The Parity of Directed Hamiltonian Cycles

Andreas Björklund and Thore Husfeldt*

January 31, 2013†

Abstract

We present a deterministic algorithm that given any directed graph on \( n \) vertices computes the parity of its number of Hamiltonian cycles in \( O(1.618^n) \) time and polynomial space. For bipartite graphs, we give a \( 1.5n^{\text{poly}(n)} \) expected time algorithm.

Our algorithms are based on a new combinatorial formula for the number of Hamiltonian cycles modulo a positive integer.

1 Introduction

It is known since the 1960s that Hamiltonian cycles in an \( n \)-vertex graph can be detected and counted in \( O(2^n n^2) \) time \([1, 8]\). In an influential survey, Woeginger \([11]\) asked if this could be significantly improved. Recently, two results using different techniques have met this challenge:

1. a randomized \( O(1.657^n) \) time algorithm for the decision problem in undirected graphs \([2]\),

2. a randomized \( O(1.888^n) \) time algorithm for the decision problem in directed bipartite graphs \([5]\).

For the general directed graph case, no such algorithm has appeared yet.

Inspired by the fact that the algorithm for the bipartite case in \([5]\) actually computes the parity of the number of Hamiltonian cycles, we show how to compute this value for any directed graph in \( O(1.618^n) \) time.

While this does not seem to shed any direct light on the decision problem in directed graphs, it does however ask a related interesting question: Could it really be easier to solve a \( \oplus P \)-complete problem than its decision counterpart? Even the known algorithm for the undirected graph decision case \([2]\) is slower than our present algorithm. We note in passing that for another well-known problem, Set Cover, current evidence points in the opposite direction:

† Revision 7663789.
It is known that a fast algorithm for computing the parity of the number of set covers would disprove the Strong Exponential Time Hypothesis [4], whereas no such connections are known for the decision variant.

1.1 Results

Let $\mathcal{H}$ denote the set of (directed) Hamiltonian cycles of a directed input graph $G = (V, E)$ on $n = |V|$ vertices.

Our main result is that the parity $\oplus \mathcal{H}$ of the number of directed Hamiltonian cycles can be computed much faster than in $2^n$ time.

**Theorem 1.** We can compute $\oplus \mathcal{H}$ for a general $n$-vertex digraph in time within a polynomial factor of the $n$th Fibonacci number $F_n \in O(1.618^n)$ and polynomial space.

For the restricted family of bipartite graphs, we can show a stronger bound. This result is also somewhat easier to prove.

**Theorem 2.** We can compute $\oplus \mathcal{H}$ for a bipartite $n$-vertex digraph in expected time within a polynomial factor of $O(1.5^n)$ and polynomial space.

Both results rely on a new characterization of the number of Hamiltonian cycles in terms of a local property.

**Theorem 3.** For a vertex subset $X$, let $d_v(X)$ denote the number of directed edges from vertex $v$ to a vertex in $X$. For integer $K \geq 2$,

$$|\mathcal{H}| = \frac{1}{K} \sum_{Z,Y_1,\ldots,Y_K} (-1)^{|V \setminus Z|} \left( \prod_{z \in Z} d_z(V \setminus Z) \right)^K \prod_{k=1}^K \left( \prod_{y \in Y_k} d_y(Y_k) \right) \pmod{K},$$

where the sum is over all $(K + 1)$-partitions of $V$.

Our algorithms use this result for $K = 2$, but we state (and prove) it for general $K$.

1.2 Related results

There are nontrivial examples of hard counting problems where computing the parity is easy. In fact an important example is given by a closely related problem: computing the number $\# \mathcal{C}$ of disjoint cycle covers in a directed graph. This is a hard counting problem, equivalent to computing the permanent of the adjacency matrix. On the other hand, the parity $\oplus \mathcal{C}$ equals the parity of the determinant and is therefore computable in polynomial time by Gaussian elimination. However, the problem studied in the present paper, $\oplus \mathcal{H}$, remains complete for the complexity class $\oplus P$, even for very restricted classes of graphs [10].

Counting the number of Hamiltonian cycles in an $n$-vertex directed graph can be done in $o(2^n)$ time [3]. However, the improvement over the classic algorithms [1 8] is relatively small (within a factor of $\exp(O(\sqrt{n/\log n}))$). The
parity problem appears to be easier. First, for undirected graphs it is known
that when all vertex degrees are odd, there is an even number of Hamilton-
ian cycles passing through each (directed) edge [9]. Second, a recent paper of
Cygan, Kratsch, and Nederlof [5] includes a deterministic $O(1.888^n)$ time,
exponential space algorithm computing the parity of the number of Hamiltonian
cycles for undirected and directed bipartite graphs. Our present algorithm is
faster, uses only polynomial space, and works for unrestricted directed graphs
as well. On the other hand, the algorithm from [5] works for weighted graphs.
This is a crucial property because it allows the use of the Isolation lemma to
construct a (randomized) decision algorithm. Our constructions do not seem
to allow this extension.

The parity and decision problems can be compared on the promise prob-
lem of detecting a unique Hamiltonian cycle. The result of [2] provides a
randomized algorithm for undirected graphs; our result also applies to di-
rected graphs, and is slightly faster on undirected graphs ($O(1.618^n)$ versus
$O(1.657^n)$).

1.3 Open questions

Our paper accentuates the fact that the exponential time complexity of count-
ing or deciding the Hamiltonian cycles in a directed graph is not very well un-
derstood. While there are several examples of $\oplus$P-complete problems whose
decision analogue is computationally easier (e.g., $\oplus$2-Satisfiability), examples
of the converse are not known to the authors.

