatory behaviour resolved in time and space. Furthermore, the maps can be clustered in sub-networks and averaged separately to pinpoint local events in time. It should be mentioned that averaging can be lower than the amplitude of each data point averaged (figure 5).}

3. Results

3.1. Wounding induces fan growth at cut site

We observe specimens before and after a quick and complete severing of a tube to follow the response of *P. polypephalum* to wounding (see figure 4, movs. S1 and S5). Bright field movies reveal that cutting of main tubes distal to fans triggers cessation of contractions followed by stalling of cytoplasmic flow ($n = 15$ out of 21). After contractions resume the severed tube fuses back together ($n = 21$ out of 21), i.e. flow is re-established, and a fan starts to grow at the cut site. Furthermore, we observe accumulation of body mass close to the cut site which is most prominent in peripheral cuts (figure S2). However, the growth is transient and after a given time the initial morphology is restored and the organism returns to typical behaviour comparable to before wounding.

In consideration of previously mentioned technical limits, we selected one representative dataset with prominent discernible features for network-based analysis. The following findings are derived from this dataset and later compared with other experiments. The specific timing of events in the representative data set is as follows (see figure 4). Two tubes are severed at 17.3 min effectively dividing the network into two parts. In both sub-networks, the size-wise bigger and smaller part, flows stall transiently around 30 min. At 38 min a connecting tube is reinstated and starts to re-establish cytoplasmic flows across the cut site. Until about 63 min a transient fan is created at the cut site. At 90 min the initial morphology is restored and fans are grown elsewhere.

3.2. Spatial mapping reveals localized stalling

We perform network-based analysis on the wounded specimen to extract the interplay of contractions during the healing response. In particular, we map out the amplitude and frequency of contractions spatially (see figure 4, movs. S2 and S3). This allows us to exactly localize the onset of stalling as it goes hand in hand with low values of amplitude and frequency. Likewise, patterns in contraction dynamics in a region of interest are identified by spatially averaging amplitude and frequency in this region (see figure 5). In the representative dataset, wounding separates the network into two sub-networks. Spatial mapping reveals that...
