The low energy effective action of gravity in any even dimension generally acquires non-local terms associated with the trace anomaly, generated by the quantum fluctuations of massless fields. The local auxiliary field description of this effective action in four dimensions requires two additional scalar fields, not contained in classical general relativity, which remain relevant at macroscopic distance scales. The auxiliary scalar fields depend upon boundary conditions for their complete specification, and therefore carry global information about the geometry and macroscopic quantum state of the gravitational field. The scalar potentials also provide coordinate invariant order parameters describing the conformal behavior and divergences of the stress tensor on event horizons. We compute the stress tensor due to the anomaly in terms of its auxiliary scalar potentials in a number of concrete examples, including the Rindler wedge, the Schwarzschild geometry, and de Sitter spacetime. In all of these cases, a small number of classical order parameters completely determine the divergent behaviors allowed on the horizon, and yield qualitatively correct global approximations to the renormalized expectation value of the quantum stress tensor.

I. INTRODUCTION

Gravitation is a macroscopic phenomenon, governing the behavior of matter at scales from a few cm. up to the largest scales of cosmology, $10^{28}$ cm. On the other hand quantum phenomena are associated generally with microscopic distances, on the order of atomic scales, $10^{-8}$ cm. or smaller. The physical and mathematical frameworks used to describe physics at these disparate scales are quite different as well, and at first sight appear even to be irreconcilable. In general relativity gravitation is founded on the Equivalence Principle, which finds its mathematical expression in differential equations which transform covariantly under a local change of frame at every spacetime point. In classical physics this idealization of spacetime as a local differentiable structure is quite natural. Yet because of quantum fluctuations it is very likely that the classical description of spacetime as a smooth pseudo-Riemannian manifold fails at very short distance scales, of the order of the Planck length, $L_{Pl} = \sqrt{\hbar G/c^3} \sim 10^{-33}$ cm.

Perhaps less widely appreciated is that quantum theory also raises questions about the purely local, classical description of the gravitational interactions of matter, even at macroscopic distances. This is because of the peculiarly quantum phenomena of phase coherence and entanglement, which may be present on any scale, given the right conditions. Indeed macroscopic quantum states are encountered in virtually all branches of physics on a very wide variety of scales. Some of the better known examples occur in non-relativistic many-body and condensed matter systems, such as Bose-Einstein condensation, superfluidity, and superconductivity. These quantum coherence effects due to the wave-like properties of matter have their close analogs in relativistic field theories as well, in spontaneous symmetry breaking by the Higgs mechanism in electroweak theory, and chiral quark pair condensation in low energy QCD. In each of these cases the ground state or “vacuum” is a macroscopic quantum state, described at very long wavelengths by a non-vanishing quasi-classical order parameter, in a low energy effective field theory.

The strictly classical theory of general relativity would seem to preclude any incorporation of macroscopic coherence and entanglement effects of quantum matter, on any scale. Taking account of the quantum wave-like properties of matter, and its propensity to form phase correlated states over macroscopic distance scales at low enough temperatures and/or high enough densities requires at the least a semi-classical treatment of the effective stress-energy tensor source for Einstein’s equations. The corresponding one-loop effective action for gravity can be determined by the methods of effective field theory (EFT). Our principal purpose in this paper is to demonstrate that
non-local macroscopic coherence effects are contained in the low energy EFT of gravity, provided that Einstein’s classical theory is supplemented by the contributions of the one-loop quantum trace anomaly of massless fields.

The low energy EFT of gravity is determined by the same general principles as in other contexts \[1\], namely by an expansion in powers of derivatives of local terms consistent with symmetry. Short distance effects are parameterized by the coefficients of local operators in the effective action, with higher order terms suppressed by inverse powers of an ultraviolet cutoff scale \( M \). The effective theory need not be renormalizable, as indeed Einstein’s theory is not, but is expected nonetheless to be quite insensitive to the details of the underlying microscopic degrees of freedom, because of decoupling \[1\]. It is the decoupling of short distance degrees of freedom from the macroscopic physics that makes EFT techniques so widely applicable, and which we assume applies also to gravity.

As a covariant metric theory with a symmetry dictated by the Equivalence Principle, namely invariance under general coordinate transformations, general relativity may be regarded as just such a local EFT, truncated at second order in derivatives of the metric field \( g_{ab}(x) \) \[2\]. When quantum matter is considered, the stress tensor becomes an operator whose expectation value acts as a source for the Einstein equations in the semi-classical limit. Fourth order terms in derivatives of the metric are necessary to absorb divergences in the expectation value of the stress tensor in curved spacetime, but the effects of such higher derivative local terms in the gravitational effective action are suppressed at distance scales \( L \gg L_{Pl} \) in the low energy EFT limit. Hence surveying only local curvature terms, it is often tacitly assumed that Einstein’s theory contains all the low energy macroscopic degrees of freedom of gravity, and that general relativity cannot be modified at macroscopic distance scales, much greater than \( L_{Pl} \), without violating general coordinate invariance and/or EFT principles. However, this presumption should be re-examined in the presence of quantum anomalies.

When a classical symmetry is broken by a quantum anomaly, the naive decoupling of short and long distance physics assumed by an expansion in local operators with ascending inverse powers of \( M \) fails. In this situation even the low energy symmetries of the effective theory are changed by the presence of the anomaly, and some remnant of the ultraviolet physics survives in the low energy description. An anomaly can have significant effects in the low energy EFT because it is not suppressed by any large energy cutoff scale, surviving even in the limit \( M \rightarrow \infty \). Any explicit breaking of the symmetry in the classical Lagrangian serves only to mask the effects of the anomaly,
but in the right circumstances the effects of the non-local anomaly may still dominate the local terms. A well known example is the chiral anomaly in QCD with massless quarks, whose effects are unsuppressed by any inverse power of the EFT ultraviolet cutoff scale \( M \sim \Lambda_{QCD} \). Although the quark masses are non-zero, and chiral symmetry is only approximate in nature, the chiral anomaly gives the dominant contribution to the low energy decay amplitude of \( \pi^0 \rightarrow 2\gamma \) in the standard model [3, 4], a contribution that is missed entirely by a local EFT expansion in pion fields. Instead the existence of the chiral anomaly requires the explicit addition to the local effective action of a \textit{non-local} term in four physical dimensions to account for its effects [1, 5].

Although when an anomaly is present, naive decoupling between the short and long distance degrees of freedom fails, it does so in a well-defined way, with a coefficient that depends only on the quantum numbers of the underlying microscopic theory. In fact, since the chiral anomaly depends on the color charge assignments of the short distance quark degrees of freedom, the measured low energy decay width of \( \pi^0 \rightarrow 2\gamma \) affords a clean, non-trivial test of the underlying microscopic quantum theory of QCD with three colors of fractionally charged quarks [1, 4, 6]. The bridge between short and long distance physics which anomalies provide is the basis for the anomaly matching conditions [7].

In curved space an anomaly closely related to the chiral anomaly also appears in massless quantum field theory [8, 9]. This conformal or trace anomaly provides us with additional infrared relevant terms that do not decouple in the limit \( M_{Pl}^{-1} = L_{Pl} \rightarrow 0 \), and which should be added to the Einstein-Hilbert action of classical relativity, to complete the EFT of low energy gravity.

That the trace anomaly terms are necessary for the low energy completion of the EFT of gravity may be seen from the classification of possible terms in the gravitational effective action according to their behavior under global Weyl rescalings [10]. The terms in the classical Einstein-Hilbert action scale with positive powers (\( \sim L^4 \) and \( \sim L^2 \)) under rescaling of distance, and are clearly relevant operators of the low energy description. The non-local anomalous terms scale logarithmically (\( \sim \log L \)) with distance under Weyl rescalings, and therefore should be considered \textit{marginally relevant}. Unlike local higher derivative terms in the effective action, which are either neutral or scale with negative powers of \( L \) under global Weyl rescalings of the metric, the anomalous terms cannot be discarded in the low energy, large distance limit. The addition of the anomaly term(s) to the low energy effective action of gravity amounts to a non-trivial infrared modification of general relativity, fully consistent with both quantum theory and the Equivalence Principle [10].

The anomalous terms in the effective action lead to corresponding additional terms in the stress
tensor and equations of motion of the low energy EFT of gravity. These terms are most conveniently expressed in terms of two auxiliary scalar fields which permit the non-local effective action of the trace anomaly and its variations to be cast into local form. The additional scalar degrees of freedom in these terms take account of macroscopic effects of quantum matter in gravitational fields, which are not contained in the purely classical, local metric description of Einstein’s theory.

In this paper we give explicit formulae for the stress tensor due to the trace anomaly of massless fields to be added to the classical Einstein equations in the low energy EFT limit, and expose its macroscopic effects in a number of familiar geometries. The most interesting effects are associated with geometries that have horizons, boundaries, or non-trivial global topologies. For example, the two new auxiliary fields in the effective action generically diverge as the apparent horizon of Rindler, Schwarzschild, and de Sitter spacetimes is approached. This behavior of the scalar auxiliary fields gives a coordinate invariant semi-classical order parameter description of possible divergences of stress tensors of quantum field theories on spacetime horizons, enabling an understanding of such divergences in terms of the global properties of the geometry. The Casimir energy density between two conducting plates is an example of a bounded space without horizons or curvature which also admits a simple description in terms of the scalar auxiliary fields. The various examples taken together suggest that the degrees of freedom contained in the scalar potentials induced by the trace anomaly should be regarded as semi-classical macroscopic order parameter fields (condensates), whose non-vanishing values are connected with non-trivial boundary conditions, horizons, or the topology of spacetime.

The paper is organized as follows. In the next section we review the auxiliary field form of the effective action of the trace anomaly in two dimensions, recovering results for the stress tensor of conformal fields in the two dimensional Rindler wedge, Schwarzschild and de Sitter metrics. In Section III we discuss the general form of the effective action in four dimensions, and give the additional terms in the stress tensor in terms of the auxiliary fields, as well as the conserved Noether current associated with it. In Section IV we consider the effects of these additional terms and the new local scalar degrees of freedom of low energy gravity they represent in flat, Rindler and the conformally flat de Sitter spacetime. In Section V we discuss the approximate conformal symmetry which pertains in the vicinity of any static, spherically symmetric Killing horizon and give the explicit form of the auxiliary fields in the Schwarzschild case. We characterize the possible singularities of the stress tensor on the Schwarzschild horizon, and find approximate stress tensors for the Hartle-Hawking, Boulware, and Unruh states, comparing our results with numerical results.
for $\langle T^{ab} \rangle$ of massless fields of various spins. We conclude in Section VI with a summary of our results and their implications for quantum effects in gravity. The Appendix contains the explicit formulae for the components of the stress-energy in static spherically symmetric spacetimes, upon which the Schwarzschild and de Sitter results are based.

II. EFFECTIVE ACTION AND STRESS TENSOR IN TWO DIMENSIONS

The effective action for the trace anomaly in any even dimension is non-local when expressed in terms only of the metric $g_{ab}$. It can be made local by the introduction of scalar auxiliary field(s). To illustrate this procedure and introduce the general framework which we will use extensively in four dimensions, we consider first the somewhat simpler case of two physical dimensions. In $d = 2$ the trace anomaly takes the simple form

$$\langle T^{a}_{a} \rangle = \frac{N}{24 \pi} R, \quad (d = 2)$$

(2.1)

where $N = N_S + N_F$ is the total number of massless fields, either scalar ($N_S$) or fermionic ($N_F$). The fact that the anomalous trace is independent of the quantum state of the matter field(s), and dependent only on the geometry through the local Ricci scalar $R$ suggests that it should be regarded as a geometric effect. However, no local coordinate invariant action exists whose metric variation leads to (2.1).

A non-local action corresponding to (2.1) can be found by introducing the conformal parameterization of the metric,

$$g_{ab} = e^{2\sigma} \bar{g}_{ab}, \quad (2.2)$$

and noticing that the scalar curvature densities of the two metrics $g_{ab}$ and $\bar{g}_{ab}$ are related by

$$R \sqrt{-g} = \bar{R} \sqrt{-\bar{g}} - 2 \sqrt{-g} \Box \sigma, \quad (d = 2)$$

(2.3)

a linear relation in $\sigma$ in two (and only two) dimensions. Multiplying (2.1) by $\sqrt{-g}$, using (2.3) and noting that $\sqrt{-g} \langle T^{a}_{a} \rangle$ defines the conformal variation, $\delta \Gamma^{(2)}/\delta \sigma$ of an effective action $\Gamma^{(2)}$, we conclude that the $\sigma$ dependence of $\Gamma^{(2)}$ can be at most quadratic in $\sigma$. Hence the Wess-Zumino effective action in two dimensions, $\Gamma^{(2)}_{WZ}$ is

$$\Gamma^{(2)}_{WZ}[\bar{g}; \sigma] = \frac{N}{24 \pi} \int d^2x \sqrt{-g} \left( -\sigma \Box \sigma + \bar{R} \sigma \right). \quad (2.4)$$
This action functional of the base metric $\bar{g}_{ab}$ and the Weyl shift parameter $\sigma$ may be regarded as a one-form representative of the cohomology of the local Weyl group in two dimensions. This means that $\Gamma^{(2)}_{WZ}[\bar{g};\sigma]$ is closed under the co-boundary (i.e. anti-symmetrized) composition of Weyl shifts,

$$\Delta_{\sigma_2} \circ \Gamma^{(2)}_{WZ}[\bar{g};\sigma_1] = \Gamma^{(2)}_{WZ}[ge^{2\sigma_1};\sigma_2] - \Gamma^{(2)}_{WZ}[ge^{2\sigma_2};\sigma_1] + \Gamma^{(2)}_{WZ}[\bar{g};\sigma_1] - \Gamma^{(2)}_{WZ}[\bar{g};\sigma_2] = 0. \quad (2.5)$$

but is non-exact, in the sense that $\Gamma^{(2)}_{WZ}$ cannot itself be written as the co-boundary shift of a local single-valued covariant scalar functional of the metric $\bar{g}_{ab}$, it is straightforward to find a non-local scalar functional $S_{anom}[\bar{g}]$ such that

$$\Gamma^{(2)}_{WZ}[\bar{g};\sigma] = \Delta_{\sigma} \circ S^{(2)}_{anom}[\bar{g}] \equiv S^{(2)}_{anom}[\bar{g}] - S^{(2)}_{anom}[\bar{g}]. \quad (2.6)$$

Indeed by solving (2.3) formally for $\sigma$, and using the fact that $\sqrt{-g} = \sqrt{-\bar{g}}$ is conformally invariant in two (and only two) dimensions, we find that $\Gamma^{(2)}_{WZ}$ can be written as a Weyl shift (2.6) with

$$S^{(2)}_{anom}[\bar{g}] = -\frac{Q^2}{16\pi} \int d^2x \sqrt{-\bar{g}} \int d^2x' \sqrt{-\bar{g}'} R(x) \square^{-1}(x,x') R(x'), \quad (2.7)$$

and $\square^{-1}(x,x')$ denoting the Green’s function inverse of the scalar differential operator $\square$. The parameter $Q^2$ is $-N/6$ if only matter fields in a fixed spacetime metric are considered. It becomes $(25 - N)/6$ if account is taken of the contributions of the metric fluctuations themselves in addition to those of the $N$ matter fields, thus effectively replacing $N$ by $N - 25$. In the general case, the coefficient $Q^2$ is arbitrary, and can be treated as simply an additional free parameter of the low energy effective action, to be fixed by experiment.

The anomalous effective action (2.7) is a scalar under coordinate transformations and therefore fully covariant and geometric in character. However since it involves the Green’s function $\square^{-1}(x,x')$, which requires boundary conditions for its unique specification, it is quite non-local, and dependent upon more than just the local curvature invariants of spacetime. The non-local and non-single valued functional of the metric, $S^{(2)}_{anom}$ may be expressed in a local form by the standard method of introducing auxiliary fields. In the case of (2.7) a single scalar auxiliary field, $\varphi$ satisfying

$$-\square \varphi = R \quad (2.8)$$
is sufficient. Indeed, varying
\[ S^{(2)}_{\text{anom}}[g; \varphi] \equiv \frac{Q^2}{16\pi} \int d^2x \sqrt{-g} \left( \nabla_a \varphi \nabla^a \varphi - 2R \varphi \right) \tag{2.9} \]
with respect to \( \varphi \) gives the Eq. of motion (2.8) for the auxiliary field, which when solved (formally) by \( \varphi = -\Box^{-1} R \) and substituted back into \( S^{(2)}_{\text{anom}}[g; \varphi] \) returns the non-local form of the anomalous action (2.7), up to a surface term. The non-local information in addition to the local geometry which was previously contained in the specification of the Green’s function \( \Box^{-1}(x, x') \) now resides in the auxiliary local field \( \varphi(x) \), and the freedom to add to it homogeneous solutions of (2.8).

