We present a toy model of fuzzy Schwarzschild space slice (as a noncommutative manifold) which quantum mean values and quantum quasi-coherent states (states minimizing the quantum uncertainties) have properties close to the classical slice of the \((r, \theta)\) Schwarzschild coordinates (the so-called Flamm’s paraboloid). This fuzzy Schwarzschild slice is built as a deformation of the noncommutative plane. Quantum time observables are introduced to add a time quantization in the model. We study the structure of the quasi-coherent state of the fuzzy Schwarzschild slice with respect to the quasi-coherent state and the deformation states of the noncommutative plane. The quantum dynamics of a fermion interacting with a fuzzy black hole described by the present model is studied. In particular we study the decoherence effects appearing in the neighborhood of the fuzzy event horizon. An extension of the model to describe a quantum wormhole is also proposed, where we show that fermions cross the wormhole not by traveling by its internal space but by quantum tunneling, in accordance with the non-traversable character of classical Einstein-Rosen bridges.

I. INTRODUCTION

Fuzzy manifolds \([1,2]\) are simple examples of noncommutative manifolds, which can be used as quantum gravity models by proposing a spacetime quantization based on the Connes’ noncommutative geometry \([3]\). These models can be also interpreted as matrix models in string theory. Basically, in \(\mathbb{R}^3\), we can define a fuzzy manifold \(\mathcal{M}\) by quantization of the coordinate observables \((x, y, z)\) of a classical manifold, which become quantum observable operators \((X, Y, Z)\), generating the algebra of the “noncommutative functions” of \(\mathcal{M}\) and satisfying a relation similar to the embedding equation for \((x, y, z)\). Two simple examples are the noncommutative plane and the fuzzy sphere. A classical plane being defined by the embedding equation \(z = 0\), a non-commutative plane can be defined by

\[
X = \frac{a + a^+}{2}, \quad Y = \frac{a - a^+}{2i}, \quad Z = 0
\]

(1)

where \(a\) and \(a^+\) are the quantum harmonic oscillator annihilation and creation operators ensuring that \([X, Y] = \frac{i}{2} \neq 0\). A classical sphere being defined by the embedding equation \(x^2 + y^2 + z^2 = r^2\), a fuzzy sphere can be defined by

\[
X^2 + Y^2 + Z^2 = \lambda^2 (j + 1)
\]

(2)

(with \(\lambda > 0\) a parameter) implying that \((X/\lambda, Y/\lambda, Z/\lambda)\) are the generators of the \((2j + 1)\) dimensional irreducible representation of the quantum angular momentum algebra. In this paper, we are interested by fuzzy manifolds mimicking the Schwarzschild geometry of a neutral non-rotating black hole, as a model of quantum micro black hole \([4,5]\).

Various approaches have been used to built quantum black hole models from noncommutative geometry: by identifying the event horizon with a fuzzy sphere \([6,7]\); by using a Moyal-type star product with an embedding geometry in \(\mathbb{R}^7\) \([8]\), or by considering a classical geometry modified by a non-commutative parameter \([9,10]\). In this paper we propose another approach with a toy model based on a deformation of the noncommutative plane in order to its mean values in the quasi-coherent state (the quantum state closest to a classical one) corresponds to the classical embedding in \(\mathbb{R}^3\) of a “space slice” of the Schwarzschild geometry. The quantization of time observables is then obtained from an analysis of the dynamics of the model. Such a model permits to study the quantum dynamics of a fermionic particle in the neighborhood of the quantum black hole in the quasi-coherent representation.

This paper is organized as follows. Section II presents the general theoretical framework used in this paper: fuzzy manifolds, their Dirac operators and the notion of quasi-coherent states. Section III introduces the model of fuzzy Schwarzschild slice and introduces associated quantum time observables. The Dirac operator is not self-adjoint and includes a dissipator which can be interpreted as modeling the particle absorption by the black hole singularity. Section IV studies the quasi-coherent states of the fuzzy Schwarzschild slice (especially the classical geometry closest to the fuzzy geometry). Quantum dynamics governed by the Dirac operator of the fuzzy Schwarzschild spacetime are studied section V. The evolution of the quantum coherence of the states is studied and the mean value and the quasi-coherent wave packet of the quantum dynamics are compared with the classical dynamics of a probe D0-brane (viewed as a classical point particle and driving the quantum evolution). Section VI extends the present model to white holes and to structures like wormholes. We show in this section, that a particle crossing the wormhole do not travel by its internal space but crosses it by quantum tunneling. Appendix A presents the case of...
a simple noncommutative plane to compare with the fuzzy Schwarzschild slice and Appendix B presents the numerical method used for the computations.

