Introduction

Faithful chromosome segregation to both daughter cells is essential for stable inheritance of genetic material and depends on proper function of the M-phase spindle. Spindle microtubules capture and coordinately align all chromosomes into a common plane in metaphase via interactions with kinetochores and chromosome arms. They further exert the mechanical forces that mediate synchronous segregation of sister chromatids to the spindle poles in anaphase. To cope with these functions during M phase, the general parameters determining microtubule dynamics not only change early in M phase but also at the onset of anaphase concomitant with chromosome segregation (Verde et al., 1990; for reviews see Compton, 2000; Mitchison and Salmon, 2001; Wittmann et al., 2001; Cassimeris and Skibbens, 2003; Gadde and Heald, 2004; Kline-Smith and Waleczak, 2004).

At the molecular level, anaphase onset is defined by the activation of the anaphase-promoting complex/cyclosome (APC/C), a multisubunit E3 ubiquitin ligase that destines securin/Pds1 and mitotic cyclins for degradation. Degradation of securin is required for the activation of separase. Active separase cleaves the SCC1 subunit of the cohesin complex, which mediates chromatid cohesion until anaphase onset (Nasmyth, 2002; Yanagida, 2005).

In contrast, the molecular mechanisms, which induce the changes in microtubule behavior at the beginning of anaphase, are less well understood. Changes in microtubule dynamics in early M phase are governed by an increase in the activity of Cdk1, the general regulator of M phase (Verde et al., 1990). Cdk1 is activated in the presence of rising levels of M-phase cyclins and modulates the activity of a variety of microtubule-associated proteins (MAPs) and motor proteins (Cassimeris and Spittle, 2001). In turn, degradation of M-phase cyclins and thus declining Cdk1 activity upon activation of the APC/C are assumed to determine changes in microtubule behavior at the onset of anaphase.
Spindle assembly, chromosome segregation, and spindle depolymerization in anaphase can be recapitulated in the cell-free system of *Xenopus laevis* egg extracts (Murray, 1991; Sawin and Mitchison, 1991; Holloway et al., 1993). M-phase extracts assemble astral arrays of microtubules from purified human centrosomes (Tournier et al., 1991), meiotic spindles around chromatin beads (Heald et al., 1996), and complete bipolar spindles from sperm nuclei (Sawin and Mitchison, 1991). Moreover, the addition of GTP-locked Ran, e.g., of the hydrolysis-deficient mutant RanQ69L, is sufficient to induce the formation of microtubule assemblies in *Xenopus* M-phase extracts (Carazo-Salas et al., 1999). Assaying Ran-GTP-induced microtubule assembly has been successfully used to analyze molecular details about M-phase spindle assembly pathways (Clarke and Zhang, 2004; Gruss and Vernos, 2004; Ciciarello et al., 2007).

Like intact unfertilized vertebrate eggs, *Xenopus* M-phase egg extracts are held in metaphase by the activity of the cytoplasmic factor (CSF), the central activity of which is the *Xenopus* Emi1-related protein (XErp). XErp largely inhibits the APC/C-dependent cyclin destruction and consequently maintains high Cdk1 activity (Schmidt et al., 2005; Tung et al., 2005). Upon fertilization, reentry into the cell cycle is triggered by a transient increase in free intracellular calcium (Busa and Nuccitelli, 1985). In the cell-free system, the direct addition of calcium likewise mimicks fertilization (Murray, 1991). In both intact eggs and cell-free egg extracts, calcium-activated calcium-calmodulin-dependent kinase II (CaMKII) directly phosphorylates XErp. Phosphorylation-dependent degradation of XErp eventually leads to the activation of APC/C and, in turn, to the degradation of cyclin B and securin, inducing anaphase onset (Liu and Maller, 2005; Rauh et al., 2005; Hansen et al., 2006).

At the same time, the stability of spindle microtubules changes significantly in the *Xenopus* system. Both kinetochore and nonkinetochore microtubules apparently shorten from their plus ends, which results in an overall decrease in microtubule density in the central part of the spindle (Holloway et al., 1993; Murray et al., 1996; Desai et al., 1998; Maddox et al., 2003). The characteristic reduction in spindle microtubule density upon induction of anaphase is also observed in the presence of non-degradable mitotic cyclin (cyclinBΔ90) at concentrations that allow chromosome segregation but avoid mitotic exit (Holloway et al., 1993; Murray et al., 1996). However, more recent experiments show that high Cdk1 activity blocks sister chromatid separation even upon activation of APC/C and securin degradation (Stemmann et al., 2001). Therefore, the previous data are consistent with the idea that a partial reduction of the metaphase Cdk1 activity might be responsible for the observed changes in microtubule stability in anaphase.

In this study, we systematically investigate the role of APC/C activation and the reduction in Cdk1 activities on changes in microtubule stability in anaphase of *Xenopus* egg extracts. Our data indicate that there is a general decrease in microtubule stability in meiotic anaphase, which can be recapitulated in complete spindles, centrosomally or chromatin-nucleated microtubules, as well as in Ran-GTP-mediated microtubule assemblies. The general reduction in microtubule stability is marked by a twofold increase in microtubule catastrophe rates. We show that high Cdk1 levels cannot rescue microtubule stability after induction of anaphase. Moreover, neither the degradation of cyclin B nor the activation of APC/C is required for microtubule destabilization. However, the addition of free calcium or constitutively active purified CaMKII still leads to the destabilization of microtubules. Strikingly, constitutively active CaMKII disassembles spindles even in the presence of the APC/C inhibitor XErp and thus stable securin and cyclin B. Our data demonstrate the existence of a novel CaMKII-dependent mechanism that initiates the destabilization of spinele microtubules in CSF-arrested *Xenopus* egg extracts parallel to APC/C activation at the metaphase to anaphase transition.

