I. INTRODUCTION

Type II Magnetoelectric multiferroics are materials which exhibit coexistence between certain types of long-range magnetic order and a ferroelectric order. These materials are usually characterized by a strong magnetoelectric coupling between their electric and magnetic degrees of freedom. The magnetoelectric effect enables the control of the electric polarization by a magnetic field, or the control of the magnetization by an electric field. The study of magnetoelectric multiferroics is thus of great interest in condensed matter physics, both from basic research and technological applications points of view.1,2

In recent years, the interest in this field has grown after the discovery of new materials with a large magnetoelectric effect, such as TbMnO$_4$, TbMn$_2$O$_7$, Ni$_x$V$_2$O$_8$, CuFeO$_2$, and CoCr$_2$O$_4$. In these oxides, ferroelectricity appears in conjunction with a noncollinear spiral magnetic phase, which breaks spatial inversion symmetry, and therefore allows the appearance of an electric polarization.

There are two different approaches to the theoretical treatment of such noncollinear magnetoelectric multiferroics. One approach is based on first principles calculations using the density functional theory (DFT).1,2,5 The second approach constructs a model Hamiltonian dictated by symmetry considerations.7,11,12 Different mechanisms for the magnetoelectric coupling can then be suggested.1,13-15 In this paper we develop a semi-phenomenological model for describing the magnetic phase transitions of Mn$_{1-x}$Fe$_x$WO$_4$ (M=Fe, Zn, Mg) and the induced ferroelectric polarization. The model is semi-phenomenological in the sense that some of the parameters can be deduced from existing experimental data, while the others are purely phenomenological. The multiferroic MnWO$_4$ is a natural choice for such an approach, due to the vast experimental data that exists in the literature.

MnWO$_4$ crystallizes in the wolframite structure, which belongs to the monoclinic space group P2$_1$/c with $\beta \approx 91^\circ$. The unit cell includes two magnetic Mn$^{2+}$ ions with spin $S = 5/2$ and orbital angular momentum $L = 0$ at positions $\tau_1 = (0.5, y, 0.25)$ and $\tau_2 = (0.5, 1 - y, 0.75)$ (in units of the primitive lattice vectors) with $y = 0.685$. In zero magnetic field, MnWO$_4$ undergoes three successive phase transitions at temperatures $T_{N1} \approx 13.5K$, $T_{N2} \approx 12.3 - 12.7K$ and $T_{N3} \approx 7 - 8K$ to phases which are called AF3, AF2, and AF1, respectively.16-18

According to neutron diffraction experiments,19 AF3 is an incommensurate (IC) antiferromagnetic phase with a collinear sinusoidal structure, AF2 is an incommensurate antiferromagnetic phase with an elliptical-spiral structure, and AF1 is a commensurate (C) antiferromagnetic phase with a collinear $\uparrow\uparrow\downarrow\downarrow$ structure. The propagation vectors are $q_{IC} = (-0.214, 0.5, 0.457)$ (in units of the primitive reciprocal lattice vectors) for AF2 and AF3, and $q_{C1.2} = (0.25, 0.5, 0.5)$ for AF1. In AF3 and AF1, the magnetic moments of the Mn$^{2+}$ ions align along the easy axis of magnetization, which lies in the ac-plane and forms an angle of $\approx 35^\circ - 37^\circ$ with the a axis. Different studies17-18 reveal that a ferroelectric polarization, which is oriented along the b axis, develops in the AF2 phase.

As opposed to MnWO$_4$, other isomorphic wolframite structures like FeWO$_4$, CoWO$_4$ and NiWO$_4$ show only a single magnetic phase transition to a simple commensurate antiferromagnetic phase with the propagation vector...
$q = (0.5, 0, 0)$\textsuperscript{22}. Those observations suggest that unlike the isomorphic structures, MnWO$_4$ constitutes a highly frustrated system with complex competing interactions. The competition between the different interactions manifests itself in the sensitivity of the phase diagram to doping with different transition metal ions at the Mn sites. It turns out that a small Fe concentration suppresses the ferroelectric phase AF2 and expands the stabilization range of AF3 and AF1.\textsuperscript{20,22} In contrast to Fe doping, it has been reported\textsuperscript{21} that a small Co concentration stabilizes the ferroelectric phase at the expense of the AF1 phase. A quantitative and microscopic understanding of the effect of Fe and Co doping on the multiferroic properties and the phase diagram of MnWO$_4$ is quite complicated, since the exchange couplings of the M-M and M-Mn (M=Fe, Co) interactions, as well as the anisotropy parameters are not known. In order to overcome some of these problems, a much simpler magnetic system has been achieved by the partial substitution of Mn ions by the non-magnetic ions Zn$^{2+}$ and Mg$^{2+}$.\textsuperscript{23}Those studies reveal that the AF1 phase is strongly suppressed as a result of magnetic ions dilution by non-magnetic substituents.

The frustrated nature of MnWO$_4$ was demonstrated by Ehrenberg et al.\textsuperscript{26} Using inelastic neutron scattering they extracted 9 exchange couplings $J_{1-9}$ for the superexchange interactions among the Mn ions. Later, Tian et al.\textsuperscript{27} proposed different values for the 9 exchange couplings based on DFT calculations. Those values depend on an unknown on-site repulsion energy. Moreover, the authors have noted that generally DFT calculations tend to overestimate the magnitude of exchange interactions.\textsuperscript{28} Recently, the experimental data have been expanded.\textsuperscript{23} In that study, Ye et al. suggested some corrections for the values of the exchange couplings, and included two additional ones, $J_{10}$ and $J_{11}$. The two sets of experimental exchange couplings are summarized in Table I. The model we describe may help to compare these different sets of exchange couplings, by examining their consistency with different experimental observations.

The outline of the paper is as follows: in Sec. II we define the model. In Sec. III the results of the model are derived. In Sec. IV the model parameters are fitted by comparing its results with different experimental observations. Here we compare the two sets of experimental exchange couplings with the fitted parameters. In Sec. V the Ginzburg criterion is applied to the specific case of the multiferroic MnWO$_4$, in order to examine whether the mean-field theory approach is valid. We conclude in Sec. VI with a brief summary.