Under the Exponential Time Hypothesis, the decision problem does not
allow $\exp(\epsilon n)$-time algorithms for arbitrary $\epsilon > 0$, but there are no arguments
for or against an $O(1.999^n)$-time algorithm for the decision problem.

For comparison, it is now known that the parity of the number of set covers
of a given set system on $n$ elements requires $O(2^{(1-\epsilon)n})$ time under the Strong
Exponential Time Hypothesis [4].

1.4 Overview

We first describe the top level algorithm in section 2 based on theorem 3. In
sections 3 and 4 we address the specific parts of the algorithm for the bipartite
and the general input case, respectively. Finally, in section 5 we give the proof
of theorem 3.

2 Algorithm

By specializing the expression from theorem 3 to $K = 2$, we get

$$\oplus \mathcal{H} = \frac{1}{2} \sum_{Z, Y_1, Y_2 \subseteq Z} \left( \prod_{z \in Z} d_z(V \setminus Z) \right) \left( \prod_{y \in Y_1} d_y(Y_1) \right) \left( \prod_{y \in Y_2} d_y(Y_2) \right) \pmod{2}.$$
In particular, we removed the factor \((-1)^{|V\setminus Z|}\), because \(-1 = +1 \mod 2\).

We introduce \(X = Y_1\), \(Y = Y_2\) and let \(Z\) denote the vertex complement \(Z = V \setminus Z\). Finally, we separate the expression into the contributions of \(X\) and \(Y \cup Z\), respectively:

\[
\oplus \mathcal{H} = \sum_X f(X) \prod_{x \in X} d_x(X) \mod 2, \tag{1}
\]

where

\[
f(X) = \frac{1}{2} \sum_{Y, Z} \left( \prod_{y \in Y} d_y(Y) \right) \prod_{z \in Z} d_z(Z). \tag{2}
\]

Still, the sum is over all tripartitions \(X, Y, Z\), of the vertices and thus has \(3^n\) terms, so it does not in itself serve as a fast algorithm.

There are two parts to our algorithm. First, for many \(X\), already the factor \(\prod_{x \in X} d_x(X)\) in (1) will be zero modulo 2. Hence, these subsets contribute nothing and we will avoid explicitely listing them. Second, for any \(X\) for which it is not zero, the value of \(f(X)\) modulo 2 can be computed in polynomial time in \(|V|\) via linear algebra.

On the top level our algorithm is simply an evaluation of (1) and (2).

**Algorithm P (Parity.)** Given a directed graph \(G = (V, E)\), compute \(\oplus \mathcal{H}\).

- **P1** [Initialise.] Set \(s = 0\).
- **P2** [Locate.] List every \(X \subseteq V\) such that \(\prod_{x \in X} d_x(X)\) is odd.
- **P3** [Contribute.] Compute \(f(X) \mod 2\) for every such \(X\) and add it to \(s\).
- **P4** [Report.] Return \(s \mod 2\).

Note that steps P2 and P3 can be interleaved in order to avoid storing all \(X\).

We proceed by explaining how to execute steps P2 and P3 efficiently.

### 2.1 Step P2: Locating Subsets that Contribute

We say that a subset \(X \subseteq V\) is **contribution** if \(\prod_{x \in X} d_x(X)\) is odd. Our aim is to generate the contributing subsets. We identify \(V\) with \(\{1, \ldots, n\}\) and introduce the indicator variables \(x_1, \ldots, x_n \in \{0, 1\}\) for \(X \subseteq V\) with \(x_i = 1\) if and only if \(i \in X\). Then the constraint that \(d_i(X)\) is odd can be expressed in terms of the adjacency matrix \(A\) of \(G\) as

\[
\sum_{j=1}^n a_{ij} x_j = 1 \mod 2 \quad \text{for all } i \in X,
\]

equivalently,

\[
x_i \left( \sum_{j=1}^n a_{ij} x_j \right) = x_i \mod 2 \quad \text{for all } i = 1, \ldots, n.
\]
We will view these constraints as a system of \( n \) quadratic equations over GF(2) in the variables \( x_1, \ldots, x_n \):

\[
\begin{align*}
  x_1(a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n) &= x_1 \\
  x_2(a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n) &= x_2 \\
  &\vdots \\
  x_n(a_{n1}x_1 + a_{n2}x_2 + \cdots + a_{nn}x_n) &= x_n.
\end{align*}
\]

This system can be succinctly expressed as a matrix equation over GF(2):

\[
\textbf{x} \circ A \textbf{x} = \textbf{x} \tag{3}
\]

where \( \textbf{x} = (x_1, \ldots, x_n) \) and the operator \( \circ \) denotes the coordinate-wise (or Hadamard, or Schur) product.

2.2 Random self-loops

\textit{A priori}, listing the solutions to (3) requires \( 2^n \) steps. In fact, already the size of the solution set is easily seen to be of order \( 2^n \) for some graphs. For instance, every vector \( \textbf{x} \) with an odd number of 1s solves (3) if \( A \) is the all-1s matrix corresponding to a directed clique with self-loops.

This motivates the main algorithmic insight in our construction. Because no Hamiltonian cycle can use a self-loop, we can add self-loops to the vertices \( G \) (or remove them) without changing \( \mathcal{H} \). Algebraically, manipulation of self-loops corresponds to flipping the diagonal entries of \( A \).

We show that adding these loops at random reduces the expected solution size for all graphs.

\textbf{Lemma 1.} Let \( A \) be an \( n \times n \) matrix with 0,1-entries. Choose the diagonal entries \( a_{11}, \ldots, a_{nn} \in \{0,1\} \) uniformly and independently at random. Then the expected number of solutions to (3) is \( 1.5^n \).

