Combination of the Liouville equation with the $q$-averaged energy $U_q = \langle H \rangle_q$ leads to a microscopic framework for nonextensive $q$-thermodynamics. The resulting von Neumann equation is nonlinear: $i\dot{\rho} = [H, \rho]$. In spite of its nonlinearity the dynamics is consistent with linear quantum mechanics of pure states. The free energy $F_q = U_q - TS_q$ is a stability function for the dynamics. This implies that $q$-equilibrium states are dynamically stable. The (microscopic) evolution of $\rho$ is reversible for any $q$, but for $q \neq 1$ the corresponding macroscopic dynamics is irreversible.

Standard thermodynamics is based on the Gibbs-Shannon-von Neumann entropy $S_1 = -k_B \text{Tr} (\rho \ln \rho)$ and the internal energy $U_1 = \text{Tr} \rho H$. The equilibrium density matrix $\rho_0$ minimizes the free energy $F_1 = U_1 - TS_1$. A microscopic foundation for thermodynamics is based on the von Neumann equation (vNE)

$$i\dot{\rho} = [H, \rho].$$

Equilibrium states are stable fixedpoints of this dynamics.

It is perhaps not so widely known that the vNE can be regarded as a classical Hamiltonian system with Hamiltonian function $U_1$. In this context $F_1$ is a stability function for the underlying Hamiltonian Lie-Poisson dynamics. We shall elaborate on these points later but first we want to pose the following problem. It is known that the structure of this theory is analogous to the ordinary one, with one exception: Instead of $U_1$, $S_1$ and $F_1$ one takes their $q \neq 1$ generalizations $U_q$, $S_q$ and $F_q$ (see below). The question is whether there exists an underlying dynamics for nonextensive thermodynamics. Is it given by the standard vNE (as worked out in \cite{9,10}) or, maybe the dynamics should also be $q$-modified?

The analysis given below is based on one single Ansatz: the $q$-averaged energy $U_q$ is also the Hamiltonian function of the quantum system. As we shall see, this implies that $F_q$ is again a stability function for the microscopic dynamics. In particular, the equilibrium states of $q$-thermodynamics are dynamically stable.

The vNE is an immediate consequence of the Schrödinger equation (SE)

$$i\dot{\psi} = H\psi$$

if $\rho$ represents a pure state, i.e. $\rho = \varrho = |\psi\rangle\langle\psi|$ (we use $\varrho$ to denote pure state density matrices or their reductions to subsystems). However, in real experimental situations one does not deal with pure states since (a) there exists a classical lack of knowledge about quantum sources and (b) entangled states lead to non-pure density matrices when reduced to a subsystem. Indeed, if the classical state of the device that prepares the quantum ensemble is not exactly known, and the experiment is repeated several times, one has to apply a purely classical averaging over the classical configurations of the source. This results in a non-pure density matrix

$$\rho = \int d\varrho \, w(\varrho) \varrho$$

where one integrates over quantum-mechanical pure states whose distribution is given by $w(\varrho)$. $\rho$ can be used to calculate experimental averages since the latter are linear in $\varrho$:

$$\text{Tr} \rho A = \int d\varrho \, w(\varrho) \text{Tr} \varrho A.$$

The distinction between the state $\varrho$ and the distribution $w(\varrho)$ (function defined on the space of states) leads ultimately to a sharp distinction between the Liouville equation (LE) and the vNE. In order to explain this main point let us first note that the vNE (7) can be written as a classical Hamiltonian system (8,9):

$$i\dot{\varrho}_a = \{\varrho_a, \langle H \rangle_1\}$$

where $\varrho_a = \langle \alpha | \varrho | \alpha' \rangle$ are the components of $\varrho$ taken in some basis, $\langle H \rangle_1 = \text{Tr} \varrho H$ is the average energy, and the bracket

$$\{A, B\} = \varrho_B \Omega^a_{\alpha c} \delta A \delta B \frac{\partial \Omega^c_{\beta e}}{\partial \varrho_a \varrho_e}.$$

is a Lie-Poisson bracket on the manifold of states $\mathbb{S}$. Here $\Omega^a_{\alpha c}$ are structure constants of a Lie algebra $[gl(n,C)$ for finite dimensional Hilbert spaces] and the summation convention means summation or integration with respect to an appropriate measure $\mathcal{D}\varrho$. Using the standard argument one derives the LE

$$i\dot{\varrho} = \{w, \langle H \rangle_1\}.$$
that an experimentalist can control the form of \( w \) by improving the measurement device.