II. THE MODEL

In this section we develop the semi-phenomenological model. The spin Hamiltonian consists of a Heisenberg term with a single-ion anisotropy, which favors an easy axis in the $ac$-plane. According to experiments, the spin component along the hard axis in the $ac$-plane does not order in any of the phases. Furthermore, the transitions are almost not influenced by an external magnetic field along the hard axis. Hence we omit the hard axis component from the calculations and write the spin as $S(R + \tau) = S_x(R + \tau)\hat{x} + S_y(R + \tau)\hat{y}$, where $x$ denotes the easy axis in the $ac$-plane and $b$ denotes the axis perpendicular to the $ac$-plane. Here $S(R + \tau)$ is the thermal average of the dimensionless classical spin at position $R + \tau$, where $R$ is a lattice vector and $\tau$ is one of the two basis vectors $\tau_1, \tau_2$ in the unit cell, indicating the locations of the Mn$^{2+}$ ions. We study the following Hamiltonian:

$$H_{\text{mag}} = -\frac{1}{2} \sum_{R,R'} \sum_{\tau,\tau'=\tau_1,\tau_2} J(R + \tau, R' + \tau') S(R + \tau) \cdot S(R' + \tau') - \frac{1}{2} D \sum_{R} \sum_{\tau = \tau_1,\tau_2} S_x^2(R + \tau). \quad (1)$$

Here $J(R + \tau, R' + \tau')$ is the superexchange interaction energy which couples the spins at $R + \tau$ and $R' + \tau'$, and $D$ is a positive single-ion anisotropy energy. To find an expression for the magnetic free energy of the system, we expand the entropy in the spin components up to the fourth order

$$TS = -\frac{1}{2} a T \sum_{R} \sum_{\tau = \tau_1,\tau_2} S^2(R + \tau)$$

$$- b \sum_{R} \sum_{\tau = \tau_1,\tau_2} S^4(R + \tau), \quad (2)$$

where $a$ and $b$ are positive parameters, and $T$ is the temperature. Equation (2) gives the entropy relative to the high temperature paramagnetic phase (denoted by P) and thus the expression is negative. Combining Eqs. (1) and (2) we obtain the magnetic free energy.
TABLE I: Superexchange couplings for the Mn$^{2+}$ ion at $\tau_1 = (0.5, y, 0.25)$ according to different inelastic neutron scattering studies. We denote $z = 1 - y$, $w = 2 - y$ and $u = 1 + y$. The values are presented in units of $k_B R_{\text{eff}}^{29}$.

\[ F_{\text{mag}} = \frac{1}{2} \sum_{R, R'} \sum_{\tau, \tau' = \tau_1, \tau_2} \sum_{\alpha, \beta = 1}^{4} \chi_{\alpha\beta}^{-1}(R + \tau, R' + \tau') S_{\alpha}(R + \tau) S_{\beta}(R' + \tau') + b \sum_{R} \sum_{\tau = \tau_1, \tau_2} S^4(R + \tau), \quad (3) \]

where the $4 \times 4$ inverse susceptibility matrix is block diagonal

\[ \chi_{\alpha\beta}^{-1}(R + \tau, R' + \tau') = [(aT - D_{\alpha}) \delta_{R, R'} - J(R + \tau, R' + \tau')] \delta_{\alpha, \beta}, \quad (4) \]

with $D_1 = D_x = D$ and $D_2 = D_y = 0$. Below, we exploit the Fourier transforms of the spin components,

\[ S_{\alpha}(q, \tau) = \frac{1}{N} \sum_{R} S_{\alpha}(R + \tau) e^{iq \cdot (R + \tau)}, \]

\[ S_{\alpha}(R + \tau) = \sum_{\{q\}} S_{\alpha}(q, \tau) e^{-iq \cdot (R + \tau)}. \quad (5) \]

\[ f_{\text{mag}} = \frac{1}{2} \sum_{\tau, \tau' = \tau_1, \tau_2} \sum_{\alpha, \beta = 1}^{2} \sum_{\{q\}} \chi_{\alpha\beta}^{-1}(q; \tau, \tau') S_{\alpha}^*(q, \tau) S_{\beta}(q, \tau') + b \sum_{G} \sum_{\tau = \tau_1, \tau_2} \sum_{\{q_1, q_2, q_3, q_4\}} e^{-iG \cdot \tau} [S_{x}(q_1, \tau) S_{y}(q_2, \tau) S_{x}(q_3, \tau) S_{y}(q_4, \tau) + S_{y}(q_1, \tau) S_{x}(q_2, \tau) S_{y}(q_3, \tau) S_{x}(q_4, \tau)] \delta(q_1 + q_2 + q_3 + q_4 - G), \quad (6) \]

where $G$ is a reciprocal lattice vector and the Fourier transform of the inverse susceptibility matrix is given by the block diagonal hermitian matrix

\[ \chi_{\alpha\beta}^{-1}(q; \tau, \tau') = [(aT - D_{\alpha}) \delta_{\tau, \tau'} - J(q; \tau, \tau')] \delta_{\alpha, \beta}, \quad (7) \]

with $J(q; \tau, \tau')$ being the Fourier transform of the $2 \times 2$ matrix $J(R + \tau, R' + \tau')$

\[ J(q; \tau, \tau') = \sum_{R} J(\tau, R + \tau') e^{-iq \cdot (R + \tau' - \tau)}. \quad (8) \]

In the last expression the sum is over all lattice vectors $R$. The four eigenvalues of the matrix (7) are

\[ \zeta_{\pm, x}(q, T) = aT - D - \lambda_{\pm}(q), \]

\[ \zeta_{\pm, y}(q, T) = aT - \lambda_{\pm}(q), \quad (9) \]
We denote the wave vector for which one of the eigenvalues vanishes. At high enough temperatures, the eigenvalues (9) are all positive and therefore the stable phase is the paramagnetic order parameters for a magnetic structure with energy (6) is therefore

\[
\lambda_\pm = \pm e^{-\phi(q)}.
\]

Here, \( \lambda_\pm \) are the two eigenvalues of the matrix \( S \) and \( \phi(q) \) is the phase of \( J(q; 1, 2) \). Assuming 11 exchange couplings as in Ref. 28, these two eigenvalues are given by

\[
\lambda_\pm(q) = \pm 2 \sqrt{\lambda_2^2(q) + \Lambda_3^2(q) + 2 \cos(2\pi q_a) \Lambda_2(q) \Lambda_3(q)} + 2 \Lambda_1(q),
\]

with the following definitions:

\[
\Lambda_1(q) = J_3 \cos(2\pi q_a) + J_4 \cos(2\pi q_e) + J_{11} \cos \left[ 2\pi (q_a - q_e) \right],
\]

\[
\Lambda_2(q) = J_1 \cos(\pi q_c) + J_6 \cos \left[ 2\pi (q_a + q_e) \right] + J_7 \cos \left[ 2\pi (q_a + \frac{q_e}{2}) \right],
\]

\[
\Lambda_3(q) = J_2 \cos(\pi q_c) + J_8 \cos \left[ 2\pi (q_a + \frac{q_e}{2}) \right] + J_9 \cos \left[ 2\pi (q_a - \frac{q_e}{2}) \right].
\]

Now let us transform to magnetic normal coordinates

\[
\begin{pmatrix}
S_x(q, 1) \\
S_x(q, 2) \\
S_y(q, 1) \\
S_y(q, 2)
\end{pmatrix} = \sigma_{+,x}(q) S_{+,x}(q) + \sigma_{-,x}(q) S_{-,x}(q) + \sigma_{+,b}(q) S_{+,b}(q) + \sigma_{-,b}(q) S_{-,b}(q).
\]

Here, \( \sigma_{+,x}(q) \), \( \sigma_{-,x}(q) \), \( \sigma_{+,b}(q) \) and \( \sigma_{-,b}(q) \) are the magnetic order parameters for a magnetic structure with wave vector \( q \). The diagonal form of the magnetic free energy \( f_{mag} \) is therefore

\[
f_{mag} = \frac{1}{2} \sum_q \left[ \zeta_{+,x}(q, T) |\sigma_{+,x}(q)|^2 + \zeta_{-,x}(q, T) |\sigma_{-,x}(q)|^2 \right]
\]

\[
+ \zeta_{+,b}(q, T) |\sigma_{+,b}(q)|^2 + \zeta_{-,b}(q, T) |\sigma_{-,b}(q)|^2 \right] + O(\sigma^4).
\]

At high enough temperatures, the eigenvalues \( \lambda_\pm \) are all positive and therefore the stable phase is the paramagnetic one. As we lower the temperature, we reach a critical temperature for which one of the eigenvalues vanishes. We denote the wave vector for which one of the eigenvalues vanishes first as \( q_{IC} \). Since \( \lambda_+(q) > \lambda_-(q) \) and \( D > 0 \), the first eigenvalue which reaches zero is \( \zeta_{+,x} \).