\textbf{Proof.} Consider the \( i \)th entry of \( \textbf{x} \). If \( x_i = 0 \) then the \( i \)th equation in (3) is \( 0 = 0 \) and trivially satisfied. If \( x_i = 1 \) then the \( i \)th equation in (3) is satisfied if

\[
1 = \sum_{j=1}^{n} a_{ij}x_j = a_{ii} \cdot 1 + \sum_{j=1, j\neq i}^{n} a_{ij}x_j,
\]

which happens with probability \( \frac{1}{2} \) because \( a_{ii} \) is uniformly distributed. By independence of the choices of \( a_{ii} \), a vector \( \textbf{x} \) with \( k \) 1s satisfies all the equations with probability \( 2^{-k} \). By linearity of expectation, the expected number of solutions is

\[
\sum_{k=0}^{n} \binom{n}{k} 2^{-k} = (1 + \frac{1}{2})^n,
\]

using the binomial theorem. \( \square \)
In section 3 we show that these $1.5^n$ solutions can be efficiently listed if $G$ is bipartite. In section 4 we show that the solutions can be listed in time $O(1.618^n)$ for general graphs.

### 2.3 Gaussian elimination

We assume that the following algorithm for solving nonhomogeneous systems of linear equations is well known. We repeat it here only to recall that the solution set can be described in terms of the basis of translated vector space (the system’s null space). In particular, if a linear equation system has a solution at all, the number of solutions equals $2^d$, where $d$ is the dimension of the null space.

**Algorithm G (Gaussian elimination)** Given a nonhomogeneous system $Ax = c$ of linear equations. If the system has no solution, output “no”. Otherwise, output a vector $v$ and $d$ linearly independent vectors $b_1, \ldots, b_d$ such that the set of vectors $x$ with $Ax = c$ equals $\{v + \text{span}(b_1, \ldots, b_d)\}$.

Gaussian elimination runs in polynomial time and works over finite fields.

### 2.4 Step P3: Computing the Contributions

We return to the value $f(X)$ in [2] and show how to compute it in polynomial time, at least modulo 2.

It will be convenient to remove the factor $\frac{1}{2}$. To this end, consider a partial order $\prec$ on the subsets of $V$ such that for disjoint $X, Y \subseteq V$, not both empty, either $X \prec Y$ or $Y \prec X$. Then, from [2],

$$f(X) = \frac{1}{2} \sum_{Y, Z} \prod_{y \in Y} d_y(Y) \prod_{z \in Z} d_z(Z)$$

where $Y, Z$ always form a disjoint partition of $V \setminus X$. To see the second step, note that we never get a contribution for $Z = V$ because the term $\prod_{z \in Z} d_z(Z)$ vanishes in this case. Hence, $X \cup Y$ is non-empty for any contributing $Z$, and because of the symmetry in the formula with respect to $X$ and $Y$, each $Z$ that contributes to the sum will be counted an even number of times.

The salient feature of [4] is that modulo 2, we can now view $f(X)$ as the number of solutions to an equation system over GF(2).
We define the partial order $\preceq$ on the subsets of $V$ as follows. Identify $V$ with $\{1, \ldots, n\}$ and set $X \prec Y$ if $\min X < \min Y$, with the usual convention $\min \emptyset = \infty$. (By the previous paragraph, the case $X = Y = \emptyset$ never arises.) We will set up a system of linear equations in $y_1, \ldots, y_n$, so that $f(X)$ equals the number of solutions (mod 2). We use the obvious correspondence

$$y_i = \begin{cases} 1, & \text{if } i \in Y; \\ 0, & \text{if } i \notin Y. \end{cases}$$

First, since $Y$ belongs to the complement of $X$ we introduce the equations

$$y_i = 0 \quad \text{for } i \in X. \quad (5)$$

Second, to ensure $X \prec Y$ we introduce the equations

$$y_i = 0, \quad \text{for } i = 1, \ldots, \min X. \quad (6)$$

Finally, a subset $Y$ with $X \prec Y$ contributes to $f(X)$ if all product terms in $d$ are 1, so we need

$$d_i(Y) = 1 \pmod{2}, \quad \text{if } i \in Y$$

$$d_i(X \cup Y) = 1 \pmod{2}, \quad \text{if } i \notin Y$$

for each $i \notin X$. Since $d_i(X \cup Y) = d_i(X) + d_i(Y)$ we can rewrite the second constraint to

$$d_i(Y) = 1 + d_i(X) \pmod{2}, \quad \text{if } i \notin Y.$$ 

In terms of the variables $y_1, \ldots, y_n$ and the adjacency matrix $A$ of $G$ we have the equations

$$\sum_{j=1}^{n} a_{ij} y_j = \begin{cases} 1, & \text{if } y_i = 1; \\ 1 + d_i(X), & \text{if } y_i = 0; \end{cases}$$

for each $i \notin X$. (Note that $d_i(X)$ is a fixed value depending only on $X$.) The right hand side simplifies to $1 + d_i(X) + d_i(X) y_i$, so the resulting equations are

$$d_i(X) y_i + \sum_{j=1}^{n} a_{ij} y_j = 1 + d_i(X), \quad \text{for } i \notin X. \quad (7)$$

In summary, the solutions to the equations in (5), (6), and (7) describe exactly the subsets $Y \subseteq V \setminus X$ with $X \prec Y$ that contribute 1 to $f(X)$. The number of such solutions is odd exactly if the system of equations has a unique solution. This is determined by Gaussian elimination in time polynomial in $n$.

### 3 Bipartite Input Graphs

We first describe an algorithm for the step P2 for the case that the input graph is bipartite. We can safely assume that the input bipartite graph is balanced on
two equal sized vertex sets $V_1 \cup V_2 = V$. (Otherwise, there can be no Hamiltonian cycles.)