The second class of density matrices that are non-pure, in the sense that \( \rho^2 \neq \rho \), occurs as an entirely quantum phenomenon and is a result of entanglement between correlated quantum systems. Such states are fundamentally and irreducibly mixed. They can be written in different ways as convex combinations of pure states and all such combinations have to be regarded as physically equivalent.

On the other hand, the decomposition (1) is uniquely determined by the experimental setup. The difference in physical status of the “pure-state” decompositions of \( \rho \) and \( \varrho \) implies that there exists a physical difference between the linearity of the LE (1) and this of the vNE (1). The linearity of the latter is a postulate that is independent of both the linearity of (1) and this of the pure state SE (3). Linear SE is compatible with any equation of the form

\[
i \dot{\rho} = [H, f(\rho)]
\]  

provided \( f(\rho) = \rho \) for \( \rho^2 = \rho \), which holds for all functions satisfying \( f(0) = 0 \) and \( f(1) = 1 \). The choice of \( f(x) = x \) is convenient but does not seem to be dictated by any fundamental principle. On the contrary, we will argue that other choices of \( f \) may be physically relevant and, in particular, we will show that there exists a link of \( f(x) = x^q \) with the nonextensive \( q \)-statistics introduced by Tsallis (3) [note that \( q > 0 \) is needed to ensure \( f(0) = 0 \)].

We shall first show that the modified dynamics given by Eq. (3) has the same Lie-Poisson structure as (1). Assume \( f \) has a Taylor expansion \( f(x) = \sum_{k=1}^{\infty} f_k x^k \) with radius of convergence at least 1. Consider the Lie-Poisson dynamics

\[
i \dot{\varrho}_a = \{ \varrho_a, (H)_f \}
\]  

with the 1-homogeneous Hamiltonian function

\[
(H)_f = \text{Tr} \left\{ (\text{Tr} \varrho) f \left( \frac{\varrho}{\text{Tr} \varrho} \right) H \right\}.
\]  

Variation of \( (H)_f \) with respect to \( \varrho \) gives the effective Hamiltonian

\[
\hat{H}(\varrho) = \frac{\delta (H)_f}{\delta \varrho} = \sum_{k=1}^{\infty} f_k (\text{Tr} \varrho)^{1-k-1} \sum_{m=0}^{k-1} \varrho^{k-1-m} H \varrho^m + \text{Tr} \left\{ f \left( \frac{\varrho}{\text{Tr} \varrho} \right) H \right\} 1 - \text{Tr} \left\{ \frac{\varrho}{\text{Tr} \varrho} f' \left( \frac{\varrho}{\text{Tr} \varrho} \right) H \right\} 1,
\]

where \( f' = df/dx \). (3) when written in an operator notation is

\[
i \dot{\varrho} = [\hat{H}(\varrho), \varrho] = (\text{Tr} \varrho) \left[ H, f(\varrho/\text{Tr} \varrho) \right].
\]  

\( \text{Tr} \varrho \) is an integral of motion so we can consider solutions normalized by \( \text{Tr} \varrho = 1 \) which shows that (3) is indeed a particular case of (1). 1-homogeneity of \( (H)_f \) implies that \( (H)_f = \text{Tr} \varrho \hat{H} \). Taking \( f(x) = x^q \), a normalized \( \varrho \), and denoting the corresponding \( (H)_f \) by \( \langle H \rangle_q \), we can see that \( \langle H \rangle_q = \text{Tr} \varrho \hat{H} = \text{Tr} \varrho^q H \) i.e. the average effective energy equals the \( q \)-average of \( H \), an internal energy typical of Tsallis generalized thermodynamics. Such averages were shown to be naturally linked to nonextensive \( q \)-entropies (13, 14). Obviously, any theory that for some reasons deals with \( q \)-averages involves some degree of nonextensivity independently of what kind of entropy is used. Let us note that in the above case the vNE is nonlinear,

\[
i \dot{\varrho} = [\hat{H}(\varrho), \varrho] = [H, \varrho^q].
\]  