The last condition ensures that \( \zeta_{+,b}(q_{IC}, T) \) vanishes before \( \zeta_{-,b}(q_{IC}, T) \) as the temperature is lowered. Henceforth, we will omit the plus sign in the order parameters subscript.

To describe the electric polarization, we need to add an electric free energy and a magnetoelastic coupling term to the magnetic free energy. Assuming a homogeneous polarization, the expression for the electric free energy to lowest order is

\[
f_{el} = V_{cell} \sum_{\alpha=1}^{3} \frac{p_{\alpha}^2}{2 \chi_{el,\alpha}},
\]

where \( V_{cell} \) is the volume of the unit cell, \( P \) is the ferroelectric order parameter and \( \chi_{el,\alpha} \) is the high-temperature electric susceptibility along the \( \alpha \) direction. By symmetry considerations,11 the allowed magnetoelastic coupling term of the lowest order in the incommensurate phases is

\[
f_{int} = r |\sigma_x(q_{IC})| |\sigma_y(q_{IC})| \sin(\varphi_x - \varphi_b) P_b,
\]

where \( \varphi_x \) and \( \varphi_b \) are the phases of \( \sigma_x(q_{IC}) \) and \( \sigma_y(q_{IC}) \), respectively, and \( r \) is a small real magnetoelastic coupling parameter. Below we examine the results of the model.

### III. PHASE BOUNDARIES AND ORDER PARAMETERS

#### A. MnWO$_4$ without magnetic fields

The wave vector \( q_{IC} \) that characterizes the AF3 and AF2 phases is determined by maximizing the eigenvalue \( \lambda_+(q) \) for a given set of coupling energies \( \{J_i\} \). After carrying out the maximization procedure, we can find the first transition temperature by equating \( \zeta_{+,x} \) to zero for \( q = q_{IC} \):

\[
T_{N3}^{(0)} = \frac{\lambda_+(q_{IC}) + D}{\alpha}.
\]

The index 0 indicates that this is the transition temperature in the absence of external magnetic fields. By transforming to normal magnetic coordinates, the free energy of the incommensurate phases up to the fourth order in the magnetic order parameters is
\[ f = (aT - D - \lambda_+(q_{IC})) |\sigma_x(q_{IC})|^2 + 3b |\sigma_x(q_{IC})|^4 + (aT - \lambda_+(q_{IC})) |\sigma_y(q_{IC})|^2 + 3b |\sigma_y(q_{IC})|^4 \]
\[ + 2b |\sigma_x(q_{IC})|^2 |\sigma_y(q_{IC})|^2 [2 + \cos(2\varphi_x - 2\varphi_y)] + V_{cell} \sum_{\alpha=1}^{3} \left( \frac{P_{\alpha} q_{\alpha}^2}{2\lambda_{E,\alpha}} + r |\sigma_x(q_{IC})||\sigma_y(q_{IC})| \sin(\varphi_x - \varphi_y) \right). \]

(19)

This expression is obtained by keeping the Fourier components \( q = \pm q_{IC} \) in the total free energy \( f = f_{mag} + f_{el} + f_{int} \). Minimizing with respect to the polarization components, we find the induced polarization

\[ P_x = P_z = 0, \]
\[ P_y = -\frac{\chi_{E,h}^0}{V_{cell}} |\sigma_x(q_{IC})||\sigma_y(q_{IC})| \sin(\varphi_x - \varphi_y). \]  

(20)

Inserting Eqs. (20) into Eq. (19), we get

\[ f = (aT - D - \lambda_+(q_{IC})) |\sigma_x(q_{IC})|^2 + 3b |\sigma_x(q_{IC})|^4 + (aT - \lambda_+(q_{IC})) |\sigma_y(q_{IC})|^2 + 3b |\sigma_y(q_{IC})|^4 \]
\[ + 2b |\sigma_x(q_{IC})|^2 |\sigma_y(q_{IC})|^2 [2 + \cos(2\varphi_x - 2\varphi_y) - 2\gamma \sin^2(\varphi_x - \varphi_y)], \]

(21)

where \( \gamma \) is a dimensionless parameter given by

\[ \gamma = \frac{\chi_{E,h}^0 b^2}{8V_{cell}^2}. \]

(22)

In order to minimize the free energy (21), the phase difference \( \varphi_x - \varphi_y \) should be \( \pm \pi/2 \). In addition, we show below that \( \gamma \) is of order \( 10^{-5} \). Hence the last factor in the square brackets of Eq. (21) will be neglected in the description of the magnetic phase transitions. The minimization of the free energy (21) with respect to \( |\sigma_x(q_{IC})| \) and \( |\sigma_y(q_{IC})| \) yields

\[ |\sigma_x^0(q_{IC})| = \sqrt{\frac{a(T_{N3}^0 - T)}{6b}} , \quad |\sigma_y^0(q_{IC})| = 0 , \quad T_{N2}^0 < T < T_{N3}^0, \]
\[ |\sigma_y^0(q_{IC})| = \sqrt{\frac{a(4T_{N3}^0 - T_{N2}^0 - 3T)}{24b}} , \quad |\sigma_x^0(q_{IC})| = \sqrt{\frac{a(T_{N2}^0 - T)}{8b}} , \quad T < T_{N2}^0. \]

(23)

and the corresponding free energies are

\[ f_{AF3}^{(0)} = -\frac{a^2(T_{N3}^0 - T)^2}{12b} , \quad T_{N2}^0 < T < T_{N3}^0, \]
\[ f_{AF2}^{(0)} = -\frac{a^2[4(T_{N3}^0 - T)^2 + \frac{8}{3}(T - T_{N3}^0)(T_{N3}^0 - T_{N2}^0) + \frac{4}{3}(T_{N3}^0 - T_{N2}^0)^2]}{32b} , \quad T < T_{N2}^0. \]

(24)

with the transition temperature \( T_{N2}^0 \) given by

\[ T_{N2}^0 = T_{N3}^0 - \frac{3D}{2a}. \]

(25)

\[ \phi(q_{IC}) = 2\pi y \] for the two sets of exchange couplings. Using this relation and \( \varphi_x - \varphi_y = \pm \pi/2 \) in Eqs. (19) and (20), the spins of the two Mn\(^{2+}\) ions in the AF3 and AF2 phases are

By calculating the phase \( \phi(q_{IC}) \) of \( J(q_{IC}; \tau_1, \tau_2) \) we can find the magnetic structure of the phases AF3 and AF2. Using the experimental incommensurate wave vector \( q_{IC} = (-0.214, 0.5, 0.457) \), this phase is found to be...
The two possible signs correspond to the phase difference \( \varphi_x - \varphi_b = \pm \pi/2 \) and represent spirals with opposite chirality,

\[
S(R + \tau_1) \times S(R + \tau_2) = \\
\pm 2 \left| \sigma^0_x(q_{IC}) \right| \left| \sigma^0_b(q_{IC}) \right| \sin (\Delta \phi) \hat{z}.
\]

(28)

Here \( \hat{z} \) is a unit vector perpendicular to the spiral plane. Various studies reveal that the spin chirality is strongly correlated with the electric polarization and can be controlled by poling the polarization with an external electric field. This observation is in agreement with the form \( \chi_E \) of the electric polarization, in which \( \varphi_x - \varphi_b \) changes sign together with \( P \).