Throughout this paper, we consider the unit system such that \( \hbar = c = G = 1 \) (\( ℓ_P = t_P = m_P = 1 \) for the Planck units).

II. NONCOMMUTATIVE DIRAC OPERATOR AND QUASI-COHERENT STATES

First we recall some basic facts about fuzzy manifolds.

Let \( (X,Y,Z) \) be three coordinate self-adjoint operators defining the fuzzy manifold \( \mathcal{M} \). We denote by \( a \) the algebra generated by \( (X,Y,Z) \) (universal enveloping algebra of the algebra of the polynomials of \( X, Y \) and \( Z \)). \( a \) plays the role of a set of non-abelian functions of \( \mathcal{M} \). Let \( \mathcal{F} \) be a Hilbert space of representation of \( a \). The fundamental operator of the noncommutative geometry is the following Dirac operator \[ D_{\alpha,z} = \left( \begin{array}{cc} Z - \alpha & A^+ - \bar{\alpha} \\ A - \alpha & Z + z \end{array} \right) \in \mathcal{L}(\mathbb{C}^2 \otimes \mathcal{F}) \] where \( A = X + iy \) and \( A^+ = X - iy \), and \( (\alpha,z) \in \mathbb{C} \times \mathbb{R} \). The Hilbert space \( \mathcal{H} = \mathbb{C}^2 \otimes \mathcal{F} \) is the space of spinors on \( \mathcal{M} \) (\( \mathbb{C}^2 \) is the spin state space). \( (a, \mathcal{H}, D_{\alpha,z}) \) is a spectral triple of the Connes’ theory [3]. (Re\( \alpha, \text{Im}\( \alpha, z \) \in \mathbb{R}^3 \) is a point of the embedding space. \( (\alpha,z) \) are classical control parameters of \( D_{\alpha,z} \). In the context of string theory, in the BFFS matrix model [16], \( (X,Y,Z) \) can be viewed as the operators of a stack of D0-branes and \( D_{\alpha,z} \) is the Dirac operator of a fermionic string linking this stack to a probe D0-brane of coordinates \( (\text{Re}\( \alpha, \text{Im}\( \alpha, z \) \in \mathbb{R}^3 \) in the embedding space [1, 2] (the spacetime being reduced to 3+1 dimensions by a truncation with a supersymmetric orbifold, see [3]). \( \mathcal{F} \) plays the role of the Hilbert space of “position” states on \( \mathcal{M} \) of the end of the Hilbertic string. The string spinor \( |\psi\rangle \in \mathcal{H} \) obeys to the noncommutative Dirac equation \[ i|\dot{\psi}\rangle = D_{\alpha(\tau),z(\tau)}|\psi(\tau)\rangle \] where the dot denotes the derivative with respect to \( \tau \). This equation corresponds to the dynamics of the fermionic string induced by the transport in the embedding space of the probe D0-brane described by \( \tau \mapsto (\alpha(\tau), z(\tau)) \). Consistently, \( \tau \) is defined as the proper time of an observer comoving with the probe D0-brane.

To compare the geometry of \( \mathcal{M} \) to a classical geometry, we need to find a quantum state of \( \mathcal{M} \) closest to a classical state. For quantum systems described by a Lie algebra, the quantum states closest to classical ones are the Perelomov coherent states [17], for which the Heisenberg uncertainty relations are minimized. The equivalent notion for a fuzzy manifold \( \mathcal{M} \), called quasi-coherent states, are the eigenvectors of \( D_{\alpha,z} \) in its kernel [3]: \[ D_{\alpha,z}|\Lambda(\alpha,z)\rangle = 0 \] If \( (X,Y,Z) \) generates a Lie algebra, \( |\Lambda(\alpha,z)\rangle \) is strongly related to the Perelomov coherent state (see the example of the noncommutative plane in appendix [A]). More generally, ref. [3] shows that \( |\Lambda(\alpha,z)\rangle \) minimizes the displacement energy which can be viewed as the “tension energy” of the fermionic string. This one is large if the probe D0-brane is moved away \( \mathcal{M} \) and/or if the dispersion \( \Delta X^2 + \Delta Y^2 + \Delta Z^2 \) is large (with \( \Delta X^2 = \langle X^2 \rangle - \langle X \rangle^2 \)). This means that, from the point of view of the fermionic string, \( |\Lambda\rangle \) is the state for which the end of the string is as less delocalized as possible and for which the probe D0-bane (the other end) is closest to this end. In other words, \( |\Lambda\rangle \) is the quantum state of the fermionic string closest to a state of a classical point particle. The values of \( (\alpha, z) \) for which eq. (5) has solutions form a classical manifold in the embedding space:

\[ M_\Lambda = \{(\alpha, z) \in \mathbb{C} \times \mathbb{R}, \text{s.t. det} D_{\alpha,z} = 0 \} \subset \mathbb{R}^3 \] We call \( M_\Lambda \) the eigenmanifold of \( \mathcal{M} \), and since [3]

\[ \forall (\alpha,z) \in M_\Lambda, \]

\[ \langle \Lambda(\alpha,z)|A|\Lambda(\alpha,z)\rangle = \alpha \]

\[ \langle \Lambda(\alpha,z)|A^+|\Lambda(\alpha,z)\rangle = \bar{\alpha} \]

\[ \langle \Lambda(\alpha,z)|Z|\Lambda(\alpha,z)\rangle = z \]

We can see \( M_\Lambda \) as the “mean value” of \( \mathcal{M} \). \( M_\Lambda \) is then the classical manifold closest to the fuzzy manifold \( \mathcal{M} \), in the sense that the mean values of the coordinates operators of \( \mathcal{M} \) in the quasi-coherent states are coordinates of points of \( M_\Lambda \), with minimal quantum uncertainty \( \Delta X^2 + \Delta Y^2 + \Delta Z^2 \). For a point of view of quantum gravity, if \( \mathcal{M} \) describes a quantum space, \( M_\Lambda \) is the corresponding slice of a curved classical space revealed by the transport of the test point particle equivalent to the fermionic string in the quasi-coherent state.

The goal of this paper is to present a toy model of a fuzzy manifold for which its eigenmanifold is close to the Schwarzschild geometry.

III. THE MODEL OF FUZZY SCHWARTZSCHILD SPACETIME

A. Coordinate operators

The embedding of a space slice of the Schwarzschild geometry is defined (in Schwarzschild coordinates) by

\[ z = f(r) = 2\sqrt{r_s \sqrt{r - r_s}} \]

where \( r_s \) is the Schwarzschild radius. This embedding induces then the spatial part of the Schwarzschild metric

\[ (1 + f'(r)^2)dr^2 + r^2d\theta^2 = \left(1 - \frac{r_s}{r}\right)^{-1}dr^2 + r^2d\theta^2 \]
Let $\alpha = re^{i\theta}$ be a complex representation of the local coordinates of the Schwarzschild slice, $z$ being a non-physical dimension needed for the embedding of the curved slice. Let $a = X + iY$ and $a^+ = X - iY$ be the creation and annihilation operators of a quantum harmonic oscillator, playing here the role of the noncommutative complex coordinate operators of the fuzzy version $\mathcal{M}$ of the Schwarzschild slice. $\mathcal{F}$, the associated Fock space, plays the role of $L^2(\mathcal{M}, dX \otimes dY)$ (space of “wave functions” onto the fuzzy manifold). The third coordinate operator must satisfy a relation similar to eq. (10), we set

$$Z = f(\hat{r})$$

where $\hat{r}$ is the radius observable (the action of $f(\hat{r})$ being defined by the functional calculus). We define this operator as being

$$\hat{r} = \sqrt{a^+a} = \sum_{n=0}^{+\infty} \sqrt{n}|n\rangle\langle n|$$

where $\{|n\rangle\}_{n \in \mathbb{N}}$ is the canonical basis of $\mathcal{F}$. We choose $\hat{r}$ with this expression and not as $\sqrt{X^2 + Y^2} = \sqrt{a^+a + 1/2}$ in order to have $\langle \alpha|\hat{r}|\alpha \rangle = |\alpha|^2$ (without the shift 1/2) for $|\alpha\rangle$ a Perelomov coherent state of the harmonic oscillator (see appendix A). We have then

$$Z = \sum_{n=0}^{+\infty} f(\sqrt{n})|n\rangle\langle n|$$

Note that to apply this definition it needs to extend $f$ in the complex numbers to define its action onto negative values, the square root in the expression of $f$ being chosen in the Riemann sheet such that $\sqrt{-r} = -i\sqrt{r}$ (with $r > 0$). $Z$ is then not self-adjoint, $Z^\dagger \neq Z$, and we set

$$Z = \text{Re} Z - i\text{Im} Z$$

with Re $Z$ and Im $Z$ the following positive self-adjoint operators:

$$\text{Re} Z = 2\sqrt{r} \sum_{n=\lfloor rS \rfloor}^{+\infty} \sqrt{\sqrt{n} - rS}|n\rangle\langle n|$$

$$\text{Im} Z = 2\sqrt{r} \sum_{n=0}^{\lfloor rS \rfloor} \sqrt{rS - \sqrt{n}}|n\rangle\langle n|$$