Let

$$B = \begin{bmatrix} 0 & B_{12} \\ B_{21} & 0 \end{bmatrix}$$

denote the adjacency matrix of the input graph. Choose the random values $r_1, \ldots, r_n \in \{0,1\}$ uniformly and independently and construct the diagonal matrix $R = \text{diag}(r_1, \ldots, r_n)$. Set $A = B + R$. The equation system (3) becomes

$$x \circ (B + R)x = x \circ \begin{bmatrix} 0 & B_{12} \\ B_{21} & 0 \end{bmatrix}x + x \circ Rx = x,$$

equivalently,

$$x_1 \circ B_{12}x_2 = x_1 - x_1 \circ R_1 x_1$$
$$x_2 \circ B_{21} x_1 = x_2 - x_2 \circ R_2 x_2,$$

where $x = (x_1, x_2)$ and $R = \text{diag}(R_1, R_2)$. In this formulation it is apparent that for fixed $x_1$, the equation system (in the variables $x_2$) is linear; note in particular that $x_2 \circ R_2 x_2 = R_2 x_2$ because $R_2$ is diagonal and multiplication in $\text{GF}(2)$ is idempotent. Thus, the system can be solved by Gaussian elimination in polynomial time.

**Algorithm B (Bipartite graphs.)** Given a bipartite directed graph $G = (V, E)$ with $n = |V|$, lists the vertex subsets $X \subseteq V$ for which $d_x(X)$ is odd for all $x \in X$.

**B1** [Add random self loops.] Choose $r_1, \ldots, r_n \in \{0,1\}$ uniformly at random and add a self-loop at vertex $v_i$ if $r_i = 1$.

**B2** [Initialise.] Set $x_1 = \cdots = x_{n/2} = 0$.

**B3** [Solve.] Solve the system $x \circ Ax = x$ in the free variables $x_{n/2+1}, \ldots, x_n$ using algorithm G. If it returns “none” proceed to B5.

**B4** [Report.] (Algorithm G returned the solution set as $v, b_1, \ldots, b_d$.) Output the vectors $v + \alpha_1 b_1 + \cdots + \alpha_d b_d$ for all $2^d$ choices of $\alpha_1, \ldots, \alpha_d \in \{0,1\}$.

**B5** [Next.] If all choices of $(x_1, \ldots, x_{n/2})$ have been inspected, terminate. Otherwise generate the next choice and return to B3.

The number of choices of $x_1$ is $2^{n/2}$, so step B3 takes total time $2^{n/2}poly(n)$. This is dominated by the overall running time of step B4, which is linear in the number of contributing subsets $X$. These are $1.5^d$ in expectation according to lemma [1]. Hence the runtime is $1.5^n poly(n)$ in expectation. This finishes the proof of theorem [2].
4 General Input Graphs

For general graphs, we do not know how to list the solutions \( S \) in step \( P_3 \) to \( S' \) in time proportional to the solution set. Instead, we will efficiently list a superset \( S'' \) of the solution set of size \( O(1.618^n) \). We can then examine every \( x \in S'' \) to see that it solves \( S' \).

The superset \( S'' \) of candidate solutions to \( S \) is defined as follows. Let \( x' = (x_1, \ldots, x_{n-k}) \in \{0, 1\}^{n-k} \) and introduce the variables \( x_{n-k+1}, \ldots, x_n \). Set \( x = (x_1, \ldots, x_n) \). Consider the equation system

\[
(x', 0_k) \circ Ax = (x', 0_k).
\]

For fixed \( x' \), this is nonhomogeneous set of linear equations in the variables \( x_{n-k+1}, \ldots, x_n \). Every prefix of a solution to \( S \) is a solution to \( S' \):

**Lemma 2.** Let \( x = (x_1, \ldots, x_n) \in \{0, 1\}^n \) and \( x' = (x_1, \ldots, x_{n-k}) \) for some \( k \in \{0, 1, \ldots, n\} \). If \( x \) satisfies \( x \circ Ax = x \) then \( (x', 0_k) \circ Ax = (x', 0_k) \).

**Proof.** For \( 1 \leq i \leq n-k \), the \( i \)th equation of both \( x \circ Ax = x \) and \( (x', 0_k) \circ Ax = (x', 0_k) \) is

\[
x_i \sum_{j=1}^n a_{ij} x_j = x_i.
\]

For \( i > n-k \), the \( i \)th equation of \( (x', 0_k) \circ Ax = (x', 0_k) \) simplifies to \( 0 = 0 \), which is trivially satisfied. \( \square \)

We will show that we can avoid generating all \( 2^n \) prefixes.

Let \( \binom{n-k}{k} \) denote the family of vectors \( (x_1, \ldots, x_{n-k}) \in \{0, 1\}^{n-k} \) for which \( x_1 + \cdots + x_{n-k} = k \). Let \( \binom{n-k-1}{k} \) denote the family of vectors \( (x_1, \ldots, x_{n-k}) \in \{0, 1\}^{n-k} \) for which \( x_1 + \cdots + x_{n-k-1} = k \) and \( x_{n-k} = 1 \). The notation is motivated by the cardinalities,

\[
\left| \binom{n-k}{k} \right| = \binom{n-k}{1} \quad \text{and} \quad \left| \binom{n-k-1}{k} \right| = \binom{n-k-1}{1}.
\]

**Lemma 3.** Let \( x \in \{0, 1\}^n \). Then there is exactly one \( k \in \{0, \ldots, \lfloor n/2 \rfloor \} \) such that the \( (n-k) \)th prefix \( x' = (x_1, \ldots, x_{n-k}) \) belongs to \( \binom{n-k}{k} \) or \( \binom{n-k-1}{k} \).