The variation of (2.9) with respect to the metric yields a stress-energy tensor,
\[ T^{(2)}_{ab}[g; \varphi] \equiv -\frac{2}{\sqrt{-g}} \frac{\delta S^{(2)}_{\text{anom}}[g; \varphi]}{\delta g^{ab}} \]
\[ = \frac{Q^2}{4\pi} \left[ -\nabla_a \nabla_b \varphi + g_{ab} \Box \varphi - \frac{1}{2} (\nabla_a \varphi)(\nabla_b \varphi) + \frac{1}{4} g_{ab} (\nabla_c \varphi)(\nabla^c \varphi) \right] , \tag{2.10} \]
which is covariantly conserved, by use of (2.8) and the vanishing of the Einstein tensor, \( G_{ab} = R_{ab} - R g_{ab}/2 = 0 \) in two (and only two) dimensions. The classical trace of the stress tensor,
\[ g^{ab} T^{(2)}_{ab}[g; \varphi] = \frac{Q^2}{4\pi} \Box \varphi = -\frac{Q^2}{4\pi} R \tag{2.11} \]
reproduces the quantum trace anomaly in a general classical background (with \( Q^2 \) proportional to \( \hbar \)). Hence (2.9) is exactly the local auxiliary field form of the effective action which should be added to the action for two dimensional gravity to take the trace anomaly of massless quantum fields into account.

The full effective action of two dimensional gravity is
\[ S^{(2)}_{\text{eff}}[g, \varphi] = S^{(2)}_{\text{anom}}[g, \varphi] + S^{(2)}_{\text{cl}}[g] , \tag{2.12} \]
where \( S^{(2)}_{\text{cl}} \) is the local classical Einstein-Hilbert action,
\[ S^{(2)}_{\text{cl}}[g] = \gamma \int d^2x \sqrt{-g} R + \lambda \int d^2x \sqrt{-g} , \tag{2.13} \]
which are the only terms we would have written down according to the usual EFT approach, expanding in strictly local terms up to and including dimension two which transform as scalars under general coordinate transformations. Under global rescalings of the metric (2.2) with \( \sigma = \sigma_0 \), a spacetime constant, the volume term scales like \( e^{2\sigma_0} \) and its coefficient \( \lambda \) has positive mass dimension two. Hence it is clearly a relevant term in the effective action at large distances. The integral of the Ricci scalar is independent of \( \sigma_0 \), with a coefficient \( \gamma \) that is dimensionless, while
the integrals of all higher local curvature invariants scale with negative powers of \( e^{\sigma_0} \), multiplied by coefficients having negative mass dimensions. These terms are neglected in (2.13) since they are strictly irrelevant in the low energy EFT limit.

The anomalous term (2.7), or (2.9) scales linearly with \( \sigma_0 \), \textit{i.e.} logarithmically with distance, and is therefore a \textit{marginally relevant} operator in the infrared. Even if it is not included at the classical level it will be generated by the one-loop effects of massless fields, which do not decouple at any scale. Hence it should be retained in the full low energy effective action (2.12) of two dimensional gravity. Moreover, since the integral of \( R \) is a topological invariant in two dimensions, the classical action (2.13) contains no propagating degrees of freedom whatsoever, and it is \( S_{\text{anom}} \) which contains the only kinetic terms of the low energy EFT. In the local auxiliary field form (2.9), it is clear that \( S_{\text{anom}} \) describes an additional scalar degree of freedom \( \varphi \), not contained in the classical action \( S^{(2)}_{cl} \). This is reflected also in the shift of the central charge from \( N - 26 \), which would be expected from the contribution of conformal matter plus ghosts by one unit to \( N - 25 \).

Extensive study of the stress tensor and its correlators arising from this effective action established that the two dimensional trace anomaly gives rise to a modification or gravitational “dressing” of critical exponents in conformal field theories at second order critical points [12]. Since critical exponents in a second order phase transition depend only upon fluctuations at the largest allowed infrared scale, this dressing is clearly an infrared effect, independent of any ultraviolet cutoff. These dressed exponents are evidence of the infrared fluctuations of the additional scalar degree of freedom \( \varphi \) which are quite absent in the classical action (2.13). The appearance of the gravitational dressing exponents and the anomalous effective action (2.7) itself have been confirmed in the large volume scaling limit of two dimensional simplicial lattice simulations in the dynamical triangulation approach [13, 14].

The formal similarity between (2.4) and (2.9) suggests that the introduction of the local auxiliary field \( \varphi \) has simply undone the steps leading from (2.4) to (2.7), which eliminated the conformal factor \( \sigma \). By comparing (2.3) and (2.8), we observe that the metric

\[
\tilde{g}_{ab} = e^{-\varphi} g_{ab}
\]

(2.14)
is a metric with zero scalar curvature, \( \tilde{R} = 0 \), conformally related to the physical metric \( g_{ab} \). Hence \( \varphi(x) \) does parameterize the local Weyl transformations of the metric along the same fiber as \( \sigma(x) \) in the conformal parameterization (2.2). The difference between the two representations is that whereas \( \tilde{g}_{ab} \) was regarded as a fixed base metric related to the physical metric \( g_{ab} \) by (2.2), the
possibility of adding homogeneous solutions to \( (2.8) \) shows that \( \varphi \) and hence \( \tilde{g}_{ab} \) defined by \( (2.14) \) are not unique, and hence no \( \tilde{g}_{ab} \) plays any privileged role over any other. The only physical metric is \( g_{ab} \). The non-uniqueness of \( \varphi \) allows for additional degrees of freedom at boundaries or coordinate singularities of \( g_{ab} \), which need not be associated with any smooth \( \tilde{g}_{ab} \). The completely covariant local form of the action \( (2.9) \) makes it clear that these effects, associated with the boundary conditions on the spacetime scalar \( \varphi \) satisfying \( (2.8) \) are not coordinate artifacts which can be removed by reparameterizations of coordinates in the physical spacetime \( g_{ab} \). It is the freedom to specify boundary conditions for the classical auxiliary field \( \varphi \), or equivalently add homogeneous solutions to the non-local Green’s function \( \Box^{-1}(x, x') \) which implies the possibility of global macroscopic effects of the anomaly.

Both the auxiliary field equation of motion \( (2.8) \) and stress tensor \( (2.10) \) are left invariant by the constant shift,

\[
\varphi \rightarrow \varphi + \varphi_0 . \tag{2.15}
\]

The underlying reason for this shift symmetry is that the integral,

\[
\chi = \frac{1}{4\pi} \int d^2x \sqrt{-g} R \tag{2.16}
\]

is a topological invariant in two dimensions. For Euclidean signature metrics \( \chi = \chi_E \) is the Euler number of the manifold. This implies that in two (and only two) dimensions \( \sqrt{-g} R \) can be expressed as a total derivative, or equivalently,

\[
R = \frac{1}{\sqrt{-g}} \partial_a (\sqrt{-g} \Omega^a) \equiv \nabla_a \Omega^a , \quad (d = 2) . \tag{2.17}
\]

The topological current \( \Omega^a \), analogous to the Chern-Simons current for the gauge theory chiral anomaly \([15, 16]\), depends upon the choice of gauge or coordinate frame and is non-unique, although its line integral around a closed contour,

\[
\oint_{\partial V} \sqrt{-g} \Omega^a n_a ds = \int_{\partial V} \sqrt{-g} \Omega^a \epsilon_{ab} dx^b = \int_V \sqrt{-g} R d^2x \tag{2.18}
\]

is a coordinate invariant scalar quantity. Here we have used the notation, \( n_a = \epsilon_{ab} \frac{d x^b}{ds} \) for the normal to the boundary \( \partial V \) of the two dimensional region \( V \) and \( \epsilon_{ab} \) is the standard alternating tensor in two dimensions (with \( \epsilon_{12} = +1 \)). The existence of \( \Omega^a \) satisfying \( (2.17) \) implies that the action \( (2.9) \) may be rewritten in the alternative form,

\[
S_{\text{anom}, 2}[g; \varphi] = \frac{Q^2}{16\pi} \int_V d^2x \sqrt{-g} (\nabla^a \varphi + 2\Omega^a) \nabla_a \varphi - \frac{Q^2}{8\pi} \int_{\partial V} \sqrt{-g} \varphi \Omega^a n_a ds , \tag{2.19}
\]
leaving (2.8), (2.10) and (2.11) unchanged. Since up to the last surface term the anomalous action depends on $\varphi$ only through its derivatives, there is a frame dependent Noether current corresponding to the global Weyl rescaling (2.15),

$$J^a = \nabla^a \varphi + \Omega^a,$$  \hspace{1cm} (2.20)

which is covariantly conserved,

$$\nabla_a J^a \equiv \frac{1}{\sqrt{-g}} \partial_a (\sqrt{-g} J^a) = \Box \varphi + R = 0,$$ \hspace{1cm} (2.21)

by virtue of (2.8) and (2.17).

Within the framework of the low energy effective action (2.12) all fields may be treated classically, with $\hbar$ contained implicitly only in the c-number coefficients $\gamma, \lambda$ and $Q^2$. In this (semi-)classical framework, the auxiliary field $\varphi$ is a classical scalar potential which contains information about the macroscopic quantum state and topological boundary effects. The geometric information $\varphi(x)$ contains cannot be reduced to local geometric invariants constructed from the curvature tensor, its derivatives and contractions at $x$. Instead the massless correlation function $\Box^{-1}(x, x')$, which grows logarithmically with the invariant distance between the spacetime points $x$ and $x'$, and the existence of a conserved global charge corresponding to the Noether current $J^a$ imply that $\varphi$ is a long range field depending upon the global properties of spacetime. It is this long range behavior of $\varphi$ that enables the effective action (2.12) to incorporate macroscopic quantum coherence effects, quite absent from the purely local classical geometric action $S_{cl}^{(2)}$. Since the effective action contains $S_{\text{anom}}^{(2)}$, these non-local macroscopic quantum coherence effects are incorporated in the low energy EFT of two dimensional gravity in a natural way.

The long range macroscopic effects and the physical meaning of the Noether charge are best illustrated by means of a few simple examples. Consider first flat spacetime in Rindler coordinates,

$$ds^2 = -dt^2 + dx^2 = -\rho^2 d\eta^2 + d\rho^2,$$ \hspace{1cm} (2.22)

with $x = \rho \cosh \eta, t = \rho \sinh \eta$. The Killing vector $\partial_\eta$ generates Lorentz boosts and this vector field becomes singular on the light cone, $\rho^2 = x^2 - t^2 = 0$. If the state of the system is boost invariant then the semi-classical auxiliary field can be assumed to be independent of $\eta$. With $\varphi = \varphi(\rho)$, (2.8) has the solution (for finite non-zero $\rho$),

$$\varphi = 2q \ln \left( \frac{\rho}{\rho_0} \right),$$ \hspace{1cm} (2.23)
with $q$ and $\rho_0$ arbitrary constants.

If $q \neq 0$ the singularity of $\varphi$ at $\rho = 0$ gives a delta function contribution to the scalar curvature at the origin of the Euclidean metric obtained by replacing in (2.22), $\eta \to i\theta$, i.e.,

$$\Box \varphi = 4\pi q \frac{\delta(\rho)}{\rho}, \quad (2.24)$$

so that (2.24) should properly be considered a solution of (2.22) only in the distributional sense. If the point at $\rho^{-1} = 0$ is included in the manifold then there is also a delta function contribution to (2.24) at infinity. In the Euclidean signature metric, the operator $\Box$ is the usual two dimensional Laplacian and (2.24) is Laplace’s equation for the electrostatic potential with a point charge of magnitude $-q$ at the origin, and $+q$ at infinity. A non-zero value of $q$ corresponds to a topological defect on the Minkowski light cone, with the metric $e^{-\varphi} ds^2$, conformal to the original metric (2.22) possessing a conical singularity at $\rho = 0$ for generic $q \neq 0$.

Substituting (2.23) into the stress tensor (2.10), we find in the $(\eta, \rho)$ coordinates,

$$T^b_a = \frac{Q^2}{4\pi} \frac{(2-q)q}{\rho^2} \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}. \quad (2.25)$$

The case $q = 0$ corresponds to the Minkowski vacuum with no singularity on the light cone, $t = \pm x$. However when $q = 1$,

$$e^{-\varphi}|_{q=1} ds^2 = \rho_0^2 \left(-d\eta^2 + \frac{d\rho^2}{\rho^2}\right) = \rho_0^2 (-d\eta^2 + d\xi^2), \quad (2.26)$$

with $\xi = \ln(\rho/\rho_0)$, is again flat. The vanishing Euler number of this flat metric may be regarded as resulting from the cancellation of the $-1$ Euler charge at the origin from (2.8), (2.16) and (2.24) with the $+1$ Euler number of a circular flat disc with boundary $\partial V$ at large but finite radius, as the boundary is taken to infinity in the original metric. In the conformal metric (2.26) in $(\eta, \xi)$ coordinates, for $q = 1$ both singularities at $\rho = 0$ and $\rho = \infty$ are removed to infinity and we again obtain a flat spacetime with no singularities and no boundaries. The original flat spacetime (2.22) has been conformally mapped to another flat spacetime with a different global topology. Indeed the Euclidean signature metric $d\theta^2 + d\xi^2$ with $\theta$ $2\pi$-periodic is the metric of $R \times S^1$, with punctures at $\xi = \pm \infty$. The Euler charge of $\pm 1$ unit at $\xi = \pm \infty$ is also a consequence of general theorems relating the Euler number to the number of fixed points of the Killing field $K = \frac{\partial}{\partial \theta}$, where the metric (2.22) (or its inverse) becomes singular in the original $(\rho, \eta)$ coordinates [17].

When $q = 2$ the metric, $e^{-\varphi} ds^2$ becomes equivalent to the original flat metric (2.22) by the change of variables $\rho \to \rho_0^2/\rho$ which turns the spacetime inside out, exchanging the coordinate
singularities at $\rho = 0$ and $\rho = \infty$. Since the new metric is equivalent to the original metric up to a (singular) coordinate transformation, the stress tensor (2.25) again vanishes for $q = 2$. The invariance of the physical stress tensor (2.25) under the transformation $q \rightarrow 2 - q$ is evidence for a topological two-fold degenerate vacuum in two dimensional gravity.

For a single free scalar field $Q^2 = -1/6$ and at the value of $q = 1$, (2.25) gives

$$
T^{a \ b}_{\eta \rho} = \frac{N}{24 \pi \rho^2} \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix},
$$

(2.27)
in the ($\eta, \rho$) coordinates. This is exactly the expectation value of the stress tensor of a quantum scalar field in the boost invariant Fulling-Rindler state [18]. The preceding discussion shows that the divergence of $T^{a \ b}_{\eta \rho}$ in the Fulling-Rindler state is associated with a unit topological defect on the Minkowski light cone, contained in the auxiliary potential $\phi$, corresponding to a puncture at $\rho = 0$ (equivalently, $\rho = \infty$) in the analytically continued Euclidean signature metric. A singular conformal transformation (2.23) with $q = 1$ is required to transform the Minkowski vacuum to the Fulling-Rindler state. Whereas the Hamiltonian defined with respect to the global Minkowski time coordinate $t$ is bounded from below and possesses a well-defined vacuum state, the boost generator corresponding to the Killing field $\partial_\eta$ changes sign and is unbounded from below. These global properties distinguishing the Fulling-Rindler state from the Minkowski vacuum are reflected in the topological defect (2.24) and divergence of the stress-energy tensor (2.27) on the light cone.

A second example of macroscopic effects of topology of the trace anomaly is provided by two-dimensional static metrics of the form,

$$
ds^2 = -f dt^2 + \frac{dr^2}{f} = f(-dt^2 + dr^{*2}),
$$

(2.28)
where $f = f(r)$ and $dr^* = dr/f$. This class of metrics include the two-dimensional Schwarzschild metric, with $f(r) = 1 - 2M/r$ and de Sitter metric in static coordinates, with $f(r) = 1 - H^2r^2$. The Killing field $K = \partial_t$ is timelike for $f > 0$, and the scalar curvature corresponding to (2.28) is $R = -f''$. Hence in this case a particular inhomogeneous solution to (2.28) is $\varphi = \ln(-K^a K_a)^{1/4} = \ln f$. The conformally transformed line element $e^{-\varphi} ds^2 = -dt^2 + dr^{*2}$ is then the flat optical metric [18].

The components of the stress tensor due to the anomaly are given by

$$
T^{r \ r^*}_{\eta} = N \frac{f'}{24 \pi f} \left\{ \varphi_{r^*} + \frac{1}{4} \left( \varphi_{r^*}^2 + \varphi^2 \right) + R \right\}, \quad (2.29a)
$$

$$
T^{t \ t}_{\eta} = \frac{N}{24 \pi} \left\{ -\frac{\varphi'}{f} + \frac{f'}{2} \varphi_{r^*} - \frac{1}{4} \left( \varphi_{r^*}^2 + \varphi^2 \right) + R \right\}, \quad (2.29b)
$$

and

$$
T^{r \ t}_{\eta} = \frac{N}{24 \pi f} \left\{ \varphi_{r^*} - \frac{f'}{2} \varphi' + \frac{1}{2} \varphi_{r^*} \right\}.
$$

(2.29c)
The off-diagonal flux component is generally time dependent unless we restrict ourselves to at most linear functions of time. With this restriction, the general solution of (2.8) leading to a stationary stress tensor in the Schwarzschild case is:

\[ \varphi = c_0 + \frac{q}{2M} r^* + \frac{p}{2M} t + \ln f, \]  

(2.30)

where \( c_0, q \) and \( p \) are constants. As in the Rindler case this is a solution to (2.8) in the distributional sense, since \( \varphi \) contains delta function singularities. Indeed with \( p = 0 \) the strength of the delta function at the horizon, mapped to a point on the Euclidean section \( t \to i\tau \) for real \( \tau \), is \( 4\pi(q + 1) \). For \( q = -1 \) this horizon singularity is cancelled, although that value leads to a divergence in (2.30) as \( r \to \infty \).