### Results

To investigate changes in microtubule stability from metaphase to anaphase, we assembled spindles from sperm nuclei in CSF-arrested *Xenopus* egg extracts supplemented with Cy3-labeled tubulin. We initiated anaphase by adding 0.6 mM calcium but blocked cell cycle progression in anaphase using nondegradable cyclin B (cyclinBΔ90) to maintain high Cdk1 activity throughout the experiment (Fig. 1A). After the addition of calcium and thus anaphase initiation, the density of spindle microtubules in the central part of the spindle was decreased concomitant with chromosome segregation, but spindles did not completely depolymerize (Fig. 1B, top right). Like sperm nuclei, Ran-GTP and chromatin beads readily assembled microtubule structures in CSF-arrested *Xenopus* egg extracts (Fig. 1B, left). In contrast, neither Ran-GTP nor chromatin beads stabilized any microtubules in anaphase extracts in the presence of cyclinBΔ90, suggesting an overall reduced microtubule stability (Fig. 1B, right).

It is known that Ran-GTP produced by nuclei or chromatin beads releases the MAP TPX2 and other MAPs from importins. Only free TPX2 induces microtubule assembly and interacts with and activates aurora A/Eg2 (Gruss and Vernos, 2004). To address the efficiency of TPX2 release from importins in the presence of Ran-GTP in metaphase and anaphase, we compared the amounts of Eg2 associated with free TPX2 after the addition of RanQ69L (Fig. 1C). Eg2 was efficiently coprecipitated on TPX2 antibodies both in metaphase and anaphase (Fig. 1C). This shows that a decrease in microtubule stability in anaphase is not caused by an inefficient release of TPX2 from importins but might reflect a general feature of *Xenopus* extracts in anaphase. To confirm this, we extended our analysis to microtubules assembled from purified human centrosomes, which promote microtubule assembly independently of Ran-GTP (Fig. 1D; Carazo-Salas et al., 1999). Like Ran-GTP or chromatin beads, centrosomes did not induce de novo microtubule assembly in anaphase (Fig. 1D, middle). Also, astral arrays that preformed around purified human centrosomes in metaphase (Fig. 1D, left) quickly depolymerized in anaphase (Fig. 1D, right). These data suggest a global regulation of microtubule stability at the transition from metaphase to anaphase in *Xenopus* egg extracts.

A possible explanation for our observations is that activation of the APC/C, degradation of cyclin B, and a following drop in Cdk1 activity led to a changed phosphorylation pattern of MAPs and motors and consequently to the destabilization of
between Cdk1 activity and microtubule stability more quantitatively, we determined Ran-GTP–mediated microtubule assemblies at different concentrations of nondegradable cyclin B. When cyclinB\(\Delta90\) was added to only 40 nM and anaphase onset was induced by calcium addition, the system exited mitosis as judged from the presence of interphase microtubules. To test this, we assembled microtubule structures by the addition of Ran-GTP and subsequently observed their stability upon Cdk1 inhibition using CGP74514A (CGP), a selective chemical inhibitor of Cdk1 kinase (Fig. 2A; Skoufias et al., 2007). Surprisingly, Ran-induced structures did not disassemble upon Cdk1 inhibition before interphasic microtubules were detectable (Fig. 2A, CGP; see 15 min for coexisting M phase and interphase microtubule structures). In contrast, metaphase microtubule structures disassembled as expected upon the addition of calcium (Fig. 2A, top) despite high Cdk1 activity (Fig. 2A, bottom; Ana). This suggested that the sole reduction of Cdk1 activity is not sufficient for the observed changes in anaphase microtubule stability. To analyze the correlation between Cdk1 activity and microtubule stability more quantitatively, we determined Ran-GTP–mediated microtubule assemblies at different concentrations of nondegradable cyclin B. When cyclinB\(\Delta90\) was added to only 40 nM and anaphase onset was induced by calcium addition, the system exited mitosis as judged...
simple model that calcium and CaMKII activate only the APC/C in meiotic anaphase, which destines cyclin B for degradation leading to decreased Cdk1 activity and thus causes anaphase microtubule destabilization.

As cyclin B degradation is mediated by APC/C activity (but according to our experiments is not required to destabilize microtubules), we aimed to further determine the overall role of APC/C activation in changing microtubule stability in anaphase. We assayed Ran-GTP–induced microtubule assembly by direct fluorescence and monitored cyclin B and securin levels as well as Cdk1 activity to determine APC/C activation in metaphase, anaphase, and interphase. To inhibit APC/C activation despite calcium-induced anaphase onset and therefore uncoupling APC/C activation from other calcium-dependent processes, we used a nondegradable variant of XErp (XErp ND; Rauh et al., 2005). As expected, Ran-GTP–induced microtubule assemblies were stable in CSF-arrested extracts, and high levels of cyclin B, securin, and Cdk1 activity were maintained (Fig. 3, A–C; Meta).

These results suggested three conclusions: first, metaphase Cdk1 activity allows microtubule destabilization in meiotic anaphase, and inhibition of this activity alone does not promote microtubule destabilization. Second, elevated Cdk1 activity can partially rescue microtubule stability at anaphase onset, but, third, after anaphase induction at metaphase Cdk1 activity, the transition to less stable microtubules becomes resistant to high Cdk1 activity. These conclusions contradict the simple model that calcium and CaMKII activate only the APC/C in meiotic anaphase, which destines cyclin B for degradation leading to decreased Cdk1 activity and thus causes anaphase microtubule destabilization.