**Proof.** Let \( w_k = x_1 + \cdots + x_{n-k} \). Choose the smallest \( k \geq 0 \) with the property

(i) \( w_k = k \),

(ii) \( w_k = k+1, x_{n-k} = 1 \).

To see that such \( k \) exists consider the pairs of values \( (w_k, k) \) for \( k = 0, 1, \ldots \). The first pair is \( (x_1 + \cdots + x_n, 0) \). The left value decreases monotonically by 0 or 1 down to 0. The right value increases 0, 1, 2, \ldots. The only possibility that \( (i) \) lacks a solutions is that \( w_k \) and \( k \) pass each other, i.e., there exists \( k \) such that

\[
w_k = k+1, w_{k+1} = k.
\]
Figure 1: The sets \( \binom{n-k}{k} \) and \( \binom{n-k-1}{k} \) for \( n = 7 \) and \( k \in \{0, \ldots, \lfloor n/2 \rfloor \} \). The bottom row shows all 128 bit patterns on 7 bits.

But in that case \( x_{n-k} = 1 \) so that \((ii)\) is satisfied. Note also that if \((ii)\) holds for \( k \), then \((i)\) does not for that \( k \), and vice versa. Also note that \( k \) is at most \( \lfloor n/2 \rfloor \), since \( w_k \) is at most \( n-k \).

We have that either \((i)\) is satisfied and \( x' \) belongs to \( \binom{n-k}{k} \), or \((ii)\) is satisfied and \( x' \) belongs to \( \binom{n-k-1}{k} \).

We claim that there cannot be another solution \( k' > k \) to either \((i)\) or \((ii)\). Consider first the case that \( k' \) satisfies \((i)\) and \( k \) satisfies \((ii)\). In particular, \( k+1 = w_k = w_{k-1} + x_{n-k} = w_{k-1} + 1 \), so \( k = w_{k-1} \). Then,

\[
k' = w_{k'} \leq w_{k-1} = k,
\]

a contradiction. The remaining three cases follow from the monotonicity of the left and right hand sides.

We note in passing that the previous lemma gives a combinatorial proof of the identity

\[
\sum_k \left( \binom{n-k}{k} + \binom{n-k-1}{k} \right) 2^k = 2^n,
\]

see figure 1. For another way to verify this expression, compute

\[
\sum_k \binom{N-k}{k} 2^k = \frac{1}{3}(2^{N+1} + (-1)^{N+1}),
\]

which comes from evaluating a known, closed form for the generating function \( \sum_k \left( \frac{N-k}{k} \right) z^k \) at \( z = 2 \) [exercise 1.2.9.15]. Then add these values for \( N = n \) and \( N = n-1 \) to arrive at \( \frac{1}{3}(2^{n+1} + (-1)^{n+1} + 2^n + (-1)^n) = \frac{1}{3}(2+1)2^n = 2^n \).

Finally, we need to bound the number of solutions to (8). A priori, this is a system in \( k \) variables each ranging over \( \{0,1\} \), so the number of solutions can be \( 2^k \). However, we will show that in expectation, the number of solutions is exactly 1:

**Lemma 4.** Let \( x' \) denote a vector of fixed values \( x' = (x_1, \ldots, x_{n-k}) \) from \( \binom{n-k}{k} \) or \( \binom{n-k-1}{k} \) and introduce the variables \( x_{n-k+1}, \ldots, x_n \in \{0,1\} \). Set \( x = (x_1, \ldots, x_n) \).
Let $A$ be a matrix whose diagonal entries are chosen uniformly at random from $\{0, 1\}$. Then the expected number of solutions to

$$(x', 0_k) \circ A x = (x', 0_k) \pmod{2}$$

is 1.

**Proof.** Set $r_i = a_{ii}$. For $0 \leq i \leq n - k$, the $i$th equation has the form

$$x_i \sum_{j=1}^{n} a_{ij} x_j = x_i \pmod{2}.$$

Since there are exactly $k$ entries $x_i = 1$, there are exactly $k$ of such equations that do not trivialise to $0 = 0$. We can rewrite each of these equations to

$$\sum_{j=1}^{n} a_{ij} x_j = 1 \pmod{2}$$

or, isolating the variables on the left hand side,

$$\sum_{j=n-k+1}^{n} a_{ij} x_j = 1 + r_i + \sum_{j=1, j\neq i}^{n-k} a_{ij} x_j \pmod{2}.$$

Now it is clear that the system consists of $k$ equations in the $k$ variables $x_{n-k+1}, \ldots, x_n$. The right hand side is uniformly distributed from $\{0, 1\}$, so an assignment to the variables satisfies an equation with probability $\frac{1}{2}$. By independence of the choices of $r_i$, all $k$ equations are satisfied with probability $2^{-k}$. There are $2^k$ assignments, so the expected number of solutions is $2^k 2^{-k} = 1$. $\square$

**Algorithm C (Contributing subsets for general graphs.)** Given a graph $G = (V, E)$ with $n = |V|$, list the vertex subsets $X \subseteq V$ for which $d_\chi(X)$ is odd for all $x \in X$.

C1 [Add random self loops.] Choose $r_1, \ldots, r_n \in \{0, 1\}$ uniformly at random and add a self-loop at vertex $v_i$ if $r_i = 1$. Let $A$ denote the adjacency matrix of the resulting graph.

C2 [Initialize.] Set $k = 0$, $x' = 0_n$.

C3 [Solve.] Solve the nonhomogeneous linear equation (8) in the free variables $x_{n-k+1}, \ldots, x_n$ using algorithm $G$. If there is no solution, proceed to C5.

C4 [Filter solution.] Generate every vector $x = v + \alpha_1 b_1 + \cdots + \alpha_d b_d$ for all $2^d$ choices of $\alpha_1, \ldots, \alpha_d \in \{0, 1\}$. If $x$ solves the equation $x \circ A x = 1_n$, then output $x$.