The stress-energy tensor for \( N \) scalar (or fermion) fields in the Schwarzschild case with \( f = 1 - 2M/r \) is

\[ T_{t^t} = \frac{N}{24\pi} \left\{ -\frac{1}{4f} \left( \frac{p^2 + q^2}{4M^2} - \frac{4M^2}{r^4} \right) + \frac{4M}{r^3} \right\}, \]  

(2.31a)

\[ T_{t^r^*} = \frac{N}{192\pi M^2 f} \frac{pq}{f}, \]  

(2.31b)

\[ T_{r^* r^*} = \frac{N}{96\pi f} \left( \frac{p^2 + q^2}{4M^2} - \frac{4M^2}{r^4} \right). \]  

(2.31c)

This general form of the stress tensor for stationary states in the two-dimensional Schwarzschild metric was obtained in ref. [20], from considerations of conservation, stationarity, and the trace anomaly. The identification of the arbitrary constants \( K \) and \( Q \) in Eqs. (3.4) of that work with \( -pq/192\pi \) and \( \left( (p - q)^2 - 1 \right)/384\pi \) respectively of the present article shows that the stress tensor obtained from the anomaly, (2.30) with (2.30) coincides with that obtained in [20].

The stress tensor (2.31) is generally singular at \( r = 2M \), diverging as \( f^{-1} \) as \( f \to 0 \). The condition for finiteness on the future horizon is

\[ \left| \frac{1}{f}(T_{t^t} - T_{t^r^*} + 2T_{r^* r^*}) \right| < \infty \quad \text{as} \quad r \to 2M. \]  

(2.32)

Substituting (2.31) into this condition and expanding about \( r = 2M \) gives the condition,

\[ (q - p)^2 = 1, \quad \text{(finiteness on future horizon)} \]  

(2.33)

Finiteness on the past horizon would imply \( (q + p)^2 = 1 \). Thus, finiteness on both horizons implies \( p^2 + q^2 = 1, pq = 0 \) and zero flux. Since (2.33) cannot be satisfied with both \( q \) and \( p \) equal to zero, the solution (2.30) must diverge as either \( r^* \) or \( t \) goes to infinity. Note that this is completely
unlike the previous Fulling-Rindler case in which a finite (in fact, vanishing) stress tensor on the horizon is obtained with $\varphi = 0$, which has both zero charge on the light cone, and no divergence at infinity.

A time independent state with zero flux satisfying (2.33) is the two-dimensional Hartle-Hawking state with either $p$ or $q$ equal to zero, and the other equal to $\pm 1$. The stress tensor for this state is given by

$$T^t_t\bigg|_{HH} = \frac{N}{24\pi} \left\{ \frac{1}{4f} \left( \frac{4M^2}{r^4} - \frac{1}{4M^2} \right) + \frac{4M}{r^3} \right\},$$ (2.34a)

$$T^r_r\bigg|_{HH} = 0,$$ (2.34b)

$$T^r_r\bigg|_{HH} = \frac{N}{96\pi f} \left( \frac{1}{4M^2} - \frac{4M^2}{r^4} \right).$$ (2.34c)

The degeneracy of the stress tensor for two different values of $p$ or $q$ is similar to the behavior obtained in the Rindler case. As the horizon $r \to 2M$ is approached,

$$T^a_b\bigg|_{HH} = \frac{\pi NT_H^2}{6} \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \quad r \to 2M,$$ (2.35)

where $T_H = (8\pi M)^{-1}$ is the Hawking temperature. Thus the stress tensor approaches that of a two dimensional perfect gas at $T = T_H$ near the horizon in the Hartle-Hawking state. The same value is also obtained in the limit $r \to \infty$, showing that this state has infinite total energy.

Another state obeying the finiteness condition on the future horizon is the Unruh state $p = -q = 1/2$. Its time inverse, given by $p = q = -1/2$ is finite on the past horizon. These states have non-zero flux $T^r_t$ either outwardly or inwardly directed from the horizon extending to infinity. The non-zero $q$ in these states reflects singularities, i.e. sources or sinks of the current at both $r = 0$ and $r = \infty$.

Inspection of (2.31) shows that the only state which has vanishing stress tensor as $r \to \infty$ is the Boulware state with $p = q = 0$, which does not satisfy the finiteness condition at the horizon. Unlike the previous Fulling-Rindler example in which finiteness at both the horizon and infinity is achieved by one choice of $\varphi = 0$, in the Schwarzschild metric because of its different topology, one is forced to choose between finiteness on the horizon and falloff at infinity. In the Boulware state with $p = q = 0$,

$$T^a_b\bigg|_B \to -\frac{\pi T_H^2}{6f} \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \quad r \to 2M,$$ (2.36)
as \( r \to 2M \) and \( f \to 0 \), corresponding to the *negative* of the stress tensor of a thermal distribution of massless particles at the blue-shifted local temperature \( T_{\text{loc}} = T_H/\sqrt{f} \).

Comparing (2.36) with (2.27) we observe that the behavior of the stress tensor in the Boulware state in two dimensional Schwarzschild spacetime is *locally* the same as that of the Fulling-Rindler state in flat spacetime near the corresponding horizons, and indeed with the correspondence, \( \rho \leftrightarrow 4M\sqrt{f} \), the behavior near the horizons in the two cases may be mapped onto each other. However the two situations are quite different *globally*. The Euler number of flat space is zero, and no singular behavior of \( \varphi \) is required on either the light cone \( t = \pm x \) or infinity. The Fulling-Rindler state can be obtained only by requiring a non-zero topological charge \( q = 1 \) in the auxiliary field, which leads to \( \varphi \) of (2.23) diverging at both large and small \( \rho \).

On the other hand the scalar curvature \( R = -f'' \) is non-zero in the Schwarzschild case and the Euler number of the corresponding non-singular Euclidean signature metric is +1. This non-trivial topology of the background spacetime requires an inhomogeneous solution to (2.8), such as \( \varphi = \ln f \) in (2.30). The divergence on the horizon of this particular solution to the inhomogeneous equation can be cancelled by homogeneous solutions with non-zero \( p \) and/or \( q = -1 \) satisfying (2.33), but only at the price of a non-zero energy density, and non-trivial topological charge at infinity. Conversely the solution of (2.30) with \( c_0 = p = q = 0 \) which vanishes at infinity and produces a transformed metric \( e^{-\varphi} ds^2 \) which is flat there, necessarily has a diverging stress tensor on the horizon. Thus while particular solutions with particular boundary conditions for the auxiliary field can be chosen, the impossibility of producing a solution of (2.30) which is well-behaved at both the horizon and infinity is a global property of the Schwarzschild spacetime (2.28), which is quite distinct from flat spacetime in Rindler coordinates (2.22). The stress tensor of the anomaly and the auxiliary scalar \( \varphi \) captures these global effects of the macroscopic quantum state in terms of the classical solutions of (2.8).

Similar conclusions obtain in the two dimensional de Sitter spacetime (2.28) with \( f = 1 - H^2 r^2 \). The general solution of (2.8) leading to a stationary stress tensor is

\[
\varphi = c_0 + 2qH r^* + 2pH t + \ln f .
\]  

(2.37)
The components of the stress tensor in the general stationary state labelled by \((p, q)\) are

\[
T_t^t = \frac{NH^2}{24\pi} \left\{ -\frac{1}{f} \left( p^2 + q^2 - H^2 r^2 \right) + 2 \right\}, \quad (2.38a)
\]

\[
T_r^r = \frac{NH^2}{24\pi f} \left( p^2 + q^2 - H^2 r^2 \right). \quad (2.38b)
\]

\[
T_t^r = \frac{NH^2}{12\pi} \frac{pq}{f}. \quad (2.38c)
\]

The generic stress tensor again diverges on the horizon where \(f = 1 - H^2 r^2 = 0\), despite the finiteness of the scalar curvature \(R = -f'' = 2H^2\) there. The condition that the stress tensor be finite on the future horizon is again \((q - p)^2 = 1\). The divergence of the stress tensor can be cancelled only by the addition of a specific homogeneous solution to (2.8). States which are regular on both the past and future horizon have \(p^2 + q^2 = 1\), \(pq = 0\) and zero flux. These conditions give the Bunch-Davies state with the non-vanishing de Sitter invariant stress tensor, \(T_t^t = T_r^r = NH^2/24\pi\). The analog of the Boulware state with \(p = q = 0\) diverges as \(f \to 0\) exactly as in (2.36) with \(T_H = H/2\pi\).

In all the two dimensional examples considered, the parameter \(q\) may be viewed as an effective topological charge carried by the auxiliary field of the trace anomaly. The classical solutions of this order parameter field generally depend on global coordinate invariant quantities, such as \(\ln(-K^a K_a)\) which diverges on a horizon where a timelike Killing field \(K^a\) becomes null, notwithstanding the finiteness of the local curvature there. Thus the scalar auxiliary field provides a coordinate invariant characterization of the local divergences of the stress-energy on the horizon, in macroscopic quantum states defined globally in the spacetime.

### III. EFFECTIVE ACTION AND STRESS TENSOR IN FOUR DIMENSIONS

The low energy effective action for gravity in four dimensions contains first of all, the local terms constructed from the Riemann curvature tensor and its derivatives and contractions up to and including dimension four. This includes the usual Einstein-Hilbert action of general relativity,

\[
S_{EH}[g] = \frac{1}{16\pi G} \int d^4x \sqrt{-g} \left( R - 2\Lambda \right) \quad (3.1)
\]
as well as the spacetime integrals of the fourth order curvature invariants,

\[
S_{local}^{(4)}[g] = \frac{1}{2} \int \sqrt{-g} \left( \alpha C_{abcd} C^{abcd} + \beta R^2 \right) d^4x, \quad (3.2)
\]
with arbitrary dimensionless coefficients $\alpha$ and $\beta$. There are two additional fourth order invariants, namely $E = *R_{abcd} *R^{abcd}$ and $\Box R$, which could be added to (3.2) as well, but as they are total derivatives yielding only a surface term and no local variation, we omit them. All the possible local terms in the effective action may be written as the sum,

$$S_{\text{local}}[g] = \frac{1}{16 \pi G} \int d^4x \sqrt{-g} (R - 2\Lambda) + S^{(4)}_{\text{local}} + \sum_{n=3}^{\infty} S^{(2n)}_{\text{local}}. \quad (3.3)$$

with the terms in the sum with $n \geq 3$ composed of integrals of local curvature invariants with dimension $2n \geq 6$, and suppressed by $M^{-2n+4}$ at energies $E \ll M$. Here $M$ is the ultraviolet cutoff scale of the low energy effective theory which we may take to be of order $M_{Pl}$. The higher derivative terms with $n \geq 3$ are irrelevant operators in the infrared, scaling with negative powers of $e^{\sigma_0}$ under global rescalings of the metric, as in (2.2), and may be neglected at macroscopic distance scales. On the other hand the two terms in the Einstein-Hilbert action $n = 0, 1$ scale as $e^{4\sigma_0}$ or $e^{2\sigma_0}$ respectively, and are clearly relevant in the infrared. The fourth order terms in (3.2) are neutral under such global rescalings.

The exact quantum effective action also contains non-local terms in general. All possible terms in the effective action (local or not) can be classified according to how they respond to global Weyl rescalings of the metric. If the non-local terms are non-invariant under global rescalings, then they scale either positively or negatively under $g_{ab} \rightarrow e^{2\sigma_0} g_{ab}$. If $m^{-1}$ is some fixed length scale associated with the non-locality, arising for example by the integrating out of fluctuations of fields with mass $m$, then at much larger macroscopic distances ($mL \gg 1$) the non-local terms in the effective action become approximately local. The terms which scale with positive powers of $e^{\sigma_0}$ are constrained by general covariance to be of the same form as the $n = 0, 1$ Einstein-Hilbert terms in $S_{\text{local}}$, (3.1). Terms which scale negatively with $e^{\sigma_0}$ become negligibly small as $mL \gg 1$ and are infrared irrelevant at macroscopic distances. This is the expected decoupling of short distance degrees of freedom in an effective field theory description, which are verified in detailed calculations of loops in massive field theories in curved space. The only possibility for contributions to the effective field theory of gravity at macroscopic distances, which are not contained in the local expansion of (3.3) arise from fluctuations not associated with any finite length scale, i.e. $m = 0$. These are the non-local contributions to the low energy EFT which include those associated with the anomaly.

Classical fields satisfying wave equations with zero mass, which are invariant under conformal transformations of the spacetime metric, $g_{ab} \rightarrow e^{2\sigma} g_{ab}$ have stress tensors with zero classical trace, $T^a_a = 0$. Because the corresponding quantum theory requires a UV regulator, classical conformal
invariance cannot be maintained at the quantum level. The trace of the stress tensor is generally non-zero when $\hbar \neq 0$, and any UV regulator which preserves the covariant conservation of $T^a_b$ (a necessary requirement of any theory respecting general coordinate invariance) yields an expectation value of the quantum stress tensor with the non-zero trace\[8, 9\],

$$\langle T^{a}_{a} \rangle = bF + b' \left( E - \frac{2}{3} \Box R \right) + b'' R + \sum_{i} \beta_{i} H_{i}, \quad (3.4)$$

in a general four dimensional curved spacetime. This is the four dimensional analog of (2.1) in two dimensions. In Eq. (3.4) we employ the notation,

$$E \equiv R_{abcd} R^{abcd} = R_{abcd} R^{abcd} - 4R_{ab} R^{ab} + R^2, \quad \text{and} \quad (3.5a)$$

$$F \equiv C_{abcd} C^{abcd} = R_{abcd} R^{abcd} - 2R_{ab} R^{ab} + \frac{R^2}{3} \quad (3.5b)$$

with $R_{abcd}$ the Riemann curvature tensor, $R_{abcd} = \varepsilon_{abef} R^{ef}_{\ cd}/2$ its dual, and $C_{abcd}$ the Weyl conformal tensor. The coefficients $b, b'$ and $b''$ are dimensionless parameters proportional to $\hbar$. These terms appear in the trace of stress tensor of any massless field, provided only that it is regularized and defined in such a way as to preserve general coordinate invariance and the covariant conservation law, $\nabla_{a} \langle T^{a}_{b} \rangle = 0$, which we assume if the theory is to preserve general covariance. Additional terms denoted by the sum $\sum_{i} \beta_{i} H_{i}$ in (3.4) may also appear in the general form of the trace anomaly, if the massless field in question couples to additional long range gauge fields. Thus in the case of massless fermions coupled to a background gauge field, the invariant $H = \text{tr}(F_{ab} F^{ab})$ will appear in (3.4) with a coefficient $\beta$ determined by the beta function of the relevant gauge coupling. We shall concentrate on the universal gravitational terms in the anomaly in most of what follows, returning to consider the effect of the $\sum_{i} \beta_{i} H_{i}$ terms at the end of this section.

The form of (3.4) and coefficients $b$ and $b'$ do not depend on the state in which the expectation value of the stress tensor is computed. Instead they determined only by the number of massless fields\[9\],

$$b = \frac{1}{120(4\pi)^2} (N_{S} + 6N_{F} + 12N_{V}), \quad (3.6a)$$

$$b' = -\frac{1}{360(4\pi)^2} (N_{S} + 11N_{F} + 62N_{V}), \quad (3.6b)$$

with $(N_{S}, N_{F}, N_{V})$ the number of fields of spin $(0, \frac{1}{2}, 1)$ respectively and we have taken $\hbar = 1$.

Three local fourth order curvature invariants $E, F$ and $\Box R$ appear in the trace of the stress tensor, but only the first two ($b$ and $b'$) terms of (3.4) cannot be derived from a local effective action.
of the metric alone. If these terms could be derived from a local gravitational action we could simply make the necessary finite redefinition of the corresponding local counterterms to remove them from the trace, in which case the trace would no longer be non-zero or anomalous. This redefinition of a local counterterm (namely, the $R^2$ term in the effective action) is possible only with respect to the third $b''$ coefficient in (3.4), which is therefore regularization dependent and not part of the true anomaly. Only the non-local effective action corresponding to the $b$ and $b'$ terms in (3.4) lead to the possibility of effects that extend over arbitrarily large, macroscopic distances, unsuppressed by any ultraviolet cutoff scale. The distinction of the two kinds of terms in the effective action (local or not) is emphasized in the cohomological approach to the trace anomaly [10].