As cyclin B degradation is mediated by APC/C activity (but according to our experiments is not required to destabilize microtubules), we aimed to further determine the overall role of APC/C activation in changing microtubule stability in anaphase. We assayed Ran-GTP–induced microtubule assembly by direct fluorescence and monitored cyclin B and securin levels as well as Cdk1 activity to determine APC/C activation in metaphase, anaphase, and interphase. To inhibit APC/C activation despite calcium-induced anaphase onset and therefore uncoupling APC/C activation from other calcium-dependent processes, we used a nondegradable variant of XErp (XErp ND; Rauh et al., 2005). As expected, Ran-GTP–induced microtubule assemblies were stable in CSF-arrested extracts, and high levels of cyclin B, securin, and Cdk1 activity were maintained (Fig. 3, A–C; Meta). Calcium induced the destabilization of microtubule assembly.
active CaMKII (CaMKII 1–290 [Lorca et al., 1993] and CaMKII* [Fig. S1, available at http://www.jcb.org/cgi/content/full/jcb.200807006/DC1]). We recombinantly expressed and purified CaMKII*, and, as a control, a corresponding mutant in which a lysine in position 42 essential for nucleotide binding was replaced by an alanine (CaMKII*K42A; Hanks and Quinn, 1991). The mutant protein displayed no detectable activity on myelin basic protein, whereas the activity of the wild-type kinase could be readily detected and quantified (see Materials and methods and Fig. S1). When added to *Xenopus* egg extract, CaMKII* triggered the destabilization of preassembled microtubule structures and promoted entry into interphase as judged by typically long interphasic microtubules (Fig. 4, A and B; CaMKII*). Consistent with this, it induced the degradation of endogenous cyclin B (*X.l. cyclin B) and securin as well as decreased Cdk1 activity (Fig. 4 C, CaMKII*). In contrast, the mutant kinase had no effect on the system (Fig. 4, A and C; CaMKII*K42A). Microtubules were also destabilized by CaMKII*-induced anaphase entry in the presence of cyclinBΔ90 (Fig. 4, A and B; CaMKII* + Δ90), which rescued high Cdk1 activity, although APC/C was activated (Fig. 4 C, CaMKII* + Δ90; see degradation of endogenous securin and cyclin B). Likewise, inhibition of

**Figure 4. CaMKII induces microtubule instability in anaphase.** CSF extracts containing Cy3-tubulin and in vitro translated securin were preincubated for 10 min in the presence of RanQ69L to preassemble microtubules. (A) Reactions were treated with constitutively active CaMKII (CaMKII*), the catalytically inactive mutant (CaMKII*K42A), or CaMKII* together with cyclinBΔ90 (CaMKII* + Δ90) or XErpND (CamKII* + XErpND) as indicated. Microtubule assemblies were visualized by direct fluorescence. (B) Quantification of microtubule assemblies counted in A after 40 min. Error bars represent SD from three independent experiments; metaphase was set to 100%. (C) Reactions were performed as in A; the amounts of endogenous cyclin B (*X.l. cyclin B) were determined by immunoblotting, and the amounts of exogenously added in vitro translated (IVT) securin were determined by autoradiography; Cdk1 activities were measured by histone H1 phosphorylation (pHistone H1). (D) Inhibition of endogenous CaMKII activity; CSF extracts containing Cy3-tubulin and RanQ69L were left untreated (Meta) or incubated with calcium in the absence (–) or presence (+) of the CaMKII inhibitor II-Ntide. (left) Microtubule structures were visualized by direct fluorescence of Cy3-tubulin. (right) Cyclin B (*X.l. cyclin B) and Cdk1 activity (pHistone H1) were determined. (D, bottom) Reactions were chased using CaMKII* for the indicated time points and were visualized. Bars, 5 μm.

assemblies as well as cyclin B and securin degradation, but high Cdk1 activity was maintained in the presence of cyclinBΔ90 (Fig. 3, A–C; Ana). Likewise, microtubule destabilization was observed in the absence of cyclinBΔ90 but was followed by mitotic exit (Fig. 3 A, Inter; note the appearance of interphasic microtubules after 60 min). Although XErpND alone had no effect in metaphase (Fig. 3, A–C; XErpND), interestingly, it allowed microtubule disassembly upon calcium addition (Fig. 3, A and B; XErpND + Ca2+) despite efficient inhibition of APC/C activation as indicated by stable cyclin B and securin (Fig. 3 C, XErpND + Ca2+). These results strongly suggest that the depolymerization of microtubules in anaphase of *Xenopus* egg extracts is triggered by calcium but does not require the activation of APC/C and, therefore, the degradation of its metaphase substrates securin and cyclin B.