Nonlinear vNE has been studied recently in (20) and is used regularly in statistical physics. The nonlinearity is usually due to friction forces and should be compensated by adding a noise term to the vNE in order to keep the average energy constant. However, for a nonlinearity of the form (3) the energy is a conserved quantity. Hence there is no need for the balancing noise term. vNE’s of the form (8) were independently found in the context of a Lie-Nambu dynamics and studied in (9, 24). It was shown, in particular, that their Hermitian Hilbert-Schmidt solutions possess time-independent spectra, an important fact that allows to treat the solutions \( \varrho(t) \) as density matrices. This implies also that for any \( t_1 \) and \( t_2 \) there exists a unitary transformation satisfying \( \varrho(t_2) = U(t_2, t_1) \varrho(t_1) U(t_2, t_1)^{-1} \). Although \( U(t_2, t_1) \neq U(t_2 - t_1, 0) \) [equality would imply linearity of evolution] the local generator of \( U(t + \epsilon, t) \), for \( \epsilon \to 0 \), exists and is our effective time-dependent Hamiltonian \( \hat{H}(\varrho(t)) \). Denote \( C_n = \text{Tr} (\varrho^n), n \in N \). One finds \( \{ C_n, F \} = 0 \) for any \( F \), which shows that \( C_n \) are Casimir invariants for the dynamics. The set of invariants contains also all \( n \)-averages of \( H \) since \( \{ (H)_n, (H)_m \} = 0 \) for any natural \( n \) and \( m \). The dynamics we consider is therefore so regular and so close to the linear one that one may wonder whether such equations do possess nontrivial solutions. Fortunately, the answer is positive. An analytical Darboux-type technique of solving (12) for \( q = 2 \) has been recently developed (22) and various explicit solutions were found. In a classical context the \( q = 2 \) case was discussed in great detail in relation to Lie-algebraic generalizations of classical Euler equations (cf. (8) and references therein, in particular (23, 24)). It is also well known that similar \( q = 2 \) Lie-Poisson equations describe plasma dynamics (in the context of a generalized statistics a paper of particular relevance is (25)).

Since the description we propose is meant to provide a fundamental quantum background for a generalized statistics it must be also capable of dealing with collections of nonextensive systems. This means we have to provide a recipe for extending the von Neumann dynamics from subsystems to composite systems. The extension should be self-consistent in the sense that a dynamics of a subsystem should be independent of whether the
system is considered alone or as part of a collection of many noninteracting systems. This is achieved by taking the 2-system Hamiltonian function \( \langle H \rangle^I_{q_0} + \langle H \rangle^II_{q_0} \). The \( q_0 \)-averages occurring in the Hamiltonian function of the composite system are

\[
\langle H^I \rangle^I_{q_0} = \text{Tr}_I (\langle q \rangle^q_0 H^I), \\
\langle H^II \rangle^II_{q_0} = \text{Tr}_II (\langle q \rangle^q_0 H^II)
\]

and the density matrices \( \rho^I \) and \( \rho^II \) are the reduced density matrices of the respective subsystems. The two-system equation one obtains is

\[
i \dot{\rho}^I + i \dot{\rho}^II = [\hat{H}^I(\rho^I) \otimes \mathbb{1} + \mathbb{1} \otimes \hat{H}^II(\rho^II), \rho^I + \rho^II],
\]

where \( \hat{H}^I(\rho^I) \) and \( \hat{H}^II(\rho^II) \) are the effective Hamiltonians of the subsystems. The choice of this particular type of extension follows from the general results proved for a Lie-Poisson nonlinear quantum mechanics of density matrices in Rajagopal and \[30\]. The expressions \( C_n(\rho^I + \rho^II) = \text{Tr}_{I+II}(\rho^I + \rho^II)^n \) are time-independent (as Casimir invariants) for any natural \( n \). Therefore, if \( \rho^I + \rho^II(t) \) is a Hermitian Hilbert-Schmidt solution of (13) then its eigenvalues are time independent on the basis of the standard argument \[21\], and therefore \( \rho^I + \rho^II(t) \) is a density matrix if it is one at \( t = 0 \). On the other hand, taking partial traces of (13) one verifies that