The number of massless fields of each spin, $N_S, N_F, N_V$ is a property of the low energy effective description of matter, having no direct connection with physics at the ultrashort Planck scale. Indeed massless fields fluctuate at all distance scales and do not decouple in the far infrared. As in the case of the chiral anomaly with massless quarks, the $b$ and $b'$ terms in the trace anomaly were calculated originally by techniques usually associated with UV regularization (such as dimensional regularization, point splitting or heat kernel techniques) [9]. However just as in the case of the chiral anomaly in QCD, (3.4) and (3.6) can have significant effects in the far infrared as well.

To find the WZ effective action corresponding to the $b$ and $b'$ terms in (3.4), introduce as in two dimensions the conformal parameterization (2.14), and compute

$$\sqrt{-g} F = \sqrt{-\bar{g}} \bar{F},$$

$$\sqrt{-g} \left( E - \frac{2}{3} \Box R \right) = \sqrt{-\bar{g}} \left( \bar{E} - \frac{2}{3} \bar{\Box} \bar{R} \right) + 4 \sqrt{-\bar{g}} \Delta_4 \sigma,$$

whose $\sigma$ dependence is no more than linear. The fourth order differential operator appearing in this expression is [10, 21, 22]

$$\Delta_4 \equiv \Box^2 + 2 R^{ab} \nabla_a \nabla_b - \frac{2}{3} R \Box + \frac{1}{3} (\nabla^a R) \nabla_a,$$

which is the unique fourth order scalar operator that is conformally covariant, *viz.*

$$\sqrt{-g} \Delta_4 = \sqrt{-\bar{g}} \Delta_4,$$

for arbitrary smooth $\sigma(x)$ in four (and only four) dimensions. Thus multiplying (3.3) by $\sqrt{-g}$ and recognizing that the result is the $\sigma$ variation of an effective action $\Gamma_{WZ}$, we find immediately that up to terms independent of $\sigma$, this effective action is

$$\Gamma_{WZ}[\bar{g}; \sigma] = b \int d^4 x \sqrt{-g} F \sigma + b' \int d^4 x \sqrt{-g} \left\{ \left( \bar{E} - \frac{2}{3} \bar{\Box} \bar{R} \right) \sigma + 2 \sigma \Delta_4 \sigma \right\}.$$

(3.10)
This Wess-Zumino action is a one-form representative of the non-trivial cohomology of the local Weyl group and satisfies (2.5) just as its two dimensional analog $\Gamma_{WZ}^{(2)}$ does. Explicitly, by solving (3.7b) formally for $\sigma$ and substituting the result in (3.10) we obtain

$$\Gamma_{WZ}[\bar{g}; \sigma] = \Delta_\sigma \circ S_{\text{anom}}[\bar{g}] = S_{\text{anom}}[g = e^{2\sigma} \bar{g}] - S_{\text{anom}}[\bar{g}],$$

with

$$S_{\text{anom}}[g] = \frac{1}{8} \int d^4x \sqrt{-g} \int d^4x' \sqrt{-g'} \left( E - \frac{2}{3} \Box R \right) x \Delta_{4}^{-1}(x, x') \left[ 2bF + b' \left( E - \frac{2}{3} \Box R \right) \right]_{x', x}$$

and $\Delta_{4}^{-1}(x, x')$ denoting the Green’s function inverse of the fourth order differential operator defined by (3.8). From the foregoing construction it is clear that if there are additional Weyl invariant terms in the anomaly (3.4) they should be included in the $S_{\text{anom}}$ by making the replacement $bF \rightarrow bF + \sum \beta_i H_i$ in the last square bracket of Eq. (3.12).

Because of (3.11) the anomalous effective action is clearly fixed only up to an arbitrary (local or non-local) Weyl invariant functional $S_{\text{inv}}[g]$ of the metric, obeying

$$\Delta_\sigma \circ S_{\text{inv}}[g] = S_{\text{inv}}[e^{2\sigma} g] - S_{\text{inv}}[g] = 0.$$  

Hence the general non-local form of the exact effective action of gravity must be of the form, $S_{\text{anom}} + S_{\text{inv}}$, and behavior under the local Weyl group enables us to classify all terms in the exact effective action into three parts, viz.

$$S_{\text{exact}} = S_{\text{local}} + S_{\text{anom}} + S_{\text{inv}},$$

given by (3.3), (3.12) and (3.13) respectively. As in two dimensions, the anomalous term (3.10) or (3.12) scales linearly with $\sigma_0$, i.e. logarithmically with distance, and is therefore marginally relevant in the infrared with respect to the usual classical flat space fixed point [10]. The fluctuations generated by $S_{\text{anom}}$ also define a non-perturbative Gaussian infrared fixed point, with conformal field theory anomalous dimensions analogous to the two dimensional case [22]. This is possible only because new low energy degrees of freedom are contained in $S_{\text{anom}}$ which can fluctuate independently of the local metric degrees of freedom in $S_{\text{EH}}$. Thus the effective action of the anomaly $S_{\text{anom}}$ should be retained in the EFT of low energy gravity, which is specified then by the first two strictly relevant local terms of the classical Einstein-Hilbert action (3.1), and the logarithmic, marginally relevant $S_{\text{anom}}$, i.e.

$$S_{\text{eff}}[\bar{g}] = S_{\text{EH}}[\bar{g}] + S_{\text{anom}}[\bar{g}]$$
contains all the infrared relevant terms in low energy gravity for \( E \ll M_{Pl} \).

The low energy (Wilson) effective action \( S_{eff} \), in which infrared irrelevant terms are systematically neglected in the renormalization group program of critical phenomena is to be contrasted with the exact (field theoretic) effective action of \( S_{exact} \), in which the effects of all scales are included in principle, at least in the approximation in which spacetime can be treated as a continuous manifold. Ordinarily, i.e. absent anomalies, the Wilson effective action should contain only local infrared relevant terms consistent with symmetry \( [23] \). However, like the anomalous effective action generated by the chiral anomaly in QCD, the non-local \( S_{anom} \) must be included in the low energy EFT to account for the anomalous Ward identities, even in the zero momentum limit; and indeed logarithmic scaling with distance indicates that \( S_{anom} \) is an infrared relevant term. Also even if no massless matter fields are assumed, the quantum fluctuations of the metric itself will generate a term of the same form as \( S_{anom} \). Since all the infrared relevant terms are now included in \( S_{eff} \), it contains all the low energy degrees of freedom of gravity, including also those massless scalar degrees of freedom in the local auxiliary field description which we exhibit below, and which are those responsible for the non-perturbative infrared fixed point with vanishing \( \lambda \) found in \( [22] \). In contrast, the additional terms in \( S_{exact} \), being either marginally or strictly irrelevant in the infrared limit, contain non-universal and state dependent contributions which are not required for a consistent EFT expansion of the gravitational effective action in powers of \( E/M_{Pl} \). Since anomalies are the only way known that the decoupling hypothesis can fail, the neglected terms in \( S_{inv} \) just as those in \( S_{local} \) for \( n \geq 2 \) are also not expected to require the addition of any new degrees of freedom of the gravitational field which are relevant at low energies or macroscopic distances.

The variations of the two \((b \text{ and } b')\) terms in \( S_{anom} \) give rise to two new conserved tensors in the equations of low energy gravity. To find their explicit form and exhibit the new scalar degrees of freedom they contain, it is convenient as in the two dimensional case to rewrite the non-local action \( S_{anom} \) in local form by introducing auxiliary fields. Two scalar auxiliary fields satisfying

\[
\Delta_4 \varphi = \frac{1}{2} \left( E - \frac{2}{3} \square R \right), \tag{3.16a}
\]

\[
\Delta_4 \psi = \frac{1}{2} F, \tag{3.16b}
\]

respectively may be introduced, corresponding to the two non-trivial cocycles of the \( b \) and \( b' \) terms.
in the anomaly \[10\]. It is then easy to see that
\[
S_{\text{anom}}[g; \varphi, \psi] = \frac{b'}{2} \int d^4x \sqrt{-g} \left\{ -\varphi \Delta_4 \varphi + \left( E - \frac{2}{3} \Box R \right) \varphi \right\} 
+ \frac{b}{2} \int d^4x \sqrt{-g} \left\{ -2\varphi \Delta_4 \psi + F\varphi + \left( E - \frac{2}{3} \Box R \right) \psi \right\}
\] 
(3.17)
is the desired local form of the anomalous action \[3.12\] \[24\]. Indeed the variation of \[3.17\] with respect to the auxiliary fields \(\varphi\) and \(\psi\) yields their Eqs. of motion \[3.16\], which may be solved for \(\varphi\) and \(\psi\) by introducing the Green’s function \(\Delta_4^{-1}(x,x')\). Substituting this formal solution for the auxiliary fields into \[3.17\] returns \[3.12\]. The local auxiliary field form \[3.17\] is the most useful and explicitly contains two new scalar fields satisfying the massless fourth order wave equations \[3.16\] with fourth order curvature invariants as sources. The freedom to add homogeneous solutions to \(\varphi\) and \(\psi\) corresponds to the freedom to define different Green’s functions inverses \(\Delta_4^{-1}(x,x')\) in \[3.12\].

The auxiliary scalar fields are new local massless degrees of freedom of four dimensional gravity, not contained in the Einstein-Hilbert action.

As in the two dimensional case, the four dimensional anomalous action has an invariance, in this case \(\psi \to \psi + \psi_0\), with the corresponding Noether current given by:
\[
J^a = \nabla^a \varphi - 2 \left( R^{ab} - \frac{1}{3} g^{ab} \right) \nabla_b \varphi - \frac{1}{2} \Omega^a + \frac{1}{3} \nabla^a R,
\] 
(3.18)

where \(\Omega^a\) is the topological current whose divergence,
\[
\nabla_a \Omega^a = E = R_{abcd} R^{abcd} - 4 R_{ab} R^{ab} + R^2
\] 
(3.19)
is the Euler-Gauss-Bonnet integrand in four dimensions. The current \(J^a\) is conserved,
\[
\nabla_a J^a = \Delta_4 \varphi - \frac{E}{2} + \frac{1}{3} \Box R = 0
\] 
(3.20)
by \[3.16\], and the conserved charge may be taken to be
\[
q = \frac{1}{16\pi^2} \int_{\Sigma} J^a d\Sigma_a
\] 
(3.21)
with \(\Sigma\) a spacelike Cauchy surface on which initial data are specified or
\[
q = \frac{1}{16\pi^2} \oint_{\partial V} J^a d\Sigma_a
\] 
(3.22)
with \(\partial V\) the boundary of a Euclidean four volume \(V\). The normalization of the Noether charge is chosen so that \(q = 1\) corresponds to a delta function source of unit strength in the four dimensional Euler number,
\[
\chi = \frac{1}{32\pi^2} \int d^4x \sqrt{-g} E.
\] 
(3.23)
The constant shift in the other auxiliary field, i.e. \( \phi \rightarrow \phi + \phi_0 \) generates a global rescaling of the metric, and is not a symmetry of the action (3.17) unless \( E - 2 \Box R/3 = F = 0 \). It is worth remarking that this enhanced conformal symmetry applies to solutions of the vacuum Einstein Eqs. if and only if the cosmological term \( \Lambda = 0 \). That the effective action of the anomaly may provide a mechanism to relax the cosmological term to zero was first proposed in ref. [22].

By using the definition of \( \Delta_4 \) and integrating by parts, we may express the anomalous action also in the form,

\[
S_{\text{anom}} = b'S^{(E)}_{\text{anom}} + bS^{(F)}_{\text{anom}},
\]

with

\[
S^{(E)}_{\text{anom}} \equiv \frac{1}{2} \int d^4x \sqrt{-g} \left\{ - (\Box \phi)^2 + 2 \left( R^{ab} - \frac{R}{3} g^{ab} \right) (\nabla_a \phi)(\nabla_b \phi) + \left( E - \frac{2}{3} \Box R \right) \phi \right\};
\]

\[
S^{(F)}_{\text{anom}} \equiv \int d^4x \sqrt{-g} \left\{ - (\Box \phi)(\Box \psi) + 2 \left( R^{ab} - \frac{R}{3} g^{ab} \right) (\nabla_a \phi)(\nabla_b \psi) + \frac{1}{2} F \varphi + \frac{1}{2} \left( E - \frac{2}{3} \Box R \right) \psi \right\}
\]

(3.25)

We note that the \( S^{(E)} \) and \( S^{(F)} \) terms are very similar. Each is composed of terms at most quadratic and linear in the auxiliary fields \( \phi \) and \( \psi \). Defining the general quadratic action,

\[
A[g; \phi, \psi] \equiv \int d^4x \sqrt{-g} \left\{ - (\Box \phi)(\Box \psi) + 2 \left( R^{ab} - \frac{R}{3} g^{ab} \right) (\nabla_a \phi)(\nabla_b \psi) \right\}
\]

(3.26)

and the two linear actions,

\[
B[g; \phi] \equiv \frac{1}{2} \int d^4x \sqrt{-g} \left( E - \frac{2}{3} \Box R \right) \varphi;
\]

(3.27)

\[
C[g; \phi] \equiv \frac{1}{2} \int d^4x \sqrt{-g} F \varphi,
\]

(3.28)

as functionals of the metric and the two auxiliary scalar fields \( \phi \) and \( \psi \), we can express (3.25) in the form,

\[
S^{(E)}_{\text{anom}} = \frac{1}{2} A[g; \phi, \varphi] + B[g; \varphi];
\]

(3.29a)

\[
S^{(F)}_{\text{anom}} = A[g; \phi, \psi] + B[g; \psi] + C[g; \varphi].
\]

(3.29b)

This implies that the covariantly conserved stress tensors derived from the \( E \) and \( F \) terms in the effective action, namely,

\[
E_{ab} = -\frac{2}{\sqrt{-g}} \frac{\delta S^{(E)}_{\text{anom}}}{\delta g^{ab}}
\]

(3.30a)

\[
F_{ab} = -\frac{2}{\sqrt{-g}} \frac{\delta S^{(F)}_{\text{anom}}}{\delta g^{ab}}.
\]

(3.30b)
can be obtained from one fundamental tensor quadratic in the scalar auxiliary fields,

$$A_{ab}[g; \varphi, \psi] \equiv -\frac{2}{\sqrt{-g}} \frac{\delta A[g; \varphi, \psi]}{\delta g^{ab}} = -2 (\nabla_a \varphi)(\nabla_b \Box \psi) - 2 (\nabla_a \psi)(\nabla_b \Box \varphi)$$

$$+ 2 \nabla^c [(\nabla_c \varphi)(\nabla_a \nabla_b \psi) + (\nabla_c \psi)(\nabla_a \nabla_b \varphi)] - \frac{4}{3} \nabla_a \nabla_b [(\nabla_c \varphi)(\nabla_c \psi)]$$

$$+ \frac{4}{3} R_{ab} (\nabla_c \varphi)(\nabla^c \psi) - 4 R^c_{(a} [(\nabla_b) \varphi)(\nabla_c \psi) + (\nabla_b \psi)(\nabla_c \varphi)] + \frac{4}{3} R (\nabla_a \varphi)(\nabla_b \psi)$$

$$+ \frac{1}{3} g_{ab} \left\{ -3 (\Box \varphi)(\Box \psi) + 2 [(\nabla_c \varphi)(\nabla_c \psi)] + 2 \left( 3 R^{cd} - R g^{cd} \right) (\nabla_c \varphi)(\nabla_d \psi) \right\}, \quad (3.31)$$

which is traceless,

$$A^a_{a}[g; \varphi, \psi] = 0,$$  \hspace{1cm} (3.32)

for arbitrary \( \varphi \) and \( \psi \), and two fundamental tensors linear in the scalar auxiliary fields,

$$B_{ab}[g; \varphi] \equiv -\frac{2}{\sqrt{-g}} \frac{\delta B[g; \varphi]}{\delta g^{ab}} = \frac{2}{3} \nabla_a \nabla_b \Box \varphi - 4 C_{a b}^{c d} \nabla_c \nabla_d \varphi$$

$$- 4 R^c_{(a} (\nabla_b) \varphi + \frac{8}{3} R_{ab} \Box \varphi + \frac{4}{3} R \nabla_a \nabla_b \varphi - \frac{2}{3} (\nabla_a R)(\nabla_b \varphi)$$

$$+ \frac{1}{3} g_{ab} \left\{ 2 \Box^2 \varphi + 6 R^{cd} \nabla_c \nabla_d \varphi - 4 R \Box \varphi + (\nabla^c R) \nabla_c \varphi \right\}, \quad (3.33)$$

and

$$C_{ab}[g; \varphi] \equiv -\frac{2}{\sqrt{-g}} \frac{\delta C[g; \varphi]}{\delta g^{ab}} = -4 \nabla_c \nabla_d \left( C_{(a b}^{c d} \varphi \right) - 2 C_{a b}^{c d} R^{c d} \varphi. \quad (3.34)$$