Increasing calcium levels and subsequent CaMKII activation initiate metaphase to anaphase transition in CSF-arrested egg extracts. This conclusion was initially based on the observation that constitutively active CaMKII promotes anaphase entry also in the absence of free calcium (Lorca et al., 1993). Therefore, we aimed to test the stability of Ran-GTP-induced microtubule assemblies after anaphase induction by constitutively active CaMKII (CaMKII 1–290 [Lorca et al., 1993] and CaMKII* [Fig. S1, available at http://www.jcb.org/cgi/content/full/jcb.200807006/DC1]). We recombinantly expressed and purified CaMKII*, and, as a control, a corresponding mutant in which a lysine in position 42 essential for nucleotide binding was replaced by an alanine (CaMKII*K42A; Hanks and Quinn, 1991). The mutant protein displayed no detectable activity on myelin basic protein, whereas the activity of the wild-type kinase could be readily detected and quantified (see Materials and methods and Fig. S1). When added to *Xenopus* egg extract, CaMKII* and, as a control, a corresponding mutant in which a lysine in position 42 essential for nucleotide binding was replaced by an alanine (CaMKII*K42A; Hanks and Quinn, 1991). The mutant protein displayed no detectable activity on myelin basic protein, whereas the activity of the wild-type kinase could be readily detected and quantified (see Materials and methods and Fig. S1). When added to *Xenopus* egg extract, CaMKII* and, as a control, a corresponding mutant in which a lysine in position 42 essential for nucleotide binding was replaced by an alanine (CaMKII*K42A; Hanks and Quinn, 1991). The mutant protein displayed no detectable activity on myelin basic protein, whereas the activity of the wild-type kinase could be readily detected and quantified (see Materials and methods and Fig. S1).
As expected, no M-phase microtubules were found after anaphase induction in the absence of the inhibitor (Fig. 4 D, calcium/H11002/INtide), cyclin B was degraded, and the Cdk1 activity was reduced (Fig. 4 D, right; calcium/H11002/INtide). In contrast, Ran-GTP–induced microtubule assemblies could be readily observed in the presence of INtide despite calcium addition (Fig. 4 D, left; calcium + INtide). Cyclin B stayed stable, and the Cdk1 activity remained high (Fig. 4 D, right; calcium + INtide). Still, the addition of constitutively active CaMKII* induced both APC/C activation and microtubule destabilization even in the presence of the inhibitor (Fig. 4 D, right; + CaMKII* + INtide and bottom), indicating that its inhibitory effect is specific for CaMKII. Moreover, INtide efficiently inhibited calcium-dependent phosphorylation of autocamtide-2 in egg extracts (Fig. S1). Similar results were seen using another CaMKII inhibitor peptide (CaMKII 281–309) as well as a general calmodulin inhibitor (Lorca et al., 1993; Morin et al., 1994), whereas the addition of cyclosporin A to prevent activation of the calcium-calmodulin–dependent phosphatase calcineurin had no effect on microtubule depolymerization (Fig. S3, available at http://www.jcb.org/cgi/content/full/jcb.200807006/DC1). These results show that calcium-induced depolymerization of microtubules in anaphase of Xenopus egg extracts requires the activation of CaMKII.

The apparent changes in the stability of the aforementioned microtubules were likely caused by changes in dynamic instability parameters from metaphase to anaphase in the Xenopus system. To visualize and quantify these changes, we assembled Cy3-labeled microtubules from centrosomes and tracked them by time-lapse microscopy in metaphase or anaphase extracts (Fig. 5). It is known that in Xenopus metaphase extracts, the relatively short mean length of microtubules is largely determined by their high catastrophe frequency, which elevates at the entry into M phase to two to three catastrophes per minute (Niethammer et al., 2007). Consistent with that, microtubules in APC/C activation by XErpND (Fig. 4 C, CaMKII* + XErpND; note that cyclin B and securin are stable) did not interfere with the CaMKII*-induced reduction in microtubule stability (Fig. 4, A and B; CaMKII* + XErpND).

To judge whether the level of added CaMKII* was comparable with the physiological calcium-induced CaMKII activity, we compared phosphorylation of the CaMKII substrate autocamtide-2 (Jones and Persaud, 1998) in egg extracts upon calcium or CaMKII* addition. Within a few minutes after the addition of calcium, a transient increase in substrate phosphorylation was observed, whereas hardly any substrate phosphorylation could be detected in untreated CSF-arrested extracts (Fig. S1, −3 time points). In comparison, purified CaMKII* added to egg extracts phosphorylated autocamtide-2 with a very similar efficiency as endogenous CaMKII, whereas the activity of the same amount of the K42A mutant was undetectable in extracts (Fig. S1). Lower concentrations of CaMKII* activity resulted in less efficient substrate phosphorylation (Fig. S1, low CaMKII*). Interestingly, the addition of lower CaMKII* activity to metaphase egg extracts still led to APC/C activation in the absence or presence of cyclinBΔ90 but was insufficient to efficiently promote microtubule destabilization (Fig. S2, available at http://www.jcb.org/cgi/content/full/jcb.200807006/DC1). The latter data suggest independent mechanisms for microtubule depolymerization and APC/C activation. Collectively, our experiments support the conclusion that microtubule destabilization at anaphase onset after release from CSF arrest can be induced by constitutively active CaMKII and occurs independently of APC/C activation.