Taking into account the magnetoelectric coupling in the description of the magnetic phase transitions will introduce small corrections to the transition temperature \( T_{N2}^{(0)} \) and to the order parameters in the AF2 phase. As mentioned above, these corrections are governed by the dimensionless parameter \( \gamma \) [see Eq. (22)]. Using these corrections to the first order in \( \gamma \), we find that the electric susceptibility takes the form

\[
\chi_{E,b}(T) = \\
\begin{cases} 
\chi^0_{E,b} & T > T_{N3}^{(0)} \\
\chi^0_{E,b} \left( 1 + \frac{\chi^0_{E,b} (T_{N2}^{(0)} - T)^2}{\chi^0_{E,b} - T - T_{N2}^{(0)}} \right) & T_{N2}^{(0)} < T < T_{N3}^{(0)} \\
\chi^0_{E,b} \left( 1 + g(T) \frac{\chi^0_{E,b} (T_{N2}^{(0)} - T)^2}{\chi^0_{E,b} - T - T_{N2}^{(0)}} \right) & T_{N1}^{(0)} < T < T_{N2}^{(0)} \\
\chi^0_{E,b} & T < T_{N1}^{(0)}.
\end{cases}
\]

(29)

where \( T_{N2}^{(0)} \) is the shifted transition temperature:

\[
T_{N2}^{(0)} \approx T_{N2}^{(0)} + \gamma \left( T_{N3}^{(0)} - T_{N2}^{(0)} \right).
\]

The function \( g(T) \) is

\[
g(T) = \frac{f_2(T)}{f_1(T) (T_{N3}^{(0)} - T_{N2}^{(0)})} - 1,
\]

(31)

where

\[
f_1(T) = -8T + \frac{32}{3} T_{N3}^{(0)} - \frac{8}{3} T_{N2}^{(0)}, \\
f_2(T) = 14T^2 + \nu_1 T + \nu_2,
\]

(32)

with \( \nu_1 = -\frac{1}{\eta} \left( 95 T_{N3}^{(0)} + 73 T_{N2}^{(0)} \right) \) and \( \nu_2 = 16 \left( T_{N3}^{(0)} \right)^2 - \frac{27}{8} T_{N2}^{(0)} T_{N3}^{(0)} + \frac{81}{8} \left( T_{N2}^{(0)} \right)^2 \).

The first order phase transition AF2→AF1 can be treated in the following way. Since the AF1 phase is characterized by the commensurate wave vectors \( q_{C1,2} = (\pm \frac{1}{4}, \frac{1}{2}, \frac{1}{4}) \), we calculate the free energy \( f_{AF1}^{(0)} \) for this phase and then look for a temperature below which \( f_{AF1}^{(0)} < f_{AF2}^{(0)} \). Since \( q_{C2} = -q_{C1} + (0,1,1) \) we need to consider only the Fourier components \( q = \pm q_{C} = \pm (\frac{1}{4}, \frac{1}{2}, \frac{1}{4}) \) in Eq. (30). After some algebra we find the free energy

\[
f = (aT - D + \lambda_+ (q_C)) |\sigma_+ (q_C)|^4 \\
+ b |\sigma_- (q_C)|^4 \left[ 3 + \cos(4\varphi - 4\pi y) \right].
\]

(33)

Here \( \varphi \) is the phase of \( \sigma_+ (q_C) \), determined to be \( \pi (y + \frac{1}{4}) \) in order to minimize the free energy. Therefore the equilibrium order parameter and the corresponding free energy are

\[
|\sigma_+ (q_C)| = \sqrt{\frac{\lambda_+ (q_C) + D - aT}{4b}},
\]

(34)

\[
f_{AF1}^{(0)} = \frac{(\lambda_+ (q_C) + D - aT)^2}{8b}.
\]

(35)

For the commensurate wave vector \( q_C = (\frac{1}{4}, \frac{1}{2}, \frac{1}{4}) \) we find the phase \( \phi (q_C) = 2\pi y - \pi \) of \( J(q_C; \tau_1, \tau_2) \) for both sets of exchange couplings. Using this relation and \( \varphi = \pi (y + \frac{1}{4}) \) in Eqs. (11) and (12), the spins of the two Mn\(^{2+}\) ions in the AF1 phase are

\[
S(R + \tau_1) = \sqrt{2} |\sigma^0_+ (q_C)| \cos (q_C \cdot R + \frac{\pi}{4}) \hat{x},
\]

\[
S(R + \tau_2) = -\sqrt{2} |\sigma^0_- (q_C)| \cos (q_C \cdot R - \frac{\pi}{4}) \hat{x}.
\]

(36)

Equations (36) describe a magnetic structure of the type \( \uparrow \uparrow \downarrow \downarrow \) along both the \( a \) and \( c \) axes, in agreement with the structure observed in experiments.\(^{16}\) We note again that this is the observed structure out of the two possible structures suggested by group theory.

The solution of the inequality \( f_{AF1}^{(0)} < f_{AF2}^{(0)} \) of the form \( T < T_{N1}^{(0)} \) provided that

\[
\epsilon > \max \left\{ 2 (1 - \eta), \frac{2}{3} \left( 1 - \sqrt{3}\eta^2 - 2 \right) \right\},
\]

(37)

where \( \epsilon = \frac{D}{\lambda_+ (q_{IC})} \) and \( \eta = \frac{\lambda_+ (q_{IC})}{\lambda_+ (q_{IC})} \). In this case, the transition temperature \( T_{N1}^{(0)} \) is given by

\[
T_{N1}^{(0)} = \frac{4 (\eta^2 - 1) + 4\epsilon - 3\epsilon^2}{4(2(\eta - 1) + \epsilon)} + \frac{\lambda_+ (q_{IC})}{a}.
\]

(38)
We study below the effects of magnetic field on the transition temperatures.