The latter of these is also traceless, whereas the \( B_{ab} \) tensor has a non-zero trace whose value depends on which auxiliary field is substituted, \textit{i.e.}

$$B^a_{a}[g; \varphi] = 2 \Delta_4 \varphi = E - \frac{2}{3} \Box R \quad (3.35a)$$

$$B^a_{a}[g; \psi] = 2 \Delta_4 \psi = F. \quad (3.35b)$$

From (3.24), (3.25), (3.29), (3.31), (3.33) and (3.34) we have

$$T^{\text{anom}}_{ab} = -\frac{2}{\sqrt{-g}} \frac{\delta S_{\text{anom}}}{\delta g^{ab}} = b'E_{ab} + b F_{ab} \quad (3.36)$$

with

$$E_{ab} = \frac{1}{2} A_{ab}[g; \varphi, \varphi] + B_{ab}[g; \varphi] \quad \text{and} \quad (3.37a)$$

$$F_{ab} = A_{ab}[g; \varphi, \psi] + B_{ab}[g; \psi] + C_{ab}[g; \varphi]. \quad (3.37b)$$
Explicitly,

\[ E_{ab} = -2 (∇_a ϕ)(∇_b ϕ) + 2 ∇^c [(∇_c ϕ)(∇_a ϕ)] - \frac{2}{3} ∇_a ∇_b [(∇_c ϕ)(∇^c ϕ)] 
+ \frac{2}{3} R_{ab} (∇_c ϕ) (∇^c ϕ) - 4 R^c_{(a}(∇_b ϕ)(∇_c ϕ) + \frac{2}{3} R (∇_a ϕ)(∇_b ϕ) 
+ \frac{1}{6} g_{ab} \left\{-3 (∇_c ϕ) + 4 [(∇_c ϕ)(∇^c ϕ)] + 2 \left(3R^{cd} - Rg^{cd}\right) (∇_c ϕ)(∇_d ϕ) \right\} \]

\[ - \frac{2}{3} ∇_a ∇_b ϕ - 4 C^c_{a b} ∇_c ∇_d ϕ - 4 R^c_{(a} ∇_b ϕ + \frac{8}{3} R_{ab} ϕ + \frac{4}{3} R ∇_a ∇_b ϕ 
- \frac{2}{3} (∇_a R) (∇_b ϕ) + \frac{1}{3} g_{ab} \left\{2 ∇^2 ϕ + 6 R^{cd} ∇_c ∇_d ϕ - 4 R ∇_a ϕ + (∇^c R)(∇_c ϕ) \right\} , \] (3.38)

and

\[ F_{ab} = -2 (∇_a ϕ)(∇_b ϕ) - 2 (∇_a ϕ)(∇_b ϕ) + 2 ∇^c [(∇_c ϕ)(∇_a ϕ)] + (∇_c ϕ)(∇^c ϕ) 
- \frac{2}{3} R_{ab} (∇_c ϕ)(∇^c ϕ) + \frac{2}{3} R (∇_a ϕ)(∇_b ϕ) 
+ \frac{1}{6} g_{ab} \left\{-3 (∇_c ϕ)(∇_d ϕ) + [∇_c ϕ)(∇^c ϕ)] + 2 \left(3R^{cd} - Rg^{cd}\right) (∇_c ϕ)(∇_d ϕ) \right\} \]

\[ - \frac{2}{3} ∇_a ∇_b ϕ - 4 C^c_{a b} ∇_c ∇_d ϕ - 4 R^c_{(a} ∇_b ϕ + \frac{8}{3} R_{ab} ϕ + \frac{4}{3} R ∇_a ∇_b ϕ 
- \frac{2}{3} (∇_a R) (∇_b ϕ) + \frac{1}{3} g_{ab} \left\{2 ∇^2 ϕ + 6 R^{cd} ∇_c ∇_d ϕ - 4 R ∇_a ϕ + (∇^c R)(∇_c ϕ) \right\} . \] (3.39)

Each of these two tensors are individually conserved and they have the local traces,

\[ E_a^a = 2Δ_4 ϕ = E - \frac{2}{3} ∇^2 R , \] (3.40a)

\[ F_a^a = 2Δ_4 ψ = F = C_{abcd}C^{abcd} , \] (3.40b)

corresponding to the two terms respectively in the trace anomaly in four dimensions (with \( β_i = 0 \)).

Results for the \( E_{ab} \) tensor in terms of the decomposition (2.2), and the \( F_{ab} \) tensor in a slightly different notation were presented previously in refs. 25 and 10, and partial results for \( E_{ab} \) appear also in 24.

It is straightforward to generalize the above development to include the effects of any additional Weyl invariant terms in the trace anomaly, transforming under (2.2) by

\[ √\tilde{g} H_i = √\tilde{g} H_i . \] (3.41)

By making the replacement \( F → F + \sum_i β_i H_i / b \) in (3.16a), (3.17), and (3.24), we observe that \( C[g; ϕ] \) should undergo the replacement,

\[ C[g; ϕ] → C[g; ϕ] + \sum_i β_i H_i / 2b \int d^4 x √\tilde{g} H_i ϕ , \] (3.42)
with the corresponding additional terms in $C_{ab}$ and $F_{ab}$ in (3.34), (3.37b), (3.39), and (3.40b) to take account of any additional contributions to the trace anomaly. Hence no additional scalar auxiliary fields beyond $\varphi$ and $\psi$ are required in the general case.

As in two dimensions, $S_{anom}$ in four dimensions contains massless scalar degrees of freedom which remain relevant at low energies and macroscopic distances, and must be retained in addition to the usual EFT local derivative expansion in order to take account of the non-decoupling of massless fields. In contrast, the Weyl invariant terms in (3.2) or $S_{inv}$ do not contain additional degrees of freedom of the gravitational field which are relevant at energies far below the Planck scale $M_{Pl}$, and are either marginally or strictly irrelevant in the infrared.

In a given fixed spacetime background the solutions of the fourth order differential equations (3.16) for the scalar auxiliary fields $\varphi$ and $\psi$ may be found, and the results substituted into the stress tensors $E_{ab}$ and $F_{ab}$. The freedom to add homogeneous solutions of (3.16) to any given inhomogeneous solution corresponds to the freedom to change the Weyl invariant part of the effective action and corresponding traceless parts of the stress tensors, without altering their local traces (3.40). The traceless terms in the stress tensor thus depend on the state of the underlying quantum field(s) which can be fixed by specifying boundary conditions on the auxiliary fields. When the spacetime is conformally flat or approximately so, the Weyl invariant action $S_{inv}$ can be taken to vanish, as it does in the conformally related flat spacetime, and the low energy effective action (3.15) should become a good approximation to the exact effective action (3.14). In order to test this hypothesis we evaluate the corresponding anomalous stress tensor (3.36) in conformally flat spacetimes for a number of different macroscopic states.

**IV. STRESS-ENERGY TENSOR IN CONFORMALLY FLAT SPACETIMES**

**A. Flat Spacetime**

In flat Minkowski spacetime, $E = F = \Box R = 0$, and the auxiliary fields satisfy the homogeneous wave eqs.,

$$\Delta_{4}^{flat} \varphi = \Box^{2} \varphi = 0 = \Box^{2} \psi.$$  (4.1)

For the trivial solutions $\varphi = \psi = 0$ (or an arbitrary spacetime constant), the stress tensor vanishes identically. This corresponds to the ordinary Lorentz invariant vacuum state, with vanishing renormalized $\langle T_{a}^{b} \rangle$. Hence flat spacetime will continue to satisfy the Einstein equations modified
by the trace anomaly terms (with vanishing cosmological term).

In flat spacetime the wave Eq. (4.1) has plane wave solutions obeying the massless dispersion relation, $\omega_k = \pm |k|$. Since the wave operator here, $\Box^2$ is fourth order, there are two sets of massless scalar modes for each auxiliary field, $\varphi$ and $\psi$. These are new local scalar degrees of freedom for the gravitational field not present in classical general relativity, and give rise to scalar gravitational waves. These scalar gravitational waves of the augmented effective theory have as their sources the fourth order curvature invariants, $E, F$ and $\Box R$ which are quite small for most astrophysical sources, excepting perhaps those of cosmological origin. Hence in the flat space limit the scalar degrees of freedom decouple completely. Even in the presence of matter, they couple only indirectly through the effects of spacetime curvature, and only very weakly at that. Localized sources act as only very weak generators of scalar gravitational radiation in the $\varphi$ and $\psi$ fields, and primordial scalar gravitational radiation, even if present, would be difficult to detect, except indirectly through the gravitational effects of the stress-energy (3.36). The effects on the production of scalar gravitational waves from the coupling of $\psi$ to gauge fields through the $H_i$ terms in the trace (3.4) is also possible, and merits a separate investigation.

For non-vanishing $\varphi$ the tensor $E_{ab}$ in flat space becomes

$$E_{ab}\big|_{\text{flat}} = -2 (\nabla(a \varphi)(\nabla(b \Box \varphi)) + 2(\Box \varphi)(\nabla_a \nabla_b \varphi) + \frac{2}{3}(\nabla_c \varphi)(\nabla^c \nabla_a \nabla_b \varphi) - \frac{4}{3}(\nabla_a \nabla_c \varphi)(\nabla_b \nabla^c \varphi) + \frac{1}{6} g_{ab} \left\{-3 (\Box \varphi)^2 + (\Box (\nabla_c \varphi \nabla^c \varphi)\right\} - \frac{2}{3} \nabla_a \nabla_b \Box \varphi,$$  \hspace{1cm} (4.2)

in general curvilinear coordinates. We note that although the energy density for the scalar auxiliary fields is not positive definite, this does not lead to any instability at macroscopic distances in flat space, because of the decoupling of the auxiliary fields in the flat space limit. In ref. 25, the physical state space of the conformal scalar fluctuations of $S_{\text{anom}}$ (proportional to $\varphi$), once decoupled from metric fluctuations, was shown to have positive norm, and be free of any tachyon or ghost modes. When $S_{\text{anom}}$ is considered together with the classical Einstein-Hilbert terms, because of the higher derivatives in the auxiliary field stress tensor, instability in flat space appears only at ultrashort Planck scale wavelengths 26, i.e. at the order of the cutoff scale and outside the range of validity of the low energy EFT approach. At the Planck scale the local expansion of the effective action in powers of $E^2/M_{pl}^2$ clearly breaks down. For $E \ll M_{pl}$ where the low energy effective action (3.15) can be applied, the auxiliary fields are coupled very weakly and indirectly to matter and propagate as very nearly non-interacting free field scalar excitations. This shows that empty flat space is stable to the effects of $S_{\text{anom}}$ on macroscopic distance scales, and more subtle signatures...
of the presence of $S_{\text{anom}}$ in nearly flat spacetimes must be sought.

As a simple example of how the stress tensor (4.2) may be used to evaluate macroscopic semi-classical effects of quantum fields in flat space, consider the special solution to (4.1),

$$\varphi = \frac{c_1 z^2}{2a^2}$$  \hspace{1cm} (4.3)

for some constant $a$ with dimensions of length and $c_1$ dimensionless. With a similar ansatz for $\psi = c_2 z^2/2a^2$ the total stress tensor of the anomaly (3.36) becomes

$$T_{ab}^{(\text{anom})} = \frac{C}{3a^4} \text{diag} \left(-1, 1, 1, -3\right), \quad (4.4)$$

with $C = c_1^2 b' + 2bc_2^2$. This is the form of the stress tensor of the Casimir effect in region between two infinite parallel plates a distance $a$ apart in the $z$ direction. The constants $c_1, c_2$ and $C$ depend on the boundary conditions which the quantum field(s) obey on the plates, and parameterize the discontinuities in the components of the stress tensor there, but the generic form of the stress tensor appropriate for the geometry of two parallel conducting plates follows from the simple ansatz (4.3) for the classical auxiliary fields together with (3.36). Thus the low energy effective action of the trace anomaly in curved space correctly determines the form of the traceless components of the macroscopic quantum stress tensor for the parallel plate geometry in flat space.

If instead of (4.3) we choose

$$\varphi = \frac{c_1}{2} T^2 t^2$$  \hspace{1cm} (4.5)

with $\psi = c_2 T^2 t^2/2$ the stress tensor (3.36) becomes

$$T_{ab}^{(\text{anom})} = C T^4 \frac{6}{6} \text{diag} \left(-3, 1, 1, 1\right), \quad (4.6)$$

with $C = -c_1^2 b' + 2bc_2^2$ which is the form of the stress tensor for massless radiation at temperature $T$, which is again traceless in flat space. The same form for the anomalous stress tensor is also obtained by considering the general static spherically symmetric ansatz, $\varphi = \varphi(r)$. Then

$$\varphi = \frac{c_{-1}}{r} + c_0 + c_1 r + c_2 r^2,$$  \hspace{1cm} (4.7)

with $c_{-1} = 0$ to ensure a regular stress tensor at the origin. We note that although a thermal state is a mixed state for the radiation field, it is a macroscopic pure coherent state for the gravitational auxiliary potentials at the semi-classical level, where fluctuations around the mean stress tensor $\langle T_{ab} \rangle = T_{ab}^{(\text{anom})}$ are neglected.
For the four dimensional Rindler metric,

$$ds^2 = -\rho^2 d\eta^2 + d\rho^2 + dy^2 + dz^2$$

and $\varphi = \varphi(\rho)$, $\Delta_4 \varphi = \Box^2 \varphi = 0$ has the non-trivial solutions $\rho^2 \ln \rho, \rho^2$ and $\ln \rho$. The first two solutions lead to stress tensors which are non-vanishing at infinity similar to the thermal state, while the $\ln \rho$ solution for $\varphi$ and $\psi$ gives

$$T_a^b = \frac{C}{\rho^4} \text{diag}(-3, 1, 1, 1).$$

Adding a term linear in $\eta$ to the solution for $\varphi(\rho)$ gives a stress tensor of the same form as (4.9) with a different constant $C$. In either case the form of the stress tensor (4.9) is that of the Fulling-Rindler state in four dimensions [27]. Because of (2.24), the solution gives rise to a singularity in $\Box \varphi$ at $\rho = 0$ proportional to $\delta(\rho)/\rho$, and therefore is a solution only in the distributional sense, as in the two dimensional case. The higher order derivatives in the Noether current in four dimensions produce higher order singularities at $\rho = 0$, and the conformally transformed metric $e^{-\varphi}ds^2$ is singular at $\rho = 0$ for any $c_1 \neq 0$.

**B. de Sitter Spacetime**

In conformally flat spacetimes with $g_{ab} = e^{2\sigma} \eta_{ab}$, one can choose $\varphi = 2\sigma$ and $\psi = 0$ to obtain the stress tensor of the state conformally transformed from the Minkowski vacuum. In this state $E_{ab}$ vanishes, and $\varphi$ can be eliminated completely in terms of the Ricci tensor with the result [10, 28, 29],

$$E_{ab} = -2 (^{(3)}H_{ab}) - \frac{1}{9} (^{(1)}H_{ab})$$

$$= \frac{2}{9} \nabla_a \nabla_b R + 2R_a^\varsigma R_{b\varsigma} - \frac{14}{9} RR_{ab} + g_{ab} \left( -\frac{2}{9} \Box R - R_{cd}R^{cd} + \frac{5}{9} R^2 \right).$$

Thus all non-local dependence on boundary conditions of the auxiliary fields $\varphi$ and $\psi$ vanishes in conformally flat spacetimes for the state conformally mapped from the Minkowski vacuum. In the special case of maximally $O(4,1)$ symmetric de Sitter spacetime, $R_{ab} = 3H^2 g_{ab}$ with $R = 12H^2$ a constant, the tensor $^{(1)}H_{ab}$ vanishes identically and

$$E_{ab} \bigg|_{dS} = -2 (^{3})H_{ab} \bigg|_{dS} = 6H^4 g_{ab}.$$
Hence we obtain immediately the expectation value of the stress tensor of a massless conformal field of any spin in the Bunch-Davies state in de Sitter spacetime,

\[
T_{ab}^{BD,dS} = 6b' H^4 g_{ab} - \frac{H^4}{960 \pi^2} g_{ab} (N_s + 11N_f + 62N_v),
\]

which is determined completely by the trace anomaly.