The observation of CaMKII*-induced microtubule depolymerization suggested that endogenous CaMKII activity would be required for calcium-induced microtubule destabilization. Therefore, we assayed the stability of metaphase microtubule assemblies (Fig. 4 D, Meta) after calcium addition in the absence or presence of a CaMKII inhibitor, which corresponds to the N-terminal inhibitory domain of CaMKII (IINtide; Chang et al., 2001). As expected, no M-phase microtubules were found after anaphase induction in the absence of the inhibitor (Fig. 4 D, calcium − IINtide), cyclin B was degraded, and the Cdk1 activity was reduced (Fig. 4 D, right; calcium − IINtide). In contrast, Ran-GTP–induced microtubule assemblies could be readily observed in the presence of IINtide despite calcium addition (Fig. 4 D, left; calcium + IINtide). Cyclin B stayed stable, and the Cdk1 activity remained high (Fig. 4 D, right; calcium + IINtide). Still, the addition of constitutively active CaMKII* induced both APC/C activation and microtubule destabilization even in the presence of the inhibitor (Fig. 4 D, right; + CaMKII* + IINtide and bottom), indicating that its inhibitory effect is specific for CaMKII. Moreover, IINtide efficiently inhibited calcium-dependent phosphorylation of autocamtide-2 in egg extracts (Fig. S1). Similar results were seen using another CaMKII inhibitor peptide (CaMKII 281–309) as well as a general calmodulin inhibitor (Lorca et al., 1993; Morin et al., 1994), whereas the addition of cyclosporin A to prevent activation of the calcium-calmodulin–dependent phosphatase calcineurin had no effect on microtubule depolymerization (Fig. S3, available at http://www.jcb.org/cgi/content/full/jcb.200807006/DC1). These results show that calcium-induced depolymerization of microtubules in anaphase of Xenopus egg extracts requires the activation of CaMKII.
at http://www.jcb.org/cgi/content/full/jcb.200807006/DC1).

The addition of calcium specifically induced an elevation of
the catastrophe frequency to 5.52 and 4.50 min⁻¹ in two time
intervals measured (Fig. 5, A and B; and Video 2, available at
http://www.jcb.org/cgi/content/full/jcb.200807006/DC1) but
did not consistently influence growth or shrinkage rates. Similar
to metaphase, microtubules after induction of anaphase by low
CaMKII* activity consistently underwent catastrophes at a fre-
cquency of 3.06 or 3.66 min⁻¹ (Fig. 5, A and B; and Video 3). In
contrast, the addition of physiological doses of CaMKII* in-
creased the catastrophe frequency to 5.16 and 5.94 min⁻¹,
whereas growth and shrinkage rates and rescue frequencies
were not significantly changed (Fig. 5, A and B; and Video 4).
These numbers are in striking agreement with the catastrophe
frequencies measured after anaphase induction with calcium.
Although microtubule dynamics measurements usually vary be-
tween different Xenopus extract preparations in absolute num-
bers, the approximately twofold relative changes in catastrophe
frequency could reproducibly be observed (see Fig. S4 for a sec-
ond independent dataset). Therefore, we conclude that reduced
microtubule stability in meiotic anaphase can be at least in part
explained by a twofold increase in microtubule catastrophe rates
from metaphase to anaphase induced by activated CaMKII.

Our experiments on Ran-GTP-induced microtubule as-
semblies and centrosomal asters suggested a novel CaMKII-
induced mechanism for anaphase microtubule destabilization.
Therefore, we intended to analyze microtubule stability at the
metaphase to anaphase transition in complete bipolar spindles
assembled around sperm nuclei in Xenopus egg extracts. We vi-
ualized and quantified spindle microtubule densities by direct
fluorescence of Cy3-labeled tubulin before and after anaphase
onset by calcium or CaMKII*. For each condition, we imaged
40–80 spindle structures. Within all acquired images, the two
poles were defined manually, and the mean fluorescence was
determined using ImageJ to assay for the overall microtubule
stability of the spindles (Fig. 6 A, intensity). A custom Matlab
macro vertically aligned the spindles along the pole to pole axis,
determined the mean pole to pole distance as a measure for
spindle size (Fig. 6 A), and subsequently rescaled all spindles to
the same size. Matlab was used to quantify and plot the fluores-
cence (i.e., microtubule) intensity distributions in a 1.5-µm-wide
area along the pole to pole axis (Fig. 6 A, blue line). Metaphase
spindles typically showed aligned chromosomes and a high
local microtubule density in the central part close to the chro-
mosomes (Fig. 6 A, Meta). Entry into anaphase after calcium
addition led to a reduction of the intensity (33%) and to a slight
(21%) decrease in spindle size (pole to pole distance; Fig. 6 A,
calcium). Anaphase onset triggered by CaMKII* promoted a
two-third decrease in intensity and an almost twofold reduction
of spindle size as compared with metaphase (Fig. 6 A, CaMKII*).
CaMKII-induced depolymerization was therefore more efficient
than what was observed upon the addition of calcium (Fig. 6 A,
CaMKII* and calcium; see average and intensity). However,
under either condition we observed a characteristic local de-
crease in microtubule density in the central part of the spindle,
which is consistent with previously published data on anaphase
spindles (Murray et al., 1996). Calcium or CaMKII* addition
led to the quick degradation of securin and cyclin B and reduced
Cdk1 activity (Fig. 6 B). Importantly, the CaMKII*-induced re-
duction in spindle size and the characteristic drop of microtu-
bule density in the central part of the spindle were also observed
upon supplementing the extract with XErp⁹⁰. Under these con-
ditions, APC/C activation was inhibited, and, therefore, securin
and cyclin B stayed stable (Fig. 6 A, CaMKII* + XErp⁹⁰). Those
partially depolymerized spindle structures were stable for
>60 min (unpublished data). Even after elevated times, we
did not visualize any spindle structures in which chromosomes
had commenced to segregate (Fig. 6 A, CaMKII* + XErp⁹⁰).
As observed for Ran-GTP-mediated microtubule assemblies,
anaphase induction by low CaMKII* activity in the presence of
cyclinBA⁹⁰ was insufficient to destabilize microtubules and
thus revealed spindles with a similar microtubule density distri-
bution but an even higher overall fluorescence than metaphase
spindles (Fig. 6 C, compare Meta with low CaMKII*). Still,
upon adding low CaMKII* activity, we observed chromosome
segregation and degradation of cyclin B after 40 min (Fig. 6 D
and not depicted).