B. The effect of an external magnetic field

The formalism presented above can be generalized to take into account the effect of a uniform external magnetic field \( \mathbf{h} \). This can be accomplished by adding to the free energy the Zeeman term \( F^Z = g\mu_B \sum R \sum_{\tau_1, \tau_2} S(R + \tau) \cdot \mathbf{h} \), or, equivalently,

\[
f^Z = \frac{F^Z}{N} = g\mu_B \sum_{\tau_1, \tau_2} S(0, \tau) \cdot \mathbf{h}.
\]

Minimizing the free energy with respect to \( S(0, \tau) \) at the paramagnetic phase, we find the response to the external magnetic field

\[
S_\alpha(0, \tau) = -\frac{\chi_\alpha(T)}{g\mu_B} h_\alpha \quad (\alpha = x, b),
\]

with the magnetic susceptibility following a Curie-Weiss law

\[
\chi_\alpha(T) = \frac{(g\mu_B)^2}{aT - D_\alpha - 2 \sum_i J_i}.
\]

Comparing Eq. (41) with the general Curie-Weiss law

\[
\chi_\alpha(T) = \frac{(g\mu_B)^2 J(J+1)}{3k_B(T - \theta_\alpha)},
\]

we identify the parameter \( a \) introduced in the expansion of the entropy [see Eq. (2)] as

\[
a = \frac{3k_B}{J(J+1)}.
\]

For Mn\(^{2+} \) ions with \( J = S = 5/2 \) this parameter is \( a_{\text{Mn}} = 0.343k_B \). The Curie-Weiss temperature is related to the exchange couplings and the anisotropy energy by:

\[
\theta_\alpha = \frac{J(J+1)}{3k_B} \left( D_\alpha + 2 \sum_{i=1}^{11} J_i \right).
\]

In the incommensurate phases AF3 and AF2, Eq. (40) is replaced by

\[
S_\alpha(0, \tau) = -\frac{\chi_\alpha(T) h_\alpha}{g\mu_B} \left[ 1 + \frac{d_{1\alpha}[\alpha^2(\mathbf{q}_{IC})]^2 + d_{2\alpha}[\alpha^2(\mathbf{q}_{IC})]^2]}{a(T - \theta_\alpha)} \right],
\]

where \( d_{1\alpha} = d_{2\alpha} = 12b \) and \( d_{2\alpha} = 4b \). The corresponding form in the AF1 phase is

\[
S_\alpha(0, \tau) = -\frac{\chi_\alpha(T) h_\alpha}{g\mu_B} \left[ 1 + \frac{e_\alpha[\alpha^2(\mathbf{q}_{IC})]^2]}{a(T - \theta_\alpha)} \right],
\]

with \( e_x = 12b \) and \( e_b = 4b \). The ferromagnetic Fourier component at \( \mathbf{q} = 0 \) couples to the incommensurate wave vectors through the fourth order term in Eq. (40). This coupling modifies the coefficients of the free energy expansion and, consequently, the transition temperatures. In the presence of an external magnetic field, the first two transition temperatures are (to second order in the magnetic field)

\[
\begin{align*}
T_{N3}(h_x) &= T_{N3}^{(0)} \left[ 1 - \frac{12b\lambda_x^2(T_{N3}^{(0)})}{aT_{N3}^{(0)}(g\mu_B)^2} h_x^2 \right] \quad h = h_x \mathbf{x}, \\
T_{N3}(h_b) &= T_{N3}^{(0)} \left[ 1 - \frac{4b\lambda_x^2(T_{N3}^{(0)})}{aT_{N3}^{(0)}(g\mu_B)^2} h_b^2 \right] \quad h = h_b \mathbf{b},
\end{align*}
\]

\[
\begin{align*}
T_{N2}(h_x) &= T_{N2}^{(0)} \left[ 1 - \frac{16\lambda_x^2(T_{N2}^{(0)})}{aT_{N2}^{(0)}(g\mu_B)^2} h_x^2 \right] \quad h = h_x \mathbf{x}, \\
T_{N2}(h_b) &= T_{N2}^{(0)} \left[ 1 - \frac{8\lambda_x^2(T_{N2}^{(0)})}{aT_{N2}^{(0)}(g\mu_B)^2} h_b^2 \right] \quad h = h_b \mathbf{b},
\end{align*}
\]

with \( \kappa = \left( \frac{1}{T_{N2}^{(0)}} + \frac{8}{3(T_{N2}^{(0)} - \theta_x)} \right) \). For an external magnetic field along the easy axis direction, the inequality which determines the stability range of the AF1 phase is

\[
T < T_{N1}^{(0)} + \frac{8\lambda_x^2(T_{N1}^{(0)})}{2(T - \theta_x)} + \frac{\lambda_x^2(T_{N1}^{(0)}) + D}{a(T - \theta_x)} T_{N1}^{(0)} + \frac{1}{T - \theta_x} \left[ \left( T - \frac{\lambda_x^2(T_{N1}^{(0)}) + D}{a(T - \theta_x)} \right)^2 - 8 \left( T_{N1}^{(0)} - T \right)^2 \right] \left( \frac{\chi_x(T)}{g\mu_B} \right)^2 h_x^2,
\]
while for a magnetic field along the b direction it is

\[
T < T_{N1}^{(0)} - \frac{8b}{2(\lambda_+ (q_C) - \lambda_+ (q_{IC})) + D} \left\{ T + \frac{\lambda_+ (q_C) + D}{a} - 2 \left( \frac{2T_{N2}^{(0)} + 2T_{N2}^{(0)}}{a} \right) \right\} \right\} \left( \frac{\lambda_+ (q_{IC})}{g\mu_B} \right)^2 h_b^2. \tag{50}
\]

Equations (47) - [50] describe the \( T - H \) phase diagrams up to second order in \( h \).

C. The effect of doping

We can gain insight on the effect of small concentrations of magnetic \( \text{Fe}^{2+} \) or non-magnetic \( \text{Zn}^{2+} \) and \( \text{Mg}^{2+} \) ions at the Mn sites in the following way. Assuming that the orbital angular momentum is quenched, we set \( J = S = 2 \) in Eq. (13) and identify the parameter \( a \) [see Eq. (24)] for the \( \text{Fe}^{2+} \) ion as \( a_{\text{Fe}} = 0.5k_B \). Using this value, we get

\[
a(x) = a_{\text{Mn},x} + a_{\text{Fe}}(1 - x), \tag{51}
\]

where \( x \) is the Fe concentration. Since the exchange couplings of Fe-Fe and Fe-Mn pairs as well as the anisotropy energy for the Fe ion are not known, we assume a linear dependence of the quantities \( \lambda_+ (q_{IC}) \), \( D \) and \( \eta = \frac{\lambda_+ (q_C)}{\lambda_+ (q_{IC})} \) for small values of \( x \):

\[
\lambda_+ (q_{IC}(x), x) = \lambda_+ (q_{IC}(0)) + c_1 x, \quad D(x) = D(0) + c_2 x, \quad \eta(x) = \eta(0) + c_3 x. \tag{52}
\]

We use the relations (52) in order to modify the expressions (18), (25) and (38) for the transition temperatures.

For the case of the non-magnetic \( \text{Zn}^{2+} \) ion we set \( a_{\text{Zn}} = D_{\text{Zn}} = 0 \) as well as \( J_{\text{Zn,Mn}} = J_{\text{Zn,Zn}} = 0 \), and find the \( x \)-dependence of the different parameters

\[
\lambda_+ (q, x) = \lambda_+ (q)(1 - x)^2, \quad a(x) = a(0)(1 - x), \quad D(x) = D(0)(1 - x), \quad \eta(x) = \eta(0). \tag{53}
\]

Using these relations the first two transition temperatures are given by

\[
T_{N3}(x) = T_{N3}^{(0)} - \frac{\lambda_+ (q_{IC})}{a} x, \quad T_{N2}(x) = T_{N2}^{(0)} - \frac{\lambda_+ (q_{IC})}{a} x. \tag{54}
\]

These results explain the linear decrease of \( T_{N3} \) and of \( T_{N2} \) as a function of \( x \) observed in experiments. The treatment of the AF2→AF1 transition is much more subtle and will be discussed below. We note that all the results above do not depend on the type of the non-magnetic ion. This is in agreement with the observed similarities of the transition temperatures in \( \text{Zn}^{2+} \) and \( \text{Mg}^{2+} \) doping.