It is also possible to consider states which are not maximally \(O(4,1)\) symmetric. For example, if de Sitter spacetime is expressed in the spatially flat coordinates,

\[
ds^2 \mid_{dS} = -d\tau^2 + e^{2H\tau} d\vec{x}^2
\]

and \(\varphi = \varphi(\tau)\), we obtain from (3.38) the stress-energy in spatially homogeneous, isotropic states. Since in this maximally symmetric spacetime the \(\Delta_4\) operator factorizes,

\[
\Delta_4 \mid_{dS} \varphi = (\Box - 2H^2) (\Box \varphi) = 12H^4.
\]

it is straightforward to show that the general solution to this equation with \(\varphi = \varphi(\tau)\) is

\[
\varphi(\tau) = 2H\tau + c_0 + c_{-1}e^{-H\tau} + c_{-2}e^{-2H\tau} + c_{-3}e^{-3H\tau}.
\]

The first (inhomogeneous) term can be understood geometrically from the fact that the conformal transformation,

\[
e^{-\varphi_{BD}} ds^2 \mid_{dS} = e^{-2H\tau} ds^2 \mid_{dS} = -d\eta^2 + d\vec{x}^2
\]

brings de Sitter spacetime to flat spacetime, with \(\eta = -H^{-1}e^{-H\tau}\) the conformal time. This value of \(\varphi = \varphi_{BD}(\tau) \equiv 2H\tau\) is exactly the one that gives the Bunch-Davies stress-energy (4.12) when substituted into (3.38). When the full solution for \(\varphi(\tau)\) of (4.15) is substituted into (3.38) we obtain additional terms in the stress tensor which are not de Sitter invariant, but which fall off at large \(\tau\), as \(e^{-4H\tau}\). The stress tensor of this time behavior is traceless and corresponds to the redshift of massless modes with the equation of state, \(p = \rho/3\). This is a special case of the detailed analysis of the stress tensor expectation value of a field of arbitrary mass in homogeneous, isotropic states in de Sitter spacetime of ref. \[29\]. It is straightforward to generalize these considerations to spatially homogeneous and isotropic states in arbitrary conformally flat cosmological spacetimes with Robertson-Walker scale factor \(a(\eta)\). Because of the reduction of the auxiliary field stress tensor \(E_{ab}\) to the local geometric form \(4.10\) in conformally flat spacetimes, it can have no significant effects in states with Robertson-Walker symmetries when the curvature is much less than the Planck scale.
States of lower symmetry in de Sitter spacetime may be considered by taking static coordinates,

\[ ds^2 = -f(r)dt^2 + \frac{dr^2}{f(r)} + r^2d\Omega^2, \tag{4.17} \]

where

\[ f(r)|_{dS} = 1 - H^2r^2. \tag{4.18} \]

If we insert the ansatz \( \varphi = \varphi(r) \) in (4.14), the general \( O(3) \) spherically symmetric solution regular at the origin is easily found:

\[ \varphi(r)|_{dS} = \ln (1 - H^2r^2) + c_0 + \frac{q}{2} \ln \left( \frac{1 - Hr}{1 + Hr} \right) + \frac{2c_0 - 2 - q}{2Hr} \ln \left( \frac{1 - Hr}{1 + Hr} \right). \tag{4.19} \]

A possible homogeneous solution proportional to \( 1/r \) has been discarded, since it is singular at the origin. An arbitrary linear time dependence \( 2Hp t \) could also be added to \( \varphi(r) \), i.e. \( \varphi(r) \rightarrow \varphi(r, t) = \varphi(r) + 2Hp t \). The particular solution,

\[ \varphi_{BD}(r, t) = \ln (1 - H^2r^2) + 2Ht = 2H\tau. \tag{4.20} \]

is simply the previous solution for the Bunch-Davies state we found in the homogeneous flat coordinates (4.13). The priveleged role of this fully \( O(4,1) \) invariant state may be understood in the static coordinates by recognizing that the line element (4.17) may be put into the alternate forms,

\[
\begin{align*}
    ds^2 &= f \left[ -dt^2 + dr^2 + \frac{r^2}{f} d\Omega^2 \right], \\
    &= f \left[ -dt^2 + \ell^2 (d\chi^2 + \sinh^2 \chi d\Omega^2) \right], \\
    &= \frac{\ell^2}{\rho^2} \left[ -d\rho^2 + \rho^2 (d\chi^2 + \sinh^2 \chi d\Omega^2) \right], \\
    &= \frac{f}{\rho^2} (-d\eta^2 + d\vec{x}^2), \\
    &= e^{\varphi_{BD}}(ds^2)_{flat}. \tag{4.21}
\end{align*}
\]

by means of the successive changes of variables, \( \ell = H^{-1} \),

\[
\begin{align*}
    \chi &= Hr^* = H \int_0^r \frac{dr}{f(r)} = \frac{1}{2} \ln \left( \frac{1 + Hr}{1 - Hr} \right), \\
    t &= -\ell \ln \rho, \\
    \eta &= \ell \rho \cosh \chi, \\
    \vec{x} &= \ell \rho \sinh \chi (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta). \tag{4.22}
\end{align*}
\]
Thus de Sitter spacetime in static coordinates is conformally related to flat spacetime by the conformal transformation $e^{\varphi_{BD}}$ with $\varphi_{BD}$ given by (4.20) as before. The benefit of carrying this out explicitly in the static coordinates is that the steps in (4.21) can be repeated essentially unchanged in the vicinity of any static Killing horizon, without reliance on the special higher symmetries of de Sitter spacetime. Then

$$\varphi_h(r,t) = \ln f(r) \pm \frac{2}{\ell} t$$

is the value of the auxiliary field which conformally transforms the local neighborhood of the horizon to flat spacetime. In de Sitter space this leading order conformal transformation mapping the vicinity of the horizon to flat space is exact, cf. (4.21).

In the general $O(3)$ symmetric state in de Sitter spacetime the radial component of the Noether current,

$$J^r = \nabla^r \square \varphi - 2H^2 \nabla^r \varphi - \frac{1}{2} \Omega^r = \frac{2Hq}{r^2},$$

in the frame in which $\Omega^r = 8H^4r$. Thus the parameter $q$ coincides with the definition (3.21) and if non-zero gives rise to a delta function singularity for $\Delta_4\varphi$ at the origin $r = 0$. It is also the strength of the puncture configurations (also called “spikes”) found in [30].

In the general $O(3)$ symmetric state centered about the origin of the coordinates $r = 0$, the stress tensor is generally dependent on $r$. In fact, it generally diverges as the observer horizon $r = H^{-1}$ is approached. From (4.19) we observe that

$$\varphi(r) \bigg|_{dS} \to c_H \ln \left( \frac{1-Hr}{2} \right) + O(1-Hr) \quad \text{as} \quad Hr \to 1,$$

so that the integration constant $c_H$ controls the singular behavior at the observer horizon $r = H^{-1}$. As in the Schwarzschild case a non-zero $c_H$ produces a higher order singular distribution for $\Delta_4\varphi$ at the horizon.

The second auxiliary field $\psi$ satisfies the homogeneous Eq., $\Delta_4\psi = 0$, which has the general spherically symmetric solution linear in $t$,

$$\psi(r,t) \bigg|_{dS} = d_0 + 2Hp't + \frac{q'}{2} \ln \left( \frac{1-Hr}{1+Hr} \right) + \frac{2d_H}{2Hr} - \frac{q'}{2Hr} \ln \left( \frac{1-Hr}{1+Hr} \right).$$

Note that the constant $d_H$ enters this expression differently than $c_H$ enters the corresponding Eq. (4.19), due to the inhomogeneous term in (4.14), which is absent from the $\psi$ equation.
Since the anomalous stress tensor is independent of $c_0$ and $d_0$, it depends on the six parameters $(c_H, d_H, q, q', p, p')$ in the general stationary $O(3)$ invariant state. However, in order to have no singularity of the stress tensor at the origin we must choose $q = q' = 0$. With no sources or sinks at the origin, the choice $q = q' = 0$ then satisfies the zero flux condition,

$$T^r_r = -4H^2 (bpq' + bp'q + b'pq) = 0$$

(4.27)

automatically, for any $p$ and $p'$. For the other components of the stress tensor $\mathbf{(3.36)}$, the conditions of finiteness on the observer horizon at $r = H^{-1}$ are

$$c_H = 1, \quad p = \pm 1, \quad d_H = \pm p'$$

(4.28)

which are satisfied by the Bunch-Davies state with $p = 1$ and $d_H = p' = 0$. On the other hand, the local vacuum state at the origin (i.e. the analog of the Boulware vacuum $\mathbf{3.1}$ in de Sitter space) we should take $p = p' = 0$. Since this is inconsistent with (4.28), this state has a diverging stress-energy on the observer horizon. There is no analog of the Unruh state $\mathbf{3.2}$ in de Sitter spacetime, since by continuity a flux through the future or past observer horizon at $r = H^{-1}$ would require a source or sink of flux at the origin $r = 0$, a possibility we have excluded by (4.27) above.

V. NEAR HORIZON CONFORMAL SYMMETRY AND STRESS TENSOR

The fact that the trace anomaly can account for even the tracefree parts of the stress tensor exactly in two dimensions and conformally flat spacetimes in higher dimensions is due to the fact that $S_{\text{inv}}$ may be neglected in these cases. In these circumstances the low energy effective action $\mathbf{(3.15)}$ becomes a good approximation to the exact effective action $\mathbf{(3.14)}$. However, as has been noted by several authors $\mathbf{3.1}$, spacetimes with a static Killing horizon are locally conformally related to flat spacetime in the vicinity of the horizon. Because of this near horizon conformal symmetry we expect the anomalous action $\mathbf{(3.12)}$ to generate a stress tensor $\mathbf{(3.36)}$ which is a good approximation to the quantum stress tensor near an arbitrary Killing horizon.

To exhibit the conformal geometry of a static Killing horizon consider the general static spherically symmetric spacetime of the form $\mathbf{(4.17)}$, where the function $f(r)$ possesses a simple zero at $r = r_+$, i.e.,

$$f(r) = \pm \frac{2}{\ell} (r - r_+) + \mathcal{O}(r - r_+)^2.$$  

(5.1)
Defining \( r^* \) in the usual way,

\[
r^* = \int_r^\infty \frac{dr}{f(r)} \simeq \pm \frac{\ell}{2} \ln f + \ldots ,
\]

(5.2)

where the ellipsis denotes regular terms as \( f \to 0 \), and

\[
\chi = -\frac{1}{2} \ln \left( \frac{\ell^2 f}{4r_+^2} \right) = \mp \frac{r^*}{\ell} + \ldots ,
\]

(5.3)

we find that near \( r = r_+ \),

\[
\frac{r^2}{f(r)} \simeq \frac{\ell^2}{4} e^{2\chi} \simeq \ell^2 \sinh^2 \chi .
\]

(5.4)

Hence we may repeat the steps [4.22] of the previous de Sitter case for an arbitrary spherically symmetric static Killing horizon, in the vicinity of the horizon. The length scale \( \ell \) is also related to the surface gravity of the horizon by \( \ell^{-1} = \kappa \). Thus we have the conformal mapping [4.21] of the near horizon metric (4.17) to the flat metric with \( \varphi \simeq \varphi_h(r,t) \) given by (4.23). Since this conformal transformation is singular at \( r = r_+ \), the exact effective action (3.14) is dominated by its anomalous contribution \( S_{\text{anom}} \), and the stress-energy is dominated by (3.36) in any state for which \( \varphi \) and the corresponding \( T_a^b \) diverges on the horizon. Hence the near horizon conformal symmetry (4.21) may be used to calculate the exact behavior of the divergent terms of the quantum stress-energy tensor from (3.36) in any spherically symmetric static spacetime with a Killing horizon. We illustrate this for the most important case of Schwarzschild spacetime.

**A. Schwarzschild Spacetime**

In the four dimensional Schwarzschild geometry, \( f(r) = 1 - \frac{2M}{r} \simeq r/2M - 1 + O(r - 2M)^2 \). Hence \( r_+ = 2M \) and \( \ell = 4M \). The conformal transformation that maps the near horizon geometry to flat spacetime is therefore

\[
\varphi_h(r,t) = \ln f \pm \frac{t}{2M} .
\]

(5.5)

Since Schwarzschild spacetime is not globally conformally flat the conformal transformation of the near horizon geometry will receive subleading corrections to (5.5). To find these subleading terms we require the general solution to (3.16). Noting that Schwarzschild spacetime is Ricci flat, we have

\[
F|_S = E|_S = R_{abcd}R^{abcd}|_S = \nabla_a \Omega^a = \frac{48M^2}{r^6} .
\]

(5.6)
A particular solution of either of the inhomogeneous Eqs. (3.16) is given then by \( \bar{\varphi}(r) \), with

\[
\left. \frac{d\bar{\varphi}}{dr} \right|_S = -\frac{4M}{3r^2f} \ln \left( \frac{r}{2M} \right) - \frac{1}{2M} \left( 1 + \frac{4M}{r} \right). \tag{5.7}
\]

Notice that this particular inhomogeneous solution to (3.16) is regular as \( r \to 2M \). The general solution of (3.16) for \( \varphi = \varphi(r) \) away from the singular points \( r = (0, 2M, \infty) \) is easily found and may be expressed in the form [24],

\[
\left. \frac{d\varphi}{dr} \right|_S = \left. \frac{d\bar{\varphi}}{dr} \right|_S + \frac{2M c_H}{r^2f} + \frac{q - 2}{2M - 2} \ln \frac{r}{2M} + \frac{c_\infty}{2M} \left( \frac{r}{2M} + 1 + \frac{2M}{r} \right)
\]

\[
= \frac{q - 2}{6M} \left( \frac{r}{2M} + 1 + \frac{2M}{r} \right) \ln \left( 1 - \frac{2M}{r} \right) - \frac{q}{6r} \left[ \frac{4M}{r - 2M} \ln \left( \frac{r}{2M} \right) + \frac{r}{2M} + 3 \right]
\]

\[
- \frac{1}{3M} - \frac{1}{r} + \frac{2M c_H}{r(r - 2M)} + \frac{c_\infty}{2M} \left( \frac{r}{2M} + 1 + \frac{2M}{r} \right). \tag{5.8}
\]

in terms of the three dimensionless constants of integration, \( c_H, c_\infty, \) and \( q \). This expression has the limits,

\[
\left. \frac{d\varphi}{dr} \right|_S \to \frac{c_H}{r - 2M} + \frac{q - 2}{2M} \ln \left( \frac{r}{2M} \right) - \frac{1}{2M} \left( 3c_H - c_H - q - \frac{5}{3} \right) + \ldots, \quad r \to 2M, \tag{5.9a}
\]

\[
\left. \frac{d\varphi}{dr} \right|_S \to \frac{c_\infty r}{4M^2} + \frac{2c_\infty q}{4M} + \frac{c_\infty}{r} - \frac{2M}{3r^2} q \ln \left( \frac{r}{2M} \right) + \frac{2M}{r^2} \left[ c_H - \frac{7}{18}(q - 2) \right] + \ldots, \quad r \to \infty. \tag{5.9b}
\]

Hence \( c_H \) controls the leading behavior as \( r \) approaches the horizon, while \( c_\infty \) controls the leading behavior as \( r \to \infty \), which is the same as in flat space. The leading behavior at the horizon is determined by the homogeneous solution to (3.16), \( c_H \ln f = c_H \ln(-K a K_a) \frac{d}{dt} \) where \( K = \partial_t \) is the timelike Killing field of the Schwarzschild geometry for \( r > 2M \). To the general spherically symmetric static solution (5.8) we may add also a term linear in \( t \), i.e. we replace \( \varphi(r) \) by

\[
\varphi(r, t) = \varphi(r) + \frac{p}{2M} t. \tag{5.10}
\]

Linear time dependence in the auxiliary fields is the only allowed time dependence that leads to a time-independent stress-energy. We see that the conformal transformation to flat space near the horizon (5.5) corresponds to the particular choice \( c_H = \pm p = 1 \), leaving the subdominant terms in (5.9a) parameterized by \( q \) and \( c_\infty \) undetermined.

The topological charge \( q \) may be identified from

\[
\nabla^\ast \Box \varphi = -\frac{8M^2}{r^5} + \frac{q}{2M r^2}, \tag{5.11}
\]

so that \( q \) is given by (3.22) in the Euclidean signature Schwarzschild geometry in the frame in which \( \Omega^r = -16M^2/r^5 \) and \( \Omega^t = 0 \). A non-zero \( q \) gives \( \Delta_4 \varphi \) a delta function singularity at the origin.
Non-zero $c_H$ or $c_\infty$ produce higher order singular distributions in $\Delta_4\varphi$ at the horizon or infinity respectively. We note that unlike in flat space there are logarithmic terms in $\varphi(r)$ and no value of $q$ which can eliminate the subleading logarithmic behavior of $\varphi'$ at both $r = 2M$ and $r = \infty$.

Since the equation for the second auxiliary field $\psi$ is identical to that for $\varphi$, its solution for $\psi = \psi(r,t)$ is of the same form as (5.8) and (5.10) with four new integration constants, $d_H, d_\infty, q'$ and $p'$ replacing $c_H, c_\infty, q$, and $p$ in $\varphi(r,t)$. Adding terms with any higher powers of $t$ or more complicated $t$ dependence produces a time dependent stress-energy tensor. Inspection of the stress tensor terms in (3.36) also shows that it does not depend on either a constant $\varphi_0$ or $\psi_0$ but only the derivatives of both auxiliary fields in Ricci flat metrics such as Schwarzschild spacetime. For that reason we do not need an additional integration constant for either of the fourth order differential equations (3.16).