To investigate the importance of APC/C activation and the
degradation of cyclin B after spindle depolymerization without
active APC/C, we first treated preassembled mitotic spindles
with CaMKII* in the presence of XErp⁻⁹⁰ (Fig. 6 A, CaMKII*
and XErp⁻⁹⁰) and chased the anaphase spindles with 1 vol of ex-
tract, which had been treated with or without CaMKII* in
the absence of XErp⁻⁹⁰ to fully activate APC/C (Fig. 6 E).
In the presence of active APC, cyclin B was degraded, and Cdk1 activ-
ity was down-regulated (Fig. 6 E, top). Under these conditions,
anaphase spindles completely depolymerized, and long inter-
phase microtubules assembled (Fig. 6 E, bottom).

Collectively, these results clearly show that the conclu-
sions made from Ran-GTP–induced microtubule assemblies are
valid for complete spindle structures. Consistently, in both model
systems, calcium and CaMKII induce the depolymerization of
microtubules in anaphase after the release from CSF arrest inde-
pendently of the activation of APC/C and thus the degradation of
securin and cyclin B and the down-regulation of Cdk1.

Discussion

Xenopus egg extracts faithfully recapitulate cell cycle prog-
ession and cell cycle–specific reorganization of the microtubule
cytoskeleton (e.g., at M-phase entry or at metaphase to ana-
phase transition). They enter anaphase after CaMKII activation
and subsequent degradation of the APC/C inhibitor XErp, which
allows chromosome segregation. The initiation of chromosome
movement is coupled to a generally reduced stability of spindle
microtubules, suggesting a global change in microtubule dy-
namics parameters. In this study, we used Ran-GTP–induced
microtubule assemblies as a straightforward tool to analyze the
signal, which is responsible for triggering reduced microtubule
stability in anaphase of Xenopus egg extracts. Indeed, although
the addition of Ran-GTP was sufficient to promote microtubule
assemblies in metaphase as expected, no microtubule assemblies
We could show further that Ran-induced microtubule assemblies are destabilized in response to calcium and CaMKII, whereas APC/C activation is not required for this destabilization. Thus, neither degradation of cyclin B nor of securin can be causative for changes in microtubule stability at anaphase onset. Similarly, our experiments in complete spindles show that reduced microtubule stability in anaphase is independent of the inactivation of Cdk1 but is triggered by CaMKII activity; we observed reduced microtubule density in the central part of the spindle upon CaMKII activation even though nondegradable XErp inhibited the APC/C and, therefore, degradation of cyclin B and securin. This is consistent with previous data suggesting could be observed upon Ran-GTP addition in anaphase.

In the past, assays using Ran-GTP–induced microtubule assemblies led to the identification of molecular mechanisms, which were subsequently confirmed in spindle assembly pathways (Gruss et al., 2001; Blower et al., 2005; Koffa et al., 2006). Likewise, our conclusions suggested from Ran-GTP–mediated microtubule assemblies were consistent with the results from microtubules nucleated by centrosomes and from complete spindles. Collectively, this clearly supports the idea of a global change in microtubule stability, which affects the Ran-GTP–dependent microtubule assembly pathway as well as centrosome-driven microtubule polymerization.

We could show further that Ran-induced microtubule assemblies are destabilized in response to calcium and CaMKII, whereas APC/C activation is not required for this destabilization. Thus, neither degradation of cyclin B nor of securin can be causative for changes in microtubule stability at anaphase onset. Similarly, our experiments in complete spindles show that reduced microtubule stability in anaphase is independent of the inactivation of Cdk1 but is triggered by CaMKII activity; we observed reduced microtubule density in the central part of the spindle upon CaMKII activation even though nondegradable XErp inhibited the APC/C and, therefore, degradation of cyclin B and securin. This is consistent with previous data suggesting...
that inactivation of Cdk1 is not necessary to induce anaphase in Xenopus egg extracts (Holloway et al., 1993; Murray et al., 1996). It also implies that the decrease in spindle microtubule density in anaphase is not directly influenced by the cohesion state of chromatin because inhibition of APC/C prevents sister chromatid separation but not microtubule destabilization. This is confirmed by our Ran-GTP experiments in which microtubules can only be destabilized in anaphase independently of chromatin structures. Consistent with that, previous data has shown that anaphase microtubule depolymerization and cytokinesis can occur independently of chromatin in grasshopper spermatocytes (Zhang and Nicklas, 1995).

Our experiments suggest a two-pathway model for spindle disassembly. The first pathway, which is reflected by the complete disassembly of Ran-mediated microtubule structures or the destabilization of central microtubules in complete spindles, is independent of Cdk1 inactivation but induced by CaMKII. In this study, CaMKII has at least one but potentially more unknown targets. Interestingly, when we tested Ran-GTP-induced microtubule assemblies in Xenopus egg extracts, which had already undergone a complete cell cycle, we found that they were completely stable despite the addition of calcium or CaMKII. These extracts had faced a first calcium activation, XErp had been degraded, and the system was rearrested in the next metaphase upon the addition of cyclinBΔ90 (Fig. S5, available at http://www.jcb.org/cgi/content/full/jcb.200807006/DC1). This observation would go along with conclusions from mitosis in human somatic cells in which CaMKII has a stabilizing effect on spindle microtubules (Holmfeldt et al., 2005). It might also suggest that additional CaMKII targets similar to XErp are inactivated after the first rise in calcium and are not functional anymore in the first mitotic cell cycle.