C5 [Next prefix.] Update $x'$ and possibly $k$ so that $x'$ is the next element of $\binom{n-k}{k}$ or $\binom{n-k-1}{k}$ for $k = 0, \ldots, \frac{1}{2} n$, and return to C3. (When all these elements have been generated, the algorithm terminates.)
**Lemma 5.** The running time of algorithm C is within a polynomial factor of
\[
\left(\frac{1 + \sqrt{5}}{2}\right)^n
\] in expectation.

**Proof.** For the running time, we first observe that the members of \(\binom{n-k}{k}\) and \(\binom{n-k-1}{k}\) can be listed with polynomial (in fact, constant) delay [7, sec. 7.2.1.3].

The number of iterations is given by the sizes of \(\binom{n-k}{k}\) and \(\binom{n-k-1}{k}\), summed over all \(k = 0, \ldots, \lfloor n/2 \rfloor\). These are well-studied quantities, and it is known [7, ex. 1.2.8.16] that
\[
\sum_k \binom{n-k}{k} + \sum_k \binom{n-k-1}{k} = F_{n+1} + F_n = F_{n+2},
\]
where \(F_n\) is the \(n\)th Fibonacci number, bounded by (9).

The running time is dominated by the time spent in steps C3 and C4. Step C3 takes polynomial time every time it is executed thanks to the polynomial running time of algorithm G. Step C4 looks more difficult to bound, because it may exhaust the entire solution space to an equation system in \(k\) unknowns. Naively, this would lead to a total running time of
\[
\sum_k \binom{n-k}{k} 2^k > 2^{n-1}.
\]
However, by lemma 4, the expected size of this solution space is 1. Thus, we expect to generate and verify only one vector \(x\), so the time spent in C4 is polynomial in expectation in each iteration. By linearity of expectation, the total time spent in C4 is within a polynomial factor of (9).

### 4.1 Derandomization

We use the method of conditional expectations to derandomise algorithm C. Our randomness is over the choices of \(r_1, \ldots, r_n\), the self-loop indicators. The expected number of candidate solutions \(S\) given a specific choice of values for the first \(k\) choices satisfies
\[
\mathbb{E}[S \mid (r_1, \ldots, r_k)] = \frac{1}{2} \mathbb{E}[S \mid (r_1, \ldots, r_k, 0)] + \frac{1}{2} \mathbb{E}[S \mid (r_1, \ldots, r_k, 1)]
\]
for all \(k \geq 0\). In particular, there is a specific assignment to \(r_1, \ldots, r_n\) such that \(\mathbb{E}[S \mid (r_1, \ldots, r_n)] \leq \mathbb{E}[S]\). Thus, by mimicking the behaviour of algorithm C, but computing the expected solution sizes of the systems (8) instead of solving them, we can choose the assignment greedily one variable at the time, until we get rid of all the randomness. The final assignment has no more candidate solutions than the original expected number.

The next lemma shows that we can efficiently compute the expectations \(\mathbb{E}[S \mid (r_1, \ldots, r_k, 0)]\) and \(\mathbb{E}[S \mid (r_1, \ldots, r_k, 1)]\).
Lemma 6. Let $x'$ and $x$ be an in lemma[2] Let $l \in \{0, \ldots, n\}$. Let $A$ be a matrix whose diagonal entries $a_{ii} = r_i$ for $l < i \leq n$ are chosen uniformly at random from $\{0, 1\}$. Then the expected number of solutions to 

$$(x', 0_k) \circ Ax = (x', 0_k) \pmod{2}$$

is given by a polynomial size linear equation system in the variables $x_{n-k+1}, \ldots, x_n$ and $r_{l+1}, \ldots, r_n$.

Proof. The only contributing equations are those for which $x_i = 1$, of the form

$$1 \cdot \sum_{j=1}^{n} a_{ij} x_j = 1 \pmod{2}$$

We can rewrite these equations as

$$\sum_{j=n-k+1}^{n} a_{ij} x_j = 1 + \sum_{j=1}^{n-k} a_{ij} x_j \pmod{2}$$

for $i \leq l$, and

$$r_i + \sum_{j=n-k+1}^{n} a_{ij} x_j = 1 + \sum_{j=1}^{n-k} a_{ij} x_j \pmod{2}$$

for $i > l$. Now it is clear that the system consists of $k$ equations in the $k + (n - l)$ variables $x_{n-k+1}, \ldots, x_n$ and $r_{l+1}, \ldots, r_n$.

If this system has $S$ solutions then the expected number of solutions to (8) is $S/2^{n-l+1}$.

Algorithm D (Derandomisation of C.) Given a graph $G = (V, E)$ with $n = |V|$, determine values $r_1, \ldots, r_n \in \{0, 1\}$ for algorithm C. Let $A$ denote the adjacency matrix of $G$.

D1 [Initialize.] Set $l = 1$. 

D2 [Initialize.] Set $k = 0, x' = 0_n, N_0 = N_1 = 0$.

D3 [Solve for each choice of $r_l$.] For $b = 0$, tentatively set $a_{ll} = b$ and solve the nonhomogeneous linear equation (8) in the free variables $x_{n-k+1}, \ldots, x_n$ and $r_{l+1}, \ldots, r_n$ using algorithm G. Let $S_b$ denote the size of the solution space. Repeat step D3 for $b = 1$.

D4 [Tally solutions.] Increase $N_b$ by $S_b/2^{n-l+1}$ for $b = 0, 1$.

D5 [Next prefix.] Update $x'$ and possibly $k$ so that $x'$ is the next element of $\binom{n-k}{k}$ or $\binom{n-k-1}{k}$ for $k = 0, \ldots, \frac{1}{2}n$, and return to D3. (When all these elements have been generated, proceed to D6.)