With the general spherically symmetric solution for $\varphi(r,t)$ and $\psi(r,t)$, we can proceed to compute the stress-energy tensor in a stationary, spherically symmetric quantum state. For example the Boulware state may be characterized as that state which approaches the flat space vacuum as rapidly as possible as $r \to \infty$ [31]. In the flat space limit this means that the allowed $r^2$ and $r$ behavior in the auxiliary fields ($r$ and constant behavior in their first derivatives) must be set to zero. Inspection of the asymptotic form (5.9b) shows that this is achieved by requiring

$$
c_\infty = d_\infty = 0 \quad \text{and} \quad q = q' = 0. \quad \text{(Boulware)} \quad (5.12a, b)
$$

If we set $p = p' = 0$ as well, in order to have a static ansatz for the Boulware state, then the remaining two constants $c_H$ and $d_H$ are free parameters of the auxiliary fields, and lead to a stress-energy which generically has the divergent behaviors,

$$s^{-2}, \quad s^{-1}, \quad \ln^2 s, \quad \text{and} \quad \ln s, \quad \text{as} \quad s \equiv \frac{r - 2M}{M} \to 0, \quad (5.13)$$

on the horizon. It is not possible to cancel all four of these divergent behaviors with the two remaining free parameters. As in the two dimensional case, it is not possible to have auxiliary fields and stress-energies which both fall off at infinity and are regular on the horizon. This macroscopic effect of the trace anomaly is a result of the non-trivial global topology of the Schwarzschild metric, notwithstanding the smallness of local curvature invariants at the horizon.

The linear time dependence (5.10) is consistent with the singular behaviors (5.13) of the stress-energy on the horizon. Since the stress-energy in the Boulware state diverges as $s^{-2}$ in any case,
we can match this leading divergence in the anomalous stress tensor by adjusting $c_H$ and $d_H$ appropriately. One then has a one parameter fit to the numerical data of \[34\]. The results of this fit of \[3.36\] with $c_H$ and $d_H$ treated as free parameters are illustrated in Figs. 1, for all three non-zero components of the stress tensor expectation value of a massless, conformally coupled scalar field in the Boulware state. The best fit values plotted were obtained with $c_H = -\frac{7}{20}$ and $d_H = \frac{55}{84}$.

For comparison purposes, we have plotted also the analytic approximation of Page, Brown, and Ottewill \[35, 36, 37\] (dashed curves in Figs. 1). We observe that the two parameter fit with the anomalous stress tensor in terms of the auxiliary $\phi$ and $\psi$ fields is more accurate than the approximation of refs. \[35, 36, 37\] for the Boulware state. In the latter case the stress-tensor is approximated by making a special conformal transformation $\sigma = \frac{1}{2} \ln f = \frac{1}{2} \ln(-K^aK_a)$ to the optical metric, obtained from the Schwarzschild line element \[4.17\] by dividing by $f(r) = 1 - \frac{2M}{r}$. This procedure was also motivated by the form of the trace anomaly, in that for ultrastatic metrics with the timelike Killing field $K^a$, the optical metric conformally related it has vanishing trace anomaly \[36\]. However, unlike the general form of the anomalous stress tensor in \[3.36\], which involves solving linear equations for two independent auxiliary fields, the approximation of refs. \[35, 36, 37\] is applicable only to special cases, such as Schwarzschild geometry which are both ultrastatic and Ricci flat, and admit a particular conformal transformation to the static optical metric. In contrast the approach based on the auxiliary field anomalous effective action does not require any special properties of the background spacetime, and because of the near horizon conformal symmetry gives the general form of the divergences of the stress-energy on horizon.

An important practical difference between these approximations and that considered here is that they yield simple algebraic approximations to the stress-energy, whereas \[3.36\] generally contains logarithmic terms as well. Evidently the general form of the effective stress-energy tensor due to the anomaly in terms of two auxiliary fields and the freedom to add homogeneous solutions to the linear Eqs. \[3.16\] allows for a better approximation to the exact stress tensor in the Boulware state than that of refs. \[35, 36, 37\] near the Schwarzschild horizon.

The stress-energy diverges on the horizon in an entire family of states for generic values of the eight auxiliary field parameters $(c_H, q, c_\infty, p; d_H, q', d_\infty, p')$, in addition to the Boulware state. Hence in the general allowed parameter space of spherically symmetric macroscopic states, horizon divergences of the stress-energy are quite generic, and not restricted to the Boulware state. On the other hand, the condition \[2.32\] that the stress-energy on the horizon be finite gives four conditions on these eight parameters, in order to cancel the four possible divergences listed in \[5.13\]. Referring
to the explicit form of the stress-energy components in static spherically symmetric spacetimes

given in the Appendix, these four conditions can be satisfied in several different ways. The simplest
possibility with the minimal number of conditions on the auxiliary field parameters is via

\[ \begin{align}
    (2b + b')c_H^2 &+ p(2bp' + b'p) = 0, \quad (s^{-2}), \\
    (b + b')c_H &= b_d H, \quad (s^{-1}), \\
    q &= q' = 2, \quad (\ln^2 s \text{ and } \ln s). \quad \text{(horizon finiteness)}
\end{align} \]

(5.14a) \hspace{1cm} (5.14b) \hspace{1cm} (5.14c)

It is noteworthy that this cancellation requires a non-zero topological charge \( q = 2 \), much as in
the two dimensional Schwarzschild case, and again unlike the Fulling-Rindler case in either two
or four dimensions. The \( q = 2 \) condition may be understood from the fact that it cancels the
logarithmic divergence of \( \ln f \) in the second form of (5.8), leaving however a logarithmic singularity
and non-trivial topological charge at both the origin and infinity.

Also noteworthy is that the auxiliary field configurations which lead to diverging stress
tensors on the horizon have \textit{finite action} (3.24). This is clear from the fact that

\[ \mathcal{L} \varphi \rightarrow \frac{q - 2}{4M^2} \ln \left( \frac{r}{2M} - 1 \right) + \text{const.} \quad \text{as} \quad r \rightarrow 2M. \]

(5.15)

Hence both \((\Box \varphi)^2\) and \((\Box \varphi)(\Box \psi)\) are proportional to \(\ln^2(r/2M - 1)\), which is integrable with
respect to the measure \(r^2dr\) as \(r \rightarrow 2M\), and the integrals in (3.25) converge at the horizon for
the general solution (5.10) of the auxiliary field equations. This is not the case at infinity, unless
the four constants \(c_\infty, d_\infty, q, q'\) are all required to vanish. From (5.8) in this case the auxiliary
fields fall off at large distances \(r \gg 2M\) similarly to the scalar potential of Newtonian gravity, or
Brans-Dicke theory [38]. Because of the very different way they couple to spacetime curvature, the
auxiliary fields of \(S_{\text{anom}}\) give only a very weak long-range interaction between massive bodies, that
falls off very rapidly with distance (at least as fast as \(r^{-7}\)). Thus from consideration of the general
form of the anomalous action and auxiliary fields in the vicinity of the Schwarzschild horizon and
their falloff at infinity, we find no \textit{a priori} justification for excluding generic states with stress-energy
tensors that grow without bound as the horizon is approached. In such states the backreaction of
the stress-energy on the geometry will be substantial in this region and lead to qualitatively new
macroscopic effects on the horizon scale.

If instead of requiring rapid falloff at infinity we require regularity of the stress-energy on the
horizon, \textit{i.e.} conditions (5.14), which is a four parameter restriction of the eight parameters in the
auxiliary fields of the form (5.8) and (5.10). These are the conditions appropriate to the Hartle-
Hawking-Israel and Unruh states [32, 39]. Because of the linear time dependence (5.10) we also
obtain a no-zero flux $\langle T_{t}^{t} \rangle$ in general. For the Hartle-Hawking state the vanishing of this flux gives a fifth condition, \textit{viz.}

$$b(qp' + q'p) + b'pq = 0, \quad \text{(zero flux)} \quad (5.16)$$

on the parameters of the auxiliary fields. Of the remaining three parameters two can be fit by the finite values of $\langle T_{t}^{t} \rangle$ on the horizon and at infinity respectively. This leaves one final parameter free to adjust for a best fit of the form of all three components of the stress-energy tensor at intermediate points.

Alternately, the conformal transformation (5.5) could be used to fix the leading order behavior of the auxiliary field $\varphi$ near the horizon, \textit{i.e.} $c_{\mu} = 1 = \pm p$. Then (5.16) fixes $p'$ which with $q = q'$ becomes redundant with the first of the conditions (5.14). Hence only $c_{\infty}$ and $d_{\infty}$ are left undetermined, and no free parameters at all are left if the values of $\langle T_{t}^{t} \rangle$ on the horizon and at infinity are fixed. Using the first method with one free parameter, the results for the $\langle T_{t}^{t} \rangle$ component of the scalar, Dirac spin $\frac{1}{2}$ and electromagnetic fields are shown in Figs. 2 (solid curves), for typical values of the parameters. The data points plotted in Figs. 2a and 2b are the numerical results of the direct quantum field theory calculations for spin 0 and $\frac{1}{2}$ of refs. [40] and [41] respectively. In the spin 1 case the dashed curve represents the numerical results of ref. [42] in an accurate analytic polynomial fit to their data provided by the same authors.

We note that the energy density in the Hartle-Hawking state computed from the general form of the anomaly is not in especially good agreement with the direct numerical calculations from the underlying quantum field theory. This is in accordance with the general discussion of the exact and low energy effective actions of the previous section. In states which have no divergences on the horizon there is no particular reason to neglect the Weyl invariant terms $S_{\text{inv}}$ in the exact effective action, and the stress-energy tensor it produces would be expected to be comparable in magnitude to that from $S_{\text{anom}}$, and both contributions are negligibly small on macroscopic scales. However in states such as the previous Boulware example, the diverging behavior of the stress tensor near the horizon is captured accurately by the terms in (3.36) arising from the anomaly, which have the same generically diverging behaviors as the quantum field theory expectation value $\langle T_{a}^{b} \rangle$. Even in states for which the expectation value remains regular on the horizon, the auxiliary field anomalous stress-energy can be matched accurately to the finite value of $\langle T_{a}^{b} \rangle$ on the horizon with suitable choice of integration constants in (5.8).

For comparison plotted also in Figs. 2a and 2b is the analytic approximation to $\langle T_{t}^{t} \rangle$ of Frolov
and Zel’nikov (FZ) \cite{43}. This latter approximation gives an improvement over that of \cite{35, 36, 37} since it permits adjustment of the value of the stress-energy on the horizon to the numerical data, rather than fixing it to an incorrect value. Once that is done, the FZ approximation automatically gives the correct asymptotic value of the stress-energy in the Hartle-Hawking state at infinity, but contains no additional free parameters. For the spin $\frac{1}{2}$ case the FZ approximation is a significant improvement of that of PBO which disagrees with the numerics even in the sign of $\langle T_t^t \rangle$ on the horizon. Although it is a noticeably better fit to the numerical data than \cite{3.36}, the FZ approximation, like that of PBO, relies on the existence of a timelike Killing field and both are therefore highly specialized to certain spacetime backgrounds such as the Schwarzschild black hole. In contrast the stress-energy tensor \cite{3.36} arising from $S_{anom}$ in the low energy EFT does not require the existence of a timelike Killing field, and can be computed in principle for arbitrary spacetimes.

For the time asymmetric Unruh state the zero flux condition \cite{5.16} is replaced by the properly normalized finite flux condition,

$$\left. \langle T_t^r \rangle \right|_U = -\frac{L}{4\pi r^2}$$  \hspace{1cm} (5.17)

where the luminosity, $L$ is given by

$$L = \frac{\pi}{M^2} \left( bqq' + bq'p + bpq' \right)$$  \hspace{1cm} (5.18)

in terms of the auxiliary field parameters. Otherwise one can proceed as in the previous Hawking-Hartle state by fixing two of the three remaining auxiliary field parameters by the values of $\langle T_t^t \rangle$ on the future horizon and at infinity which are known numerically for the scalar and electromagnetic fields in the Unruh state from the work of refs. \cite{44} and \cite{45, 46}. This leaves again one parameter free to fit. The results of that fit for the conformally coupled scalar and electromagnetic fields in the Unruh state are shown in Figs. 3 (solid lines). The dashed curves are accurate polynomial fits of \cite{47} and \cite{48} to the numerical data of \cite{45} and \cite{46} for the spin 0 and 1 fields respectively. There is at present no numerical calculation of the stress-energy tensor of the massless Dirac field in the Unruh state with which to compare.

**B. Other Spacetimes with Horizons**

The foregoing analysis of the anomalous action and stress tensor in the Schwarzschild background may be extended to other spacetimes with metrics of the form \cite{41.17}. The electrically charged Reisner-Nordstrom black hole for which $f(r) = 1 - 2M/r + e^2/r^2$ is an example in which
Eqs. (5.1)-(5.4) may also be applied. The extreme Reisner-Nordstrom geometry in which $e = M$ is particularly interesting. In that case the two zeroes of $f(r)$ at $r_{\pm}$ coincide and $f$ vanishes quadratically. The possible singularities of the stress-energy on the extreme Reissner-Nordstrom horizon are correspondingly more severe, behaving like $s^{-3}$. Nevertheless a power series expansion near $s = 0$ shows that it is possible to obtain a regular stress-energy on the horizon with (3.36) even in the extreme Reissner-Nordstrom case with appropriate choice of auxiliary field integration constants, in agreement with the direct numerical results of 41. Thus the anomaly induced effective action can reproduce the correct behaviors of the quantum stress tensor also in this case, in contrast to the approximation of 35, 36, 37 which predicts a divergent stress-energy on the horizon of an extreme Reissner-Nordstrom black hole as the only possibility. As it is not possible to solve the auxiliary field equations analytically in the black hole geometries when $e \neq 0$, and a numerical solution is required, we postpone a full discussion of these results to a future publication 49.

Finally, this study the anomalous effective action, auxiliary fields, and stress-energy could be extended to rotating Kerr black hole geometries. The previous analytical approximations of 35, 36, 37, 43 do not apply to this case. However there is no problem of principle in computing the stress tensor (3.36) in stationary spacetimes possessing only axial symmetry. Because of the lower symmetry, solutions of the auxiliary field equations (3.16) which are functions of both $r$ and $\theta$ can be sought. Hence the solutions characterizing macroscopic stationary quantum states with axial symmetry are considerably richer than the Schwarzschild case. However, a simple spherically symmetric homogeneous solution of the second order equation $\varphi = 0$ which generalizes the $\ln f$ solution found in the the Schwarzschild and de Sitter cases is

$$\varphi(r) \propto \ln \left( \frac{r - r_+}{r - r_-} \right), \quad (5.19)$$

for

$$r_\pm = M \pm \sqrt{M^2 - a^2}, \quad (5.20)$$

with $a$ the the angular momentum per unit mass of the Kerr solution. Since (5.19) diverges logarithmically on the horizon at $r = r_+$, similar conformal behavior of the stress tensor as $r \to r_+$ is expected as that found in the Schwarzschild case, which clearly merits a separate investigation.
VI. CONCLUSIONS

The suggestion that general relativity is a low energy effective field theory, comparable to the chiral EFT of pions in the strong interactions has been expressed previously \cite{2}. In this paper we have extended the EFT framework from the weak field expansion around flat space considered in \cite{2} to arbitrary curved spacetimes, provided only that the curvature invariants are small compared to the Planck scale. The EFT expansion in inverse powers of the high energy cutoff scale of order $M_{Pl}$ requires a systematic classification of relevant and irrelevant operators in the general coordinate invariant effective action. According to this classification, based on the behavior under global Weyl rescalings \cite{10}, the classical Einstein-Hilbert action should be supplemented with certain well-defined non-local terms associated with the trace anomaly of massless fields. These additional terms are non-local in terms of the metric, cf. \cite{3,4,2} but nevertheless because they scale logarithmically with distance are relevant in the infrared. The anomalous terms are unsuppressed by any inverse power of the ultraviolet cutoff scale $M_{Pl}$, and do not decouple for $E \ll M_{Pl}$. Hence they are required in the Wilson effective action \cite{6,13} for gravitational physics at macroscopic distances $L \gg L_{Pl}$. This constitutes an non-trivial infrared modification of Einstein’s theory which is completely consistent with the Equivalence Principle.

The local form of the anomaly introduces two scalar auxiliary fields, $\varphi$ and $\psi$, into the EFT for low energy gravity, one for each of the non-trivial co-cycles of the Weyl group. These scalar fields satisfy the fourth order massless wave equations \cite{8,10}, and are only very weakly coupled to ordinary matter and radiation. In the flat space limit they decouple entirely. The auxiliary fields are new local scalar degrees of freedom of the gravitational field, not contained in classical general relativity.

The anomalous terms in the effective action also generate two new conserved tensors \cite{3,38} and \cite{3,39}, local in the auxiliary fields, which contribute to the stress-energy tensor of low energy gravity \cite{3,40}, as a source for Einstein’s equations in vacuo. Since they arise from the long range effects of the fluctuations of massless fields, and require boundary conditions for their complete specification, these additional terms carry information about the global macroscopic effects of quantum matter. In the approximation where the auxiliary scalar fields are treated as classical potentials, they may be viewed as macroscopic order parameter fields of low energy gravity.