The second pathway of spindle disassembly requires inactivation of Cdk1, which allows further pole separation and finally complete spindle disassembly and return to interphase (Fig. 6E; Murray et al., 1989, 1996; Holloway et al., 1993). In Xenopus egg extracts, CaMKII is required for the second mechanism because Cdk1 inactivation depends on the activation of APC/C, which in turn requires the CaMKII-induced degradation of XErp. Upon increasing calcium levels, CaMKII will likely activate both pathways in parallel, and those will cooperate to faithfully segregate chromosomes and to disassemble the spindle.

It is almost certain that altered phosphorylation patterns of MAPs or motor proteins are involved in the regulation of both pathways. The fact that there is no change in the phosphorylation of histone H1 in anaphase induced by calcium and cyclinBΔ90 does not preclude the specific activation of counteracting phosphatases on other substrates, and an increased activity of protein phosphatases at anaphase onset might well be required for microtubule destabilization. CaMKII could directly be involved in the activation of protein phosphatases, or, in addition, calcium could trigger phosphatase activation by a different pathway. Mochida and Hunt (2007) and Nishiyama et al. (2007) recently showed that the calcium-calmodulin–dependent phosphatase calcineurin is activated upon rising calcium levels in Xenopus eggs and egg extracts and that a second, different phosphatase activity increases subsequently afterward. In our experiments, the addition of cyclosporin A alone to Xenopus CSF extracts did not interfere with microtubule depolymerization of Ran-induced structures. However, our observation that calcium addition to CSF-arrested extracts changed the capacity of cyclin B/Cdk1 to partially rescue microtubule stability (Fig. 2) would be consistent with the further activation of protein phosphatases that antagonize the action of Cdk1. We are currently investigating the contribution of different protein phosphatases on anaphase spindle microtubule stability.

What could be the key players directly mediating the changes in microtubule dynamics at anaphase onset? CaMKII action could enhance the activity of microtubule-destabilizing factors or reduce the activity of microtubule-stabilizing proteins and therefore allow more efficient microtubule depolymerization. However, previous experiments of Morin et al. (1994) suggest that CaMKII does not target proteins already associated with the metaphase spindle to induce anaphase. This argues against a release of stabilizing activities from spindle microtubules in anaphase. In turn, it might suggest that microtubule-destabilizing proteins or their regulators are recruited upon transition to anaphase and promote microtubule destabilization. A main destabilizing activity in Xenopus egg extracts is the kinesin motor protein XKCM1 (Walczak et al., 1996; Tournebize et al., 2000). The activity of XKCM1 increases significantly upon entry into M phase, resulting in a 5–10-fold increase in the catastrophe frequency in metaphase microtubules (Tournebize et al., 2000; Niethammer et al., 2007). Our microtubule dynamics measurements demonstrate that microtubules are even less stable in anaphase than in metaphase. Although lowered rescue frequencies measured in one out of two experiments (Fig. S3) might have contributed to this effect and high deviations in our dynamics measurements also do not allow us to exclude effects on growth and shrinkage rates, we consider it likely that the observed changes in microtubule stability were caused by an approximately twofold further increase in the catastrophe frequency. A higher catastrophe frequency could be caused by rising XKCM1 activity or microtubule affinity, which might be directly or indirectly triggered by CaMKII at metaphase to anaphase transition.

Collectively, our data put forward the idea that analogous to entry into M phase, a global switch in microtubule dynamics in anaphase is required to cope with the functions of microtubules in chromosome segregation and their subsequent rearrangement upon mitotic exit. These changes in microtubule dynamics are not just caused by immediately declining Cdk1 activity but are, before this, triggered by the CaMKII-dependent phosphorylation of yet unknown substrates.

The key question in the future will therefore be to determine which microtubule-binding activities are possibly meiosis-specific targets of CaMKII in the transition from metaphase to anaphase in Xenopus egg extracts. Functional assays at defined conditions using purified CaMKII* and XErpND might help to identify these activities, to understand how they are modified and modulated at the molecular level, and to understand how their regulation is integrated into global changes in microtubule stability.
Materials and methods

Preparation of Xenopus egg extracts, sperm nuclei, chromatin beads, and functional assays in Xenopus egg extracts

CSF-removed (M phase) Xenopus egg extracts were prepared as described previously (Murray, 1991); extracts were also provided by K. Ribbeck (Harvard University, Cambridge, MA), C. Casanova (University Hospital of Freiburg, Freiburg, Germany), H. Yokoyama (European Molecular Biology Laboratory, Heidelberg, Germany), S. Rybina (European Molecular Biology Laboratory, Heidelberg, Germany), and W. Antonin (Max Planck Institute for Developmental Biology, Tübingen, Germany). To obtain anaphase, M-phase extracts were incubated for 40 min at 20°C with cyclinB390 (Stemmann et al., 2001; provided by O. Stemmann [University of Bayreuth, Bayreuth, Germany] and P. Bieling [European Molecular Biology Laboratory, Heidelberg, Germany]), 0.1 mg/ml cycloheximide, and 0.6 mM calcium. Spindle assembly was monitored by adding either 200–500 nuclei/μl of sperm nuclei (Philpott et al., 1991) or chromatin beads (Heald et al., 1996b) and 0.2 mg/ml Cy3-labeled tubulin (Hyman et al., 1991) to CSF extract; a full cell cycle was allowed, and the system was reassembled in M phase using CSF extract as described previously (Sawin and Mitchison, 1991; Heald et al., 1996). To assay mitotic microtubule assembly (Fig. S5) at metaphase to anaphase transition, CSF extracts were activated and incubated for 60 min to reach interphase. The addition of cyclinB390 and further incubation for 40 min reestablished metaphase in which RanG69L-GTP–induced microtubule assemblies could be visualized. Microtubule structures were visualized in squashed fixed samples (Heald et al., 1996b) except as specified from purified human centrosomes (Tourrier et al., 1991), which were spun on coverslips (Carazo-Salas et al., 2001). Cdk1 activity was assayed as described previously (Félix et al., 1990).