IV. COMPARISON WITH EXPERIMENTS

In this section we compare the results of the preceding section with different experimental observations and examine the consistency of the phase diagrams with the experimental sets of exchange couplings of Ehrenberg et al. and Ye et al.. The results of the preceding section can be used to fit the parameters of the model within the Landau theory. We use Eqs. (13) and (20) with \( a_{\text{Mn}} = 0.343k_B \) [see Eq. (18)] and the experimental transition temperatures \( T_{N3}^{(0)} \) and \( T_{N2}^{(0)} \) in order to extract the values of the parameters \( \lambda_+ (q_{IC}) \) and \( D \) for \( \text{MnWO}_4 \). Using the experimental values \( T_{N3}^{(0)} \approx 13.5K \) and \( T_{N2}^{(0)} \approx 12.3 - 12.7K \), these parameters are found to be \( \lambda_+ (q_{IC}) \approx 4.36 - 4.45K \) and \( D = 0.27 - 0.18k_BK \). The ratio \( \eta = \frac{\lambda_+ (q_{IC})}{\lambda_+ (q_{IC})} \) is then chosen to be \( \eta \approx 0.97 - 0.98 \) in order to fit Eq. (58) to the experimental transition temperature \( T_{N1}^{(0)} \approx 7 - 8K \). These values are consistent with the condition (57).

Next we use Eqs. (22) and (44) - (50), with the experimental Curie-Weiss temperature \( \theta_x \approx \theta_b \approx -75K \) and calculate the \( T - H \) phase diagrams by fitting the parameter \( b \). In order to get the best fit to the experimental phase diagram of Arkenbout et al., the parameter \( b \) was chosen to be 0.095\( k_BK \). Figure 1 shows the results. The calculated and the experimental phase diagrams are in good agreement. Discrepancies at low temperatures or at high fields are expected due to the finite expansion of the free energy, which is terminated at fourth order.

The development of the magnetic order parameters with decreasing temperature has been studied by polarized-neutron diffractions. Generally, the magnetic moment at site \( \tau \) belonging to the unit cell at the lattice point \( \mathbf{R} \) can be written as

\[
m(\mathbf{R} + \tau) = m_x \cos (q \cdot \mathbf{R} + \phi_x) \hat{x} + m_b \sin (q \cdot \mathbf{R} + \phi_z) \hat{b}. \tag{55}
\]
lower temperatures this assumption is inconsistent with the evolution of the observed integrated intensities reported in Ref. 30 which show that both $|\sigma_0^0(q_{IC})|$ and $|\sigma_0^0(q_{JC})|$ continue to grow below $T_{N2}$, with the ellipticity $p \equiv m_b/m_a = |\sigma_0^0(q_{IC})|/|\sigma_0^0(q_{JC})|$ approaching 1 (so that the spiral is almost circular) as the temperature decreases. Therefore, we preferred to use the explicit dependence of $|\sigma_0^0(q_{IC})|$ on the temperature. Using Eqs. (57), the ellipticity below $T_{N2}$ can be written as

$$p = \frac{1}{\sqrt{1 + \omega}}$$  

(58)

where $\omega = 4(T_{N3}^0-T_{N2}^0)/(T_{N2}^0-T)$. Since the difference $T_{N3}^0-T_{N2}^0 \approx 0.8K$ is very small in the case of MnWO$_4$, the ellipticity rapidly approaches 1 with decreasing temperature in the spiral phase AF2. The small difference $T_{N3}^0-T_{N2}^0$ for MnWO$_4$ is a consequence of the small single-ion anisotropy of Mn$^{2+}$ ions. This should be compared with the case of TbMnO$_3$, for which $T_{N3} \approx 42K$ and $T_{N2} \approx 27K$. In this multiferroic, the ellipticity grows much more slowly with decreasing temperature due to the large difference $T_{N3}^0-T_{N2}^0 \approx 15K$, which is in turn a result of the larger single-ion anisotropy of Mn$^{3+}$ ions. In Fig. 2 we sketch the quantities $(|\sigma_0^0(q_{IC})| \pm |\sigma_0^0(q_{JC})|)^2 + |\sigma_0^0(q_{C})|^2$ from Eqs. (57) and (58) together with the experimental data points of Ref. 30.

The cross-sections for polarized-neutron scattering, where the neutrons are polarized parallel and antiparallel to the scattering vector, are given by

$$I = I_0 (m_x \pm m_b)^2,$$  

(56)

with $I_0$ being a constant. Using Eqs. (26) and (36), we see that these cross-sections are proportional to $(|\sigma_x^0(q_{IC})| \pm |\sigma_y^0(q_{IC})|)^2 + |\sigma_z^0(q_{C})|^2$. Then, from the second of Eqs. (30), the magnetic order parameters in the AF2 phase can be written as

$$|\sigma_x^0(q_{IC})| = \sqrt{\frac{a}{8b} \left( \frac{T_{N3}^{(0)}-T_{N2}^{(0)}}{T_{N2}^{(0)}-T} \right)},$$

$$|\sigma_y^0(q_{IC})| = \sqrt{\frac{a}{8b} \left( \frac{T_{N2}^{(0)}-T}{T_{N3}^{(0)}-T} \right)}.$$  

(57)

Tolédano et al. 35 assumed that $|\sigma_x^0(q_{IC})|$ is fixed below $T_{N2}^{(0)}$. According to the first of Eqs. (57), such an assumption is valid only for $T_{N2}^{(0)}-T \ll \frac{4}{3} (T_{N3}^{(0)}-T_{N2}^{(0)})$. At

FIG. 1: (Color online) Magnetoelectric phase diagrams of MnWO$_4$ with magnetic fields parallel to the (a) easy and (b) hard axes. The solid lines are the calculated transition temperatures and the dots describe the experimental points of Arkenbout et al. 36 The calculated phase diagrams were obtained by setting $b = 0.095k_B K$.

FIG. 2: (Color online) The temperature dependence of $(|\sigma_x^0(q_{IC})| \pm |\sigma_y^0(q_{IC})|)^2 + |\sigma_z^0(q_{C})|^2$. The red (thick) line corresponds to the + sign and the blue (thin) line to the minus sign. The integrated intensities of the polarized-neutron diffraction (scaled by 0.002) from Ref. 31 are the red dots and the blue empty squares.