Because of the conformal properties of spacetime horizons, the anomalous terms in the effective action and stress-energy become important in their vicinity, characterizing the allowed behaviors
of the stress tensor there. Near an horizon the most important terms in the effective action (3.15) are those which scale positively in the ultraviolet short distance limit under conformal rescalings, while nevertheless keeping local curvature invariants fixed and small compared to the Planck scale. Only the $S_{anom}$ term in (3.15) has this property, scaling logarithmically in both the ultraviolet and infrared limits. Because the anomalous terms depend non-locally on the geometry through the two auxiliary scalar fields $\varphi$ and $\psi$, they can be significant near horizons even for very much sub-Planckian local curvatures, where the EFT description should continue to apply. Indeed although local curvature invariants remain small on horizons, the auxiliary scalar fields depend in general on coordinate invariant global quantities such as $\ln(-K^K_a)$ which diverge on the horizon when the spacetime possesses a timelike Killing field $K^a$ which becomes null there. Whether or not this divergence actually occurs in the stress-energy of a given state is a matter of boundary conditions fixed globally over the entire spacetime. The existence of a topological current and associated Noether charge are characteristic of these global effects of the quantum state. The generic singular behavior of the stress-energy on horizons is thereby characterized in terms of spacetime invariant scalar order parameters in the low energy EFT, which is completely consistent with general coordinate invariance.

In the (semi-)classical EFT framework where both the metric and auxiliary scalars are treated as classical fields, Eqs. (3.16) may be solved classically and provide a new method to calculate the approximate quantum stress tensor of conformal matter by classical means, bypassing the standard but cumbersome procedure of field quantization and renormalization of the quantum stress tensor. When states for which the stress-energy does not diverge on the horizon are considered, approximations such as those in [35, 36, 37, 43], developed specifically for static backgrounds with a timelike Killing field yield a more accurate approximation to the expectation value of the stress-energy tensor. We conclude that in states with a finite stress-energy on the horizon the low energy Wilson effective action (3.15) is not a particularly good approximation to the exact quantum effective action (3.14), as indeed there is no reason why it should be in such states where quantum effects are negligibly small in any case.

On the other hand when the scalar potentials diverge on the horizon, the associated terms in the stress-energy yield a good approximation to the vacuum expectation value of the stress-energy tensor. Compared to previous analytic approximations (3.36) with (3.16) has the considerable advantage of being completely general, and giving all possible allowed singular behaviors of the stress tensor on horizons. In this case the auxiliary scalar potentials may be viewed as horizon order
parameters. Even when the stress-energies diverge, they are characterized by auxiliary fields with finite action, suggesting that such states should not be excluded \emph{a priori} from physical consideration.

We conclude that the effective action and stress-energy of the anomaly provides a consistent infrared modification of general relativity that incorporates long-range macroscopic quantum coherence and entanglement effects in a natural way. This low energy modification is actually required on general EFT grounds. The auxiliary fields of the anomalous action and stress-energy may be viewed as macroscopic condensates.

The study of their effective stress-energy tensor in several special fixed spacetime backgrounds presented here clearly only begins a systematic treatment of their many possible other effects. In addition to extension to other backgrounds, particularly those with horizons, and a study of the scalar gravitational waves and long range effects these scalar potentials may generate, a rich variety of new solutions are to be expected when the $T_{ab}$ of Eqs. (3.36) is used as fully dynamical sources for Einstein’s equations. Whether these effects can be used to test the theory against astrophysical observations is a most important issue for further investigation. In the case of divergent behavior of the stress-energy near the classical horizon a significant deviation of the geometry from the vacuum solutions of the purely classical Einstein equations is predicted. This raises the distinct possibility of qualitatively changing the global structure of both classical black hole and cosmological solutions. The existence of an abelian conserved Noether charge in the EFT suggests comparison with a number current similar to that of non-relativistic many-body systems at a microscopic level.

\textit{Acknowledgments}

The authors gratefully acknowledge extensive discussions with P. R. Anderson on several parts of this work, and would like to thank him and Eric Carlson for the use of his numerical data from ref. [41] in Fig. 2b. We also thank G. A. Newton for helping to develop the MathTensor code which we used to check Eqns. (3.38) and (3.39) and generate those in the Appendix. We thank P. O. Mazur for critical reading of the manuscript and several helpful suggestions prior to its submission. R. V. gratefully acknowledges support while at Los Alamos from the Univ. of Calif. Insitute for Nuclear and Particle Astrophysics and Cosmology.

APPENDIX A: STRESS-ENERGY IN STATIC, SPHERICAL, VACUUM SPACETIMES

We give in this Appendix the explicit forms for the diagonal components of the two conserved tensors $E_{\alpha \beta}$ and $F_{\alpha \beta}$, cf. Eqs. (3.38) and (3.39), for static, spherically symmetric spacetimes with line elements of the form (4.17). The auxiliary fields are assumed to be of the form,

$$\varphi = \varphi(r) + 2p\kappa t, \quad (A1a)$$

$$\psi = \psi(r) + 2p' \kappa t, \quad (A1b)$$

with $\kappa$ the surface gravity at the horizon where $f$ vanishes. All components of the two tensors were generated by MathTensor programs [52], which were separately checked for satisfying the conservation and trace conditions (3.40).

The time components of the two tensors so obtained are:

$$E_{t}^{t} = \frac{f^2}{6} \left( 2 \varphi'' \varphi' - \varphi'^{2} \right) + \frac{4f}{3} \left( f' - \frac{f}{r} \right) \varphi'' \varphi' + \frac{1}{3} \left( 2ff'' + f'^{2} - \frac{2f(1 + 2f)}{r^{2}} \right) \varphi'^{2} + \frac{2p^{2} \kappa^{2} f'^{2}}{f^{2}}$$

$$- \frac{8p^{2} \kappa^{2}}{3f} \left( ff'' + f' \frac{f}{r} + \frac{1 - f}{r^{2}} \right) - \frac{ff''}{3} \varphi'' - \frac{2}{9} \left[ \frac{ff''}{2} + 3f' + \frac{14f(1 - f)}{r^{2}} \right] \varphi''$$

$$- \frac{2}{9} \left[ \frac{ff'''}{2} + 2f'f'' + \frac{9ff'' + 8f'^{2}}{r} + \frac{(5 - 17f)f'}{r^{2}} + \frac{6f(1 - f)}{r^{3}} \right] \varphi'$$

$$+ \frac{4}{9} \left[ \frac{ff'''' + f'f''' + 2f'f'' + 3ff'''}{2} + \frac{ff'(4f - 3)}{r^{2}} + \frac{2f'(1 - 2f)'}{r^{3}} - \frac{2f(1 - f)}{r^{4}} \right], \quad (A2)$$
and

\[
F_i^r = \frac{f^2}{3} (\varphi'' \psi' + \varphi' \psi'' - \varphi'' \psi') + \frac{4f}{3} \left( f' - \frac{f}{r} \right) (\varphi'' \psi' + \varphi' \psi'') + \frac{2}{3} \left[ 2ff'' + f^2 - \frac{2f(1 + 2f)}{r^2} \right] \varphi' \psi' + \frac{4pp'2f'^2}{f^2} - \frac{16pp'2}{3f} \left( f'' + \frac{f'}{r} - \frac{1 - f}{r^2} \right) - \frac{2f}{3} \varphi'' - \frac{2}{9} \left[ \frac{ff''}{2} + 3f'^2 + \frac{8ff'}{r} + \frac{14f(1 - f)}{r^2} \right] \psi'' - \frac{2}{9} \left[ \frac{ff''}{2} + 2f'f'' + \frac{9ff'' + 8f'^2}{r} + \frac{(5 - 17f)f'}{r^2} + \frac{6f(1 - f)}{r^3} \right] \psi'
+ \frac{4f}{3} \left[ \frac{f''}{2} - \frac{f'}{r} - \frac{1 - f}{r^2} \right] \varphi'' + \frac{2}{3} \left[ 2ff'' + \frac{f''f'}{2} + \frac{f'' - f'^2}{r} - \frac{f'(1 + f)}{r^2} - \frac{2b(1 - f)}{r^3} \right] \varphi'
+ \frac{2}{9} \left[ \frac{f''}{4} - \frac{f'}{r} + \frac{2f'' - f'' + f'^2}{r^2} + \frac{2f'(1 - f)}{r^3} + \frac{(1 - f)^2}{r^4} \right] \psi',
\]

(A3)

where primes denote differentiation with respect to \( r \).

The radial pressures of the two stress tensors are:

\[
E_r^r = -f^2 \varphi' \varphi'' + \frac{f^2}{2} \varphi'' - \frac{4f}{3} \left( f' + \frac{f}{r} \right) \varphi' \varphi'' + \frac{1}{3} \left[ -2ff'' + f^2 - \frac{8ff'}{r} + \frac{2f(1 + 2f)}{r^2} \right] \varphi' \psi'' - \frac{2\kappa^2 p^2 f'^2}{3f^2} + \frac{8\kappa^2 p^2}{3rf} \left( f' + \frac{1 - f}{r} \right) + \frac{f}{3} \left( f' + \frac{4f}{r} \right) \varphi''
+ \frac{2}{3} \left[ -ff'' + 2f'^2 + \frac{8ff'}{r} + \frac{8f^2}{r^2} \right] \varphi'' + \left[ \frac{f''}{3} + \frac{2ff''}{r} + \frac{2(3f - 1)}{r^2} \right] \left( f' - \frac{2f}{r} \right) \varphi',
\]

(A4)

and

\[
F_r^r = -f^2 (\varphi' \psi'' + \psi' \varphi'' - \varphi'' \psi') - \frac{4f}{3} \left( f' + \frac{f}{r} \right) (\varphi' \psi'' + \psi' \varphi'') - \frac{4\kappa^2 pp'f'^2}{3f^2}
+ \frac{16\kappa^2 pp'}{3rf} \left( f' + \frac{1 - f}{r} \right) + \frac{2}{3} \left[ f'^2 - 2ff'' - \frac{8ff'}{r} + \frac{2f(1 + 2f)}{r^2} \right] \varphi' \psi' + \frac{f}{3} \left( f' + \frac{4f}{r} \right) \psi''
+ \frac{2}{3} \left[ -ff'' + 2f'^2 + \frac{8ff'}{r} + \frac{8f^2}{r^2} \right] \psi'' + \left[ \frac{f''}{3} + \frac{2ff''}{r} + \frac{2(3f - 1)f'}{r^2} + \frac{4f(1 - 3f)}{3r^3} \right] \psi'
+ \frac{1}{3} \left[ f'f'' - \frac{2(3f - 1)f'}{r^2} + \frac{4f(1 - f)}{r^3} \right] \varphi'
+ \frac{1}{3} \left[ f'f'' - \frac{f'^2}{2} + \frac{2(ff'' - ff'^2)}{r^2} - \frac{2(ff'' + f'^2)}{r^2} + \frac{4f f'}{r^3} + \frac{2(1 - f)^2}{r^4} \right] \varphi,'
\]

(A5)
Finally the tangential pressures of the two tensors are:

\[ E_\theta \equiv \frac{f'^2}{3} \left( \varphi' \varphi'' - \frac{\varphi'^2}{2} \right) + \frac{4f^2}{3r} \varphi' \varphi'' + \frac{f'}{3} \left( -f' + \frac{4f}{r} \right) \varphi'^2 + \frac{2\kappa p^2}{3f^2} \left( 2f f'' - f'^2 \right) \]

\[ -\frac{2f^2}{3r} \varphi'' + \frac{2f}{9} \left( f'' - \frac{2f'}{r} + \frac{7 - 13f}{r^2} \right) \varphi'' + \frac{2}{9} \left[ -\frac{f f''}{2} + f' f'' + \frac{4f^2}{r} + \frac{(7 - 22f)f'}{r^2} + \frac{6f^2}{r^3} \right] \varphi' \]

\[ + \frac{4}{9} \left[ \frac{f f'''}{2} + \frac{3f f'''}{2} + \frac{2f' f''}{r} + \frac{4f f'' - 3f'' + 2f^2}{r^2} + \frac{2f'(1 - 2f)}{r^3} + \frac{2f(f - 1)}{r^4} \right] , \quad (A6) \]

and

\[ F_\theta \equiv \frac{f^2}{3} \left( \varphi' \psi'' + \psi' \varphi'' - \varphi'' \psi' \right) + \frac{4f^2}{3r} \left( \psi' \varphi'' + \varphi' \psi'' \right) + \frac{2f}{3} \left( -f' + \frac{4f}{r} \right) \varphi' \psi' \]

\[ + \frac{4\kappa p^2}{3f^2} \left( 2f f'' - f'^2 \right) - \frac{2f^2}{3r} \psi''' + \frac{2f}{9} \left( f'' - \frac{2f'}{r} + \frac{7 - 13f}{r^2} \right) \psi'' \]

\[ + \frac{2}{9} \left[ -\frac{f f'''}{2} + f' f'' + \frac{4f^2}{r} + \frac{(7 - 22f)f'}{r^2} + \frac{6f^2}{r^3} \right] \varphi' \]

\[ + \frac{2}{3} \left[ -f f''' + \frac{f' f''}{2} + \frac{f^2}{r} + \frac{(1 - f)f'}{r^2} \right] \varphi' \]

\[ + \frac{2}{3} \left[ -\frac{(f f'' + f' f'')}{2} + \frac{f''^2}{4} - \frac{f f'' + f' f''}{r^2} + \frac{f f'' + f' f''}{r^2} - \frac{2f f' + f^2}{r^3} + \frac{f - 1}{r^2} \right] \varphi \]

\[ + \frac{4}{9} \left[ \frac{f''^2}{4} - \frac{f' f''}{2} + \frac{(f - 1)f'' + f^{''2}}{r^2} + \frac{2(1 - f)f'}{r^3} + \frac{(f - 1)^2}{r^4} \right] . \quad (A7) \]

The flux components \( E_t^r \) and \( F_t^r \) are determined by the conservation Eqn.,

\[ \frac{\partial}{\partial r} T_t^r + \frac{2}{r} T_t^r = 0 \quad (A8) \]

to be proportional to \( 1/r^2 \) with a proportionality constant given by the luminosity \( L \) as in (5.17) of the text. For the general surface gravity \( \kappa \), \( T_t^r = -L/4\pi r^2 \) with

\[ L = 16\pi \kappa^2 (bpq' + b'pq + b'pq) . \quad (A9) \]
FIG. 1a: The expectation value $\langle T_t^t \rangle$ of a conformal scalar field in the Boulware state in Schwarzschild spacetime, as a function of $s = \frac{r - 2M}{M}$ in units of $\pi^2 T_H^4 / 90$. The solid curve is Eq. 3.36 with 5.12b and $c_H = -\frac{7}{20}, d_H = \frac{55}{81}$, the dashed curve is the analytic approximation of 36, and the points are the numerical results of 34.

FIG. 1b: The radial pressure $\langle T_r^r \rangle$ of a conformal scalar field in the Boulware state in Schwarzschild spacetime. The axes and solid and dashed curves and points are as in Fig. 1a.
FIG. 1c: The tangential pressure $\langle T_\theta^\theta \rangle$ of a conformal scalar field in the Boulware state in Schwarzschild spacetime. The axes and solid and dashed curves and points are as in Fig. 1a.

FIG. 2a: The expectation value $\langle T_t^t \rangle$ of a conformal scalar field in the Hartle-Hawking state in Schwarzschild spacetime as a function of $s = r - 2M$ in units of $\pi^2 T_H^4 / 90$. The solid curve is Eq. (3.36) with $c_\infty = 0.035$, $c_H = -1.5144$, $p = 1.5144$, $q = q' = 2$, $d_\infty = 1.0262$, $d_H = 1.0096$, $p' = -1.0096$, the dashed curve is the analytic approximation of [43] and the data points are the numerical results of [40].
FIG. 2b: The expectation value $\langle T^t_t \rangle$ of a massless Dirac field in the Hartle-Hawking state in Schwarzschild spacetime. The solid curve is Eq. (3.36) with $c_\infty = 0.035, c_\mu = -1.571 = -p, q = q' = 2, d_\infty = 0.6059, d_\mu = 0.6109 = -p'$, the dashed curve is the analytic approximation of [43] and the data points are the numerical results of [41].

FIG. 2c: The expectation value $\langle T^t_t \rangle$ of the electromagnetic field in the Hartle-Hawking state in Schwarzschild spacetime. The solid curve is eq. (3.36) with $c_\infty = -0.0237, c_\mu = 1.0584 = p, q = q' = 2, d_\infty = -0.2716, d_\mu = 0.7644 = p'$, and the dashed curve is the accurate analytic fit of [42] to the numerical
FIG. 3a: The expectation value $\langle T_{t'} t' \rangle$ of a massless, conformal field in the Unruh state in Schwarzschild spacetime. The solid curve is Eq. (3.36) with $c_\infty = 0, c_H = -1.6500, p = 1.9192, q = q' = 2, d_\infty = 1.4441, d_H = 1.3244, p' = -1.0552,$ and the dashed curve is the polynomial approximation of Eq. (47) which is an accurate fit to the numerical results of Eq. (47).

FIG. 3b: The expectation value $\langle T_{t'} t' \rangle$ of the electromagnetic field in the Unruh state in Schwarzschild spacetime. The solid curve is Eq. (3.36) with $c_\infty = 0, c_H = 0.5594, p = -0.4984, q = q' = 2, d_\infty = -0.2595, d_H = 0.4125, p' = -0.3514,$ and the dashed curve is the polynomial approximation of Eq. (48) which is...