\[
i \dot{\rho}^I = [\hat{H}^I(\rho^I), \rho^I], \\
i \dot{\rho}^II = [\hat{H}^II(\rho^II), \rho^II],
\]

as required by the self-consistency of the extension. All these results have an immediate extension to more general Hamiltonian functions \( \langle H \rangle_f \).

Having established all these general results we are now in position to discuss in more detail the links to the generalized statistics proposed by Tsallis \[1\]. It is based on the internal energy \( U_q = \text{Tr} \varphi^q H \) and the corresponding entropy

\[
S_q(\varphi) = k_B \frac{\text{Tr} \varphi - \text{Tr}(\varphi^q)}{q-1}
\]

\( U_q \) is naturally associated with \( S_q \) since then various relations typical of \( q = 1 \) thermodynamics turn out to be \( q \)-independent. However, standard thermodynamics is static and the relations between \( U_q \) and \( S_q \) are evaluated in thermal equilibrium. From the dynamical point of view an equilibrium state \( \varphi_0 \) is a fixed point of the dynamics, i.e. \( \langle H, \varphi_0 \rangle = 0 \). There exists an infinite number of such states but not all of them have to be stable if a nonlinear Lie-Poisson dynamics is involved. The stability tests that are typically used in such a situation (say, in hydrodynamics and plasma physics) are the energy-momentum, energy-Casimir \[27\] or energy-invariants \[28\] methods. In the energy-Casimir method (used when one knows the Casimirs but does not control the symmetries) one looks for minima or maxima of the “stability function”

\[
X(\varphi) = h(\varphi) + \Phi(C_1, C_2, \ldots)
\]

where \( h(\varphi) \) is a Hamiltonian function of the Hamiltonian dynamical system and \( \Phi \) is a function of the Casimir invariants \( C_k \) typical of this system. The latter function is determined by the requirement that \( X(\varphi) \) has a strict minimum or maximum at \( \varphi_0 \), in particular

\[
\frac{\delta X}{\delta \varphi}(\varphi_0) = 0.
\]

In our case \( h(\varphi) = U_f = \langle H \rangle_f \) (or \( U_q \) if we restrict the analysis to \( f(x) = x^q \)), and the Casimirs are all functions \( C(\varphi) \) that can be written as a trace of a convergent power series i.e.

\[
C(\varphi) = \text{Tr} \left( \sum_k c_k \varphi^k \right) = \sum_k c_k C_k(\varphi) =: \Phi(C_1, C_2, \ldots).
\]

It is clear that the stability function \( X \) for the energy-Casimir method is nothing else but the free energy \( F \) corresponding to a generalized entropy \( S = -\Phi/T \) with \( T \) the temperature. In this way the thermodynamic relation \( F = U_f - TS \) is recovered. The equilibrium state \( \varphi_0 \) is an extremum of \( F \). If this is a strict minimum (or maximum) then the orbits of density matrices in a neighborhood of \( \varphi_0 \) are dynamically stable. Thermodynamic stability of the Tsallis thermodynamics has been raised in \[29\] and settled in \[30\]. Therefore equilibrium states extremizing \( F \) will generically be dynamically stable fixed points of the nonlinear vNE.

Once dynamic stability of \( \varphi_0 \) is established it becomes meaningful to study linear response theory \[21\]. This has been done in the context of non-extensive statistics by Rajagopal \[17\] \[32\]. However, the theory has to be modified because of the nonlinearity of the vNE. A discussion of these modifications is out of the scope of the present paper and will be presented elsewhere.