The development of the calculated order parameters is in a qualitative agreement with the temperature dependence of the integrated intensities. However, for $T_{N2}^{(0)}-T > \frac{4}{3} (T_{N3}^{(0)}-T_{N2}^{(0)})$ in the AF2 phase, the quantity $(|\sigma_x^0(q_{IC})| + |\sigma_y^0(q_{IC})|)^2$ is linear in $T$, in contradiction with the temperature dependence of the integrated intensity, as can be seen in Fig. 2. A possible explanation
for this apparent discrepancy is related to fluctuations near the transitions, that are not taken into account by the mean-field Landau theory.\textsuperscript{37} As pointed out in Ref. \textsuperscript{38} the transition P\textarrowright AF3 belongs to the universality class of the XY model, while the transition AF3\textarrowright AF2 belongs to the Ising universality class. Hence we present in Fig. 3 the same quantities as in Fig. 2 but replacing the square roots of Eqs. (177) and (178) by the critical exponent $\beta = 1/3$, roughly appropriate for these two models. As seen from the figure, these revised expressions are in good agreement with the observed integrated intensities. This behavior illustrates the possible importance of fluctuations in MnWO$_4$. Further consequences of fluctuations near the transitions will be discussed below in the context of the Ginzburg criterion.

The anisotropy energy $\varepsilon$ [see Eq. (22)] is then $\varepsilon = -21 \mu C/m^2$. The dimensionless parameter $\gamma$ [see Eq. (22)] is then $\gamma = 5.9 \cdot 10^{-5}$. This value supports the assumption that the magnetic transitions are almost unaffected by the magnetoelectric coupling.

The dielectric constant $\varepsilon_b = 1 + \varepsilon_0 \frac{\chi_{E,b}}{c_0}$ is shown in Fig. 4(b). This result is in good agreement with the experimental measurements of Ref. 18. The narrow width of the divergence region is a consequence of the small difference between $T_{N_2}(0)$ and $T_{N_2}$. Once again, the discrepancy between the linear behavior of the calculated polarization and the observed one may be reconciled by assuming a critical exponent $\beta \approx \frac{1}{3}$ for the magnetic order parameters. The behavior of the calculated polarization in this case is given in Fig. 5.

To examine the effect of Fe doping, we use the relations and $\gamma$ in the expressions for the transition temperatures and fit the slope to the experimental value according to the $x$–$T$ phase diagram of Chaudhury et al.\textsuperscript{20} This procedure yields the values $c_1 \approx -3.26 k_B K$, $c_2 \approx 13.03 k_B K$ and $c_3 \approx -1.3$. The anisotropy energy increases with increasing Fe concentration, as expected, since as opposed to the Mn$^{2+}$ ion, the Fe$^{3+}$ ion possesses a non-vanishing angular momentum.\textsuperscript{39}

Calculating the different parameters for a small Fe concentration \(x\) and repeating the calculations of the $T$–$H$ phase diagram, we can check the consistency of the above results. The resulting phase diagram for $x = 0.035$ is shown in Fig. 6. Except for high fields or low temperatures, the result is in fine agreement with the measurement of Ye et al.\textsuperscript{22} The reentrant ferroelectric phase observed at low temperatures\textsuperscript{20,40} may be explained by higher order terms in the free energy expansion.

The effect of non-magnetic ions on the transition temperatures and repeating the calculations of the $T$–$H$ phase diagram, we can check the consistency of the above results. The resulting phase diagram for $x = 0.035$ is shown in Fig. 6. Except for high fields or low temperatures, the result is in fine agreement with the measurement of Ye et al.\textsuperscript{22} The reentrant ferroelectric phase observed at low temperatures\textsuperscript{20,40} may be explained by higher order terms in the free energy expansion.
the transition temperature changes dramatically while $T_{N3}$ and $T_{N2}$ [see Eqs. 11 and 20]. A significant spin-lattice coupling in the multiferroic MnWO$_4$ has been demonstrated by the appearance of an incommensurate lattice modulation in the AF3 and AF2 phases, with a lattice propagation vector equal to twice the magnetic propagation vector. In addition, thermal expansion measurements reveal considerable discontinuities in the lattice parameters at the AF2→AF1 first order phase transition. Another indication for a dependence of the Mn-Mn exchange couplings on the non-magnetic dopant concentration is provided by the small change of the incommensurate propagation vector from $q_{IC} = (-0.214, 0.5, 0.457)$ in MnWO$_4$ to $q_{IC} = (-0.209, 0.5, 0.453)$ in Mn$_{0.85}$Zn$_{0.15}$WO$_4$.

The next step is to compare the above fitted parameters with the parameters calculated directly from the experimental sets of exchange couplings of Ehrenberg et al. and Ye et al. The calculated exchange couplings of Ref. 27 yield much higher transition temperatures than the observed ones and thus will not be discussed here. Indeed, the problem of overestimation of exchange interactions by DFT calculations has been indicated by the authors.

The first step is to maximize $\lambda_+ (q)$ [see Eq. (11)] in order to find the incommensurate wave vector $q_{IC}$ and the corresponding eigenvalue $\lambda_+ (q_{IC})$. The maximization process yields $q_{IC} = (-0.28, 0.5, 0.44)$ and $\lambda_+ (q_{IC}) = 3.82k_BK$ for the $J_1 - J_2$ values of Ehrenberg et al., while for the $J_1 - J_2$ values of Ye et al., we find $q_{IC} = (-0.3, 0.5, 0.49)$ and $\lambda_+ (q_{IC}) = 3.85k_BK$. These results are in qualitative agreement with the incommensurate wave vector $q_{IC} = (-0.214, 0.5, 0.457)$ observed in experiments. However, the differences are not negligible, suggesting possible errors in the experimental sets of exchange couplings. In addition, the transition temperatures $T_{N3}^{(0)}$ and $T_{N2}^{(0)}$ calculated from Eqs. 15 and 20 with $a_{Mn} = 0.343k_B$ [see Eq. 48] are found to be $T_{N3}^{(0)} = 12.79K$ and $T_{N2}^{(0)} = 10.3K$ for the set of Ehrenberg et al.
and \( T_{N3}^{(0)} = 13.67K, T_{N3} = 10K \) for the set of Ye et al. These values slightly differ from the observed transition temperatures, especially the second one. The ratio \( \eta = \frac{\lambda_+(q_{IC})}{\lambda_+(q_{IC})} \) is found to be \( \eta = 0.974 \) and \( \eta = 0.97 \) for the sets of Ehrenberg et al. and Ye et al., respectively. Table \( \text{I} \) summarizes the values of \( \lambda_+(q_{IC}) \), \( D \) and \( \eta \) calculated from the experimental sets of magnetic parameters and those fitted to the experimental transition temperatures.

Table II: Comparison between the model parameters calculated from the experimental sets of Ref. 26 and Ref. 28 and those fitted to the experimental transition temperatures.

| Parameter              | Ref. 26 | Ref. 28 | This work |
|------------------------|---------|---------|-----------|
| \( \lambda_+(q_{IC})(k_BK) \) | 3.82    | 3.85    | 4.36-4.45 |
| \( D(k_BK) \)          | 0.568   | 0.83    | 0.27-0.18 |
| \( \eta \)             | 0.974   | 0.97    | 0.97-0.98 |

The calculation of the Curie-Weiss temperature reveals a much more serious discrepancy. According to Eq. (44), the Curie-Weiss temperature is \( \theta_x = -7.6K, \theta_y = -9.25K \) for the set of Ehrenberg et al. and \( \theta_x = -23.2K, \theta_y = -25.65K \) for the set of Ye et al. These values do not fit the experimental Curie-Weiss temperature \( \theta \approx -75K \). \( \text{I},\text{II} \) We suspect that the origin of most of the discrepancies are errors in the set of magnetic couplings. The results suggested by our model may be used as additional constraints in the determination of those couplings. As mentioned before, an additional possible cause for the above discrepancies is related to fluctuations near the transitions, as will be discussed in the next section.