D6 If $N_0 > N_1$ then fix $a_{ll} = 1$, otherwise $a_{ll} = 0$. Increase $l$. If $l \leq n$ return to D2. Otherwise output $a_{11}, \ldots, a_{nn}$.
5 Proof of Theorem 3

Let \( C \subseteq 2^E \) denote the set of (directed) cycle covers of the directed graph \( G \). We use Iverson’s bracket notation: for a proposition \( P \), we write

\[
[P] = \begin{cases} 
1, & \text{if } P; \\
0, & \text{otherwise}.
\end{cases}
\]

\( G[Y] \) is the graph induced by \( Y \subseteq V \). We sometimes write \( e \in G[Y] \) to refer to a directed edge \( e \) in the induced graph \( G[Y] \). We will operate on sums of partitions of vertex sets, and manipulate these sums. For this purpose, we introduce the notation

\[
\sum_{Y_1, \ldots, Y_K} V
\]

for the sum over all ordered \( K \)-partitions \( Y_1, \ldots, Y_K \) of \( V \). That is, \( Y_1 \cup \cdots \cup Y_K = V \) and \( Y_i \cap Y_j = \emptyset \) (\( 1 \leq i < j \leq k \)). Parts may be empty.

For a subset \( T \subseteq E \) of directed edges define

\[
h(T) = \frac{1}{K} \sum_{Y_1, \ldots, Y_K} \prod_{e \in T} [e \in G[Y_1] \cup \cdots \cup G[Y_K]].
\]

We will show that the residue modulo \( K \) of the function \( h \) serves as an indicator variable for Hamiltonicity on \( C \). This can be viewed as an instantiation of the Cut-and-Count technique from [5].

Lemma 7. For \( C \in C \),

\[
[C \in C] = h(C) \pmod{K}.
\]  

Proof. First, we show that for \( C \in C \) we have \( h(C) = 1 \pmod{K} \). Consider a Hamiltonian cycle \( C \) and a partition \( Y_1, \ldots, Y_K \) of \( V \). First, every partition that sets \( Y_k = V \) for some \( k \in \{1, \ldots, K\} \) (and all other parts empty) has \( e \in G[Y_k] \) for all \( e \in C \), so its contribution is 1. On the other hand, consider a partition where some \( Y_k (1 \leq k \leq K) \) is neither \( \emptyset \) nor \( V \). Since \( C \) is Hamiltonian, there is a directed edge \( uv \in C \) with \( u \in Y_k \) and \( v \notin Y_k \). This directed edge belongs to none of the \( G[Y_k] \), so the product vanishes and the partition does not contribute to the sum. Thus, the total contribution of \( C \) is \( K \).

Second, we show for each \( C \notin C \) that \( h(C) = 0 \pmod{K} \). In particular, we show

\[
\sum_{Y_1, \ldots, Y_K} \prod_{e \in C} [e \in G[Y_1] \cup \cdots \cup G[Y_K]] = 0 \pmod{K^2}.
\]

Partition the non-Hamiltonian cycle cover \( C \) into cycles

\[
C = C_1 \cup \cdots \cup C_r,
\]
We first need to observe that the cycle-induced vertex partition $f$ of $e$ particular, the directed edge $e$ belongs to neither $G[Y_j]$ nor to any other of the $G[Y_i]$, contradicting (11). Hence the partition $Y_1, \ldots, Y_K$ consists of the $r$ parts of $V_1, \ldots, V_r$. There are $K'$ ways to pick these parts, each amounting to one 1 in the summation. Since $r > 1$ this shows that the total contribution of $C \notin H$ is a multiple of $K^2$ and after division of $K$ still vanishes modulo $K$. 

In particular, we can count the number of Hamiltonian cycles modulo $K$ as

$$|H| = \sum_{C \in \mathcal{H}} h(C) \pmod{K}. \quad (12)$$

We next rewrite the right hand side by an application of inclusion–exclusion.

For a vertex set $Z \subseteq V$ let $\mathcal{F}(Z)$ be the family of edge subsets in which every vertex has outdegree 1 and all terminals are in $Z$. In other words, $\mathcal{F}(Z)$ is the family of total functions $f : V \to Z$ where $vf(v)$ is a directed edge in the graph for all $v \in V$.

**Lemma 8.**

$$\sum_{C \in \mathcal{H}} h(C) = \sum_{Z \subseteq V} (-1)^{|Z\setminus V|} \sum_{C \in \mathcal{F}(Z)} h(C) \pmod{K}. \quad (13)$$

**Proof.** Consider a cycle cover $C \in \mathcal{H}$. It belongs to $\mathcal{F}(Z)$ exactly when $Z = V$, so its total contribution to the right hand side is $h(C)$. By the previous lemma, the total contribution of such $C \in \mathcal{H}$ is $|H| \pmod{K}$.

Consider now an edge subset $C \notin \mathcal{F}$ that is not a cycle cover. Let $X$ denote the set of vertices appearing as terminals for the directed edges in $C$. Then $C$ belongs to $\mathcal{F}(Z)$ for every $Z$ with $X \subseteq Z \subseteq V$. By the principle of inclusion–exclusion, the number of $Z$ with $X \subseteq Z \subseteq V$ is even (using that $X \subseteq V$ because $C$ is not a cover). In particular there are as many odd $Z$ as even ones. Thus, the contributions of all $C \notin \mathcal{F}$ cancel.