Let us illustrate the above results with the simple example of a single spin in an external field. The Hamiltonian is given by \( H = -\mu \sigma_z \) (assume \( \mu > 0 \), the \( \sigma_x, \sigma_y, \sigma_z \) are the Pauli matrices). A general Hermitian \( 2 \times 2 \) matrix with eigenvalues \( \lambda_1, \lambda_2 \) is

\[
\varphi = \frac{1}{2}(\lambda_1 + \lambda_2) \mathbb{1} + \frac{1}{2}(\lambda_1 \lambda_2 - \sigma_z \cos(\phi) \sigma_z - \sigma_y \sin(\phi)) (\cos(\psi) \sigma_x + \sin(\psi) \sigma_y). \tag{17}
\]

If \( \sin(\phi) = 0 \) or \( \lambda_1 = \lambda_2 \) then \( \varphi \) is time-invariant. In the other case Eq. (8) implies \( \dot{\psi} = 0 \), and Larmor precession frequency \( \omega \) depends in general on the eigenvalues of \( \varphi \). For this example this is the only effect induced by the nonlinearity of the vNE. Note that \( \omega = 2\mu \) is still valid for pure states — the underlying quantum mechanics remains unchanged.

One verifies that \( \langle H \rangle_q = -\mu (\lambda^q - (1 - \lambda)^q) \) and \( \hat{H}(\varphi_0) = -\gamma \sigma_z + \gamma \mu [\lambda^q + (1 - \lambda)^q] / 2 \). Now assume \( f(x) = x^q \). The internal energy is
\[ U_q = \text{Tr} \, \varrho^q H = -\mu \cos(\phi) (\lambda^q - \lambda^0). \]  \hfill (19)

The $q$-entropy equals $S_q = k_B \left( 1 - \lambda^0 \right) / (q - 1)$ In both formulas one should take $\lambda_1 = \lambda \geq 0$ and $\lambda_2 = 1 - \lambda \geq 0$. Of physical interest are minima of $F$ for which $\lambda > 1 - \lambda$ and $U_q < 0$. Hence one can take $\cos(\phi) = 1$. From $\partial^2 F / \partial \lambda^2 = 0$, with $\beta = 1/k_B T$ and assuming $0 < |q - 1|/\beta \mu < 1$ one finds that the eigenvalue $\lambda$ of $\varrho_0$ is the solution of

\[ \left( \frac{\lambda}{1 - \lambda} \right)^{q - 1} = \frac{1 + (q - 1)/\beta \mu}{1 - (q - 1)/\beta \mu}. \]  \hfill (20)

The value of $\partial^2 F / \partial \lambda^2$ at equilibrium is strictly positive. In fact, $F$ has an absolute minimum at $\varrho = \varrho_0$. This thermodynamic stability implies dynamic stability of $\varrho_0$ as a fixed point of the nonlinear vNE. One concludes that Tsallis thermodynamics is useful to analyse the dynamic stability of fixed points of the nonlinear vNE.

A special feature of the nonlinear vNE is that classical mixtures of initial conditions evolve irreversibly with time (this property has been discussed extensively in [20]). Take e.g.

\[ \rho = \int_0^1 d\lambda \int_0^\pi \sin(\phi) \, d\phi \int_0^{2\pi} d\psi \, \omega(\lambda, \phi, \psi) \rho(\lambda, \phi, \psi) \]

with $\omega(\lambda, \phi, \psi) = (1/8) \sin(\psi/2)$ and with $\rho(\lambda, \phi, \psi)$ given by (17). A short calculation then shows that

\[ \rho(t) = \frac{1}{2} \left( 1 + \frac{\pi}{24} \int_0^1 d\lambda (2\lambda - 1) \right) \cos(\omega(\lambda)t) + \sin(\omega(\lambda)t) \]

with $\omega(\lambda)$ given by (18). Due to the dependence of $\omega$ on $\lambda$ a dephasing occurs and the classical density matrix converges to $\frac{1}{2}$ as $t \to \infty$. The lack of knowledge about initial conditions leads to a true irreversible decay.

An analysis of more complicated examples including linear response theory will be presented in a forthcoming paper.

We are grateful to Juan-Pablo Ortega for his comments on stability of nonlinear Hamiltonian systems and for his interest in our work. Our collaboration is a part of the Flemish-Polish project No. 007 and was financed in part by the KBN Grant No. 2 P03B 163 15.