V. THE GINZBURG CRITERION

The results of the preceding sections have been obtained within the mean-field approximation. Here we estimate the Ginzburg range, in which fluctuations become important, near the first transition P→AF3, by two methods. First we compare the mean square fluctuation of the order parameter \( \sigma_x(q_{IC}) \) with the mean-field value, and then we compare the discontinuity in the heat capacity derived from the Landau theory with the divergent heat capacity, originating from the fluctuations at quadratic order \( \text{III} \).

Let us denote by \( \delta \sigma_x(q) = \sigma_x(q) - \langle \sigma_x(q) \rangle \) the fluctuation of the order parameter in the AF3 phase. The correlation function of these deviations is

\[
\langle \delta \sigma_x(q) \delta \sigma_x(q') \rangle = \frac{k_B T \delta q \cdot q}{4N(D + \lambda_+(q) - aT)}.
\]

with \( M_{ij} = \frac{1}{2} \frac{\partial^2 \lambda_+(q)}{\partial q_i \partial q_j} \mid_{q=q_{IC}} \). Denoting by \( \mu_1, \mu_2 \) and \( \mu_3 \) the three eigenvalues of the positive matrix \( -M_{ij} \), the three correlation lengths are

\[
\xi_i = \sqrt{\frac{\mu_i}{a \left( T_{N3}^{(0)} - T \right)}}.
\]

Substituting \( q = q_{IC} \) and \( N = \xi_1 \xi_2 \xi_3 \) in Eq. (59), the condition \( \langle |\delta \sigma_x(q_{IC})|^2 \rangle \ll |\sigma_x^2(q_{IC})| \) for the validity of the mean-field theory reads

\[
\frac{k_B T_{N3}^{(0)}}{4a \left( T_{N3}^{(0)} - T \right)} \xi_1 \xi_2 \xi_3 < \frac{a \left( T_{N3}^{(0)} - T \right)}{6b}.
\]

Inserting Eq. (61) into Eq. (62) at the Ginzburg temperature \( T_G \), we find

\[
\left| T_G - T_{N3}^{(0)} \right| \approx \frac{9k_B^2 b^2 V_{cell}^2 \left( T_{N3}^{(0)} \right)^2}{4a \mu_1 \mu_2 \mu_3}. \quad (63)
\]

Equation (63) estimates the temperature range below \( T_{N3}^{(0)} \), in which fluctuations are not negligible.

Let us now estimate the Ginzburg range according to the second method. On the one hand, according to Landau theory, the heat capacity \( c = -T \frac{\partial^2 f}{\partial T^2} \) grows discontinuously at the transition P→AF3:

\[
\Delta c_L \equiv c_L \left( T_{N3}^{(0)-} \right) - c_L \left( T_{N3}^{(0)+} \right) = a^2 \sigma_x^2(0) \frac{6b}{4a \mu_1 \mu_2 \mu_3}. \quad (64)
\]

On the other hand, assuming fluctuations at quadratic order, the singular part of the heat capacity is given by

\[
c_G = \frac{V_{cell} k_B a^2 T^2 \frac{a^2}{(2 \pi)^3} \int_{BZ} d^3q \left( aT - D - \lambda_+(q) \right)^2}{2}, \quad (65)
\]

where the integral is over the first Brillouin zone. In the neighborhood of \( T_{N3}^{(0)} \), the main contribution to the integral comes from the neighborhood of the incommensurate wave vector \( q_{IC} \) in reciprocal space. Thus we can use the expansion \( \text{III} \). Replacing the first Brillouin zone by a sphere, and taking \( T \approx T_{N3}^{(0)} \), we can estimate the integral in Eq. (65):

\[
c_G \approx \frac{k_B a^{1.5} T^2 \left( T - T_{N3}^{(0)} \right)^{-0.5}}{16 \pi \sqrt{\mu_1 \mu_2 \mu_3}}. \quad (66)
\]
Comparing Eqs. (64) and (66) at the Ginzburg temperature $T_G$, we find

$$ |T_G - T_{N3}^{(0)}| \approx \left( \frac{6}{16\pi} \right)^2 \frac{k_B^2 b^2 V_{cell}^2}{a\mu_1\mu_2\mu_3} \left( T_{N3}^{(0)} \right)^2. \quad (67) $$

Calculating the eigenvalues $\mu_1$, $\mu_2$ and $\mu_3$ from the experimental sets of exchange couplings, the Ginzburg temperature is estimated to be $|T_G - T_{N3}^{(0)}| \approx 9.41K$ and $|T_G - T_{N3}^{(0)}| \approx 6.24K$ for the sets of Ehrenberg et al. and Ye et al., respectively, by the first method [see Eq. (63)] while it is $|T_G - T_{N3}^{(0)}| \approx 0.06K$ and $|T_G - T_{N3}^{(0)}| \approx 0.04K$ by the second method [see Eq. (67)]. These values suggest that fluctuations of the order parameters can also contribute to the discrepancies between the experimental data and the mean-field Landau theory results.

VI. SUMMARY AND CONCLUSIONS

We have studied the phase diagram of Mn$_{1-x}$M$_x$WO$_4$ (M=Fe, Zn, Mg) by a semi-phenomenological Landau theory. The energy has been modelled by a Heisenberg Hamiltonian with a single-ion anisotropy, while the entropy has been expanded in powers of the classical spins. The energy has been modelled by a Heisenberg Hamiltonian with a single-ion anisotropy, while the entropy has been expanded in powers of the classical spins.

The energy has been modelled by a Heisenberg Hamiltonian with a single-ion anisotropy, while the entropy has been expanded in powers of the classical spins. The energy has been modelled by a Heisenberg Hamiltonian with a single-ion anisotropy, while the entropy has been expanded in powers of the classical spins. The energy has been modelled by a Heisenberg Hamiltonian with a single-ion anisotropy, while the entropy has been expanded in powers of the classical spins.

Beyond that, the model clarifies the effect of different dopants on the phase diagram. The sensitivity of the expression (68) for the transition temperature $T_{N1}(x)$ to small changes of the ratio $\eta = \frac{\lambda_1(q_{IC})}{3\lambda_1(q_{IC})}$ reflects the frustrated nature of the multiferroic MnWO$_4$. The origin of the complex phase diagram lies in the competition between different superexchange interactions. Small changes in the local environment of the Mn$^{2+}$ ions due to a chemical doping cause a significant change in the phase diagram. The sensitivity for the local environment manifests itself by the contrasting behavior of doping with different ions.

Looking to the future, two points should be further examined. Firstly, a new analysis of the inelastic scattering experiments, together with the additional constraints provided in this work, should improve the exchange couplings for the multiferroic MnWO$_4$. Secondly, the measurement of the critical exponents near the transitions would shed light on the effect of fluctuations. This may contribute to the general understanding of critical phenomena in multiferroics.