Recall that $d_v(X)$ denotes the number of directed edges from $v$ to a vertex in $X$. For pairwise disjoint subsets $Y_1, \ldots, Y_K$ of $V$ whose union includes all of $Z$, let $d_v(Z; Y_1, \ldots, Y_K)$ denote the number of directed edges from $v$ to a vertex in $Z$ that stay in the same part as $v$, formally

$$d_v(Z; Y_1, \ldots, Y_K) = N(Z \cap Y_k), \quad \text{where } v \in Y_k.$$
Lemma 9. For $Z \subseteq V$,

$$
\sum_{F \in \mathcal{F}(Z)} h(F) = \frac{1}{K} \prod_{v \in V \setminus Z} d_v(Z) \sum_{Y_1, \ldots, Y_K} \prod_{v \in Z} d_v(Z; Y_1, \ldots, Y_K) \quad (\text{mod } K).
$$

Proof. Expanding $h(F)$ and rearranging, we have

$$
\sum_{F \in \mathcal{F}(Z)} h(F) = \frac{1}{K} \sum_{F \in \mathcal{F}(Z)} \sum_{Y_1, \ldots, Y_K} \prod_{v \in F} [e \in G|Y_1| \cup \cdots \cup G|Y_K|]
$$

$$
= \frac{1}{K} \sum_{Y_1, \ldots, Y_K} \prod_{F \in \mathcal{F}(Z)} [e \in G|Y_1| \cup \cdots \cup G|Y_K|]
$$

$$
= \frac{1}{K} \sum_{Y_1, \ldots, Y_K} \prod_{v \in V} d_v(Z; Y_1, \ldots, Y_K),
$$

where the last step is based on counting in two different ways the number of ways that every vertex in $V$ can choose another vertex in $Z$ in the same part of $Y_1, \ldots, Y_K$.

The next step is to establish

$$
\sum_{Y_1, \ldots, Y_K} \prod_{v \in V} d_v(Z; Y_1, \ldots, Y_K) = \left( \prod_{v \in V \setminus Z} d_v(Z) \right) \sum_{Y_1, \ldots, Y_K} \prod_{v \in Z} d_v(Z; Y_1, \ldots, Y_K)
$$

(13)

by induction in $|V \setminus Z|$.

For $V = Z$ the claim is vacuous. Otherwise, select a vertex $w \in V \setminus Z$ and split the sum on the left hand side into $K$ sums according to which part includes the vertex $w$.

$$
\sum_{Y_1, \ldots, Y_K} \prod_{v \in V} d_v(Z; Y_1, \ldots, Y_K) = S_1 + \cdots + S_K,
$$

where

$$
S_k = \sum_{Y_1, \ldots, Y_k} \prod_{v \in V \setminus \{w\}} d_v(Z; Y_1, \ldots, Y_k) \cap \{w\}, \ldots, Y_K).
$$

In the product, the factor contributed by the term corresponding to $v = w$ is

$$
d_w(Z; Y_1, \ldots, Y_k \cup \{w\}, \ldots, Y_K) = d_w(Z \cap (Y_k \cup \{w\})) = d_w(Z \cap Y_k),
$$

because $w$ does not belong to $Z$. Thus,

$$
S_k = \sum_{Y_1, \ldots, Y_k} \prod_{v \in V \setminus \{w\}} d_v(Z; Y_1, \ldots, Y_K).
$$
Summing all the $S_k$ we arrive at

$$S_1 + \cdots + S_K = \sum_{Y_1, \ldots, Y_k \subseteq V \setminus \{w\}} \left( \sum_{k=1}^{K} d_w(Z \cap Y_k) \prod_{v \in V \setminus \{w\}} d_v(Z; Y_1, \ldots, Y_k) \right)$$

$$= \sum_{Y_1, \ldots, Y_k \subseteq V \setminus \{w\}} d_w(Z) \prod_{v \in V \setminus \{w\}} d_v(Z; Y_1, \ldots, Y_k)$$

$$= d_w(Z) \sum_{Y_1, \ldots, Y_k \subseteq V \setminus \{w\}} \prod_{v \in V \setminus \{w\}} d_v(Z; Y_1, \ldots, Y_k)$$

$$= \left( \prod_{w \in V \setminus Z} d_w(Z) \right) \sum_{Y_1, \ldots, Y_k \subseteq Z} \prod_{v \in Z} d_v(Z; Y_1, \ldots, Y_k),$$

where the last identity follows by induction over $w$, establishing (13).

We are ready to establish theorem 3, namely,

$$|\mathcal{V}| = \frac{1}{K} \sum_{Z, Y_1, \ldots, Y_k} (-1)^{|V \setminus Z|} \left( \prod_{z \in Z} d_z(V \setminus Z) \right) \prod_{k=1}^{K} \prod_{y \in Y_k} d_y(Y_k) \pmod{K}.$$

**Proof of theorem** Write $Z = V \setminus Z$. Combining (12) and lemmas 8 and 9 we get:

$$|\mathcal{V}| = \frac{1}{K} \sum_{Z, Y_1, \ldots, Y_k} (-1)^{|Z|} \prod_{v \in Z} d_v(Z) \prod_{v \in V \setminus Z} d_v(Z; Y_1, \ldots, Y_k) \pmod{K}$$

$$= \frac{1}{K} \sum_{Z, Y_1, \ldots, Y_k} (-1)^{|Z|} \prod_{v \in Z} d_v(Z) \prod_{v \in Z} d_v(Z; Y_1, \ldots, Y_k) \pmod{K},$$

where we just changed the original summand $Z$ to its complement $Z$.

Finally, every $y \in Z$ belongs to exactly one $Y_k$, and for this value of $k$ we have $d_y(Z; Y_1, \ldots, Y_k) = d_y(Y_k)$. Thus,

$$\prod_{y \in Z} d_y(Z; Y_1, \ldots, Y_k) = \prod_{k=1}^{K} \prod_{y \in Y_k} d_y(Y_k).$$