Data acquisition

To quantify Ran-GTP–induced microtubule assemblies, in each individual experiment at least 500 separate nuclear foci were counted in metaphase controls or after the addition of low CaMKII activity either from 8–10 randomly chosen fields or complete coverslips. The number of structures in the same sample area of anaphase was determined and plotted relative to controls. Error bars represent SDs from three independent experiments. The overall fluorescence intensity of complete spindles was averaged using ImageJ (National Institutes of Health). A custom Matlab macro (The MathWorks, Inc.) was used to compute mean spindle structures. 40–80 structures from different experiments were imaged randomly. The spindles were aligned vertically after manually marking the poles. Pole to pole distances of all spindles were averaged as a measure for spindle size, and the fluorescence distribution in a 1.5-μm broad area along the pole to pole axis was measured and plotted. Fluorescence images were taken at room temperature on a microscope (DM RXA; Leica) using a 1.25 NA 40 × oil or 1.0 NA 63 × water immersion objective, a 1.5-μm broad area along the pole to pole axis was measured and plotted. A 1.5-μm broad area along the pole to pole axis was measured and plotted. A 1.5-μm broad area along the pole to pole axis was measured and plotted. A 1.5-μm broad area along the pole to pole axis was measured and plotted. A 1.5-μm broad area along the pole to pole axis was measured and plotted.

Microtubule dynamics measurements

10 μl CSF extracts were supplemented with purified human centrosomes and 0.25 mg/ml of 1.5 labeling ratio Cy3-labeled tubulin. To reduce photobleaching, 0.5 μl of saturated hemoglobin solution and 0.3 μl of antifading mix were added to each chamber. Time lapses were recorded in 2-s intervals using a microscope (Axiovert 200; Carl Zeiss, Inc.) equipped with a camera (CoolSNAP; Roper Scientific), a 100× Plan Achromat NA 1.4 oil immersion objective lens, and a long-pass rhodamine filter (Chroma Technology Corp.). The positions of centrosomes and microtubule plus ends were tracked in ImageJ, and these coordinates were used to calculate microtubule length. Finally, plots of changes in microtubule length over time were analyzed with a custom-written Matlab macro to estimate the parameters of microtubule dynamics.

Online supplemental material

Fig. S1 and S2 demonstrate the activity of purified CaMKII* in vitro and in Xenopus egg extracts (Fig. S1) and the effects of low amounts of CaMKII* in Xenopus egg extracts on APC/C activation and microtubule stability (Fig. S2). Fig. S3 analyzes microtubule stability after the addition of calcium and selective inhibition of endogenous CaMKII or calcineurin. Changes in dynamic instability parameters from metaphase to anaphase were determined in Fig. S4 and Videos 1–4, and the effects of calcium or CaMKII* on mitotic microtubules in Xenopus egg extract is shown in Fig. S5. Online supplemental material is available at http://www.jcb.org/cgi/content/full/jcb.200807006/DC1.

CaMKII mutation generation, expression, and activity measurements

CaMKII 1–290 (CaMKII*) was cloned into pcDNA and expressed in E. coli BL21 Rosetta. A corresponding catalytically inactive mutant in which lysine 42 was replaced by alanine (K42A; Hanks and Quinn, 1991) was generated using the QuikChange Site-Directed Mutagenesis kit (Agilent Technologies). For both constructs, transformed bacteria were grown at 37°C to an OD600 of 0.7 and cooled down to 23°C. After induction of protein expression using 0.3 mM IPTG, bacterial cultures were grown overnight at 23°C. Purification on Talen beads (Clontech Laboratories, Inc.) was performed as described by the manufacturer. The volume activity of CaMKII* was determined to be 0.4 U/μl using myelin basic protein and a defined activity of purified protein kinase A (Sigma-Aldrich) in CSF buffer containing 1 mM ATP (Fig. S1). A final concentration of 0.04 U/μl CaMKII* was used for experiments in Xenopus egg extracts and low CaMKII* activities were <0.006 U/μl.

The activity of CaMKII* in Xenopus egg extracts was determined using the CaMKII substrate autocamtide-2 (Jones and Persaud, 1998) with a C-terminally His tag. This peptide was covalently coupled to BSA (Peptide Specialties Laboratories) and immobilized on Dynabeads (Talon; Invitrogen). Reactions were performed in a 3-μl extract aliquot for 3 min in the presence of 5 μCi [γ-32P]ATP and were stopped by chilling on ice and dilution into 200 μl of dilution buffer (100 mM KCl, 20 mM Hepes, pH 7.7, and 50 mM NaF). Beads were washed twice in dilution buffer and were eluted in SDS sample buffer. Signals of phosphorylated proteins were detected using a phosphoimager (F3000; Fujifilm) and the corresponding software (V1.8 image reader and image gauge V3.45; Fujifilm).