In contrast with the classical slice, we cannot exclude the points $|\alpha| < r_S$ since $Z$ is defined in the $|n\rangle$-representation and not in a $|\alpha\rangle$-representation. A formula as $Z = \int_{|\alpha| > r_S} f(|\alpha|)|\alpha\rangle\langle \alpha|\,d\alpha d\bar{\alpha}$ makes no sense because the set $\{|\alpha\rangle\}_{\alpha \in \mathbb{C}}$ is overcomplete and not orthogonal ($|\langle \beta|\alpha \rangle|^2 = e^{-|\alpha - \bar{\beta}|^2}$). $|\alpha\rangle$ represents a quantum state localized around $\alpha$, like a “gaussian wave packet” centered at $\alpha$ with half width at half maximum $\sqrt{\ln 2} \simeq 0.83$. The quantum event horizon is then not a precise circle on the slice, but is fuzzy with a Schwarzschild radius mean value $\langle r_S \rangle = \langle |\alpha|\rangle_{|\alpha|=rs}$ and quantum uncertainty $\Delta r_S = \sqrt{\langle |\alpha|^2 \rangle_{|\alpha|=rs} - \langle |\alpha| \rangle_{|\alpha|=rs}^2}$, as illustrated in fig. 1. For small values of the parameter $r_S$, $\langle r_S \rangle$ is shifted from $r_s$; for example with $r_S = 1.5$ we have $\langle r_S \rangle \pm \Delta r_S \simeq 1.36 \pm 0.61$. Since $r_S = 2M$ where $M$ is the black hole mass, this situation is similar to say that the singularity is delocalized following a Gaussian distribution and then that $M$ is smeared following a gaussian density. This is the idea used in [14, 15] to define a non-commutative geometry inspired black hole. In these papers, the authors compute the classical geometry induced by this smeared mass. In contrast, in this paper we rest at the quantum level by considering the quasi-coherent states of the fuzzy manifold $\mathcal{M}$.

B. Non-selfadjointness of the Dirac operator

The Dirac operator for the fuzzy Schwarzschild slice $\mathcal{M}$ is

$$\mathcal{D}_\alpha = \begin{pmatrix} Z - z(\alpha) & a^+ - \bar{\alpha} \\ a - \alpha & -Z^\dagger + z(\alpha) \end{pmatrix}$$

where we restrict our attention onto the values $z$ for which $(\alpha, z(\alpha)) \in \mathcal{M}_\alpha$. $\mathcal{D}_\alpha$ is not self-adjoint and we have chosen $Z \otimes |0\rangle\langle 0| - Z^\dagger \otimes |1\rangle\langle 1|$ and not $Z \otimes \sigma_z$ (where $\{|0\rangle, |1\rangle\}$ is the canonical basis of the spin state space $\mathbb{C}^2$) in order to the chosen Riemann sheet of $f$ be the same for all spin states of the fermionic string. 

$-i\text{Im} Z \otimes \text{id}_2$ is a dissipator (Im $Z$ is positive) involving that $||\psi(\tau)||$ decreases if $|\psi\rangle$ is solution of the Schrödinger like equation $i|\psi\rangle = \mathcal{D}_\alpha |\psi\rangle$. In non-hermitian quantum mechanics [18], dissipation is signature of the disappearance of the modeled quantum system. For example, in molecular physics, we can model a diatomic molecule as an anharmonic oscillator with Hilbert space
where $r$ is the internuclear distance and $r_{max}$ is the end of the description box. After photodissociation, a wave packet representing the dissociated fragment spreads. To avoid unphysical reflections on $r_{max}$ an absorbing boundary dissipates this one before it reaches $r_{max}$. The dissipation represents then the disappearance of the molecule (when the wave packet reaches $r_{max}$ in the reality, we no longer have an associated molecule or an dissociated molecule but two independent atoms not modeled in the formalism), see [18]. We can interpret in a same manner the non-selfadjointness of $D_\alpha$. $\langle \alpha | \text{Im} Z | \alpha \rangle \neq 0$ if and only if $|\alpha| < r_s$. So the quantum dissipation occurs when the “test particle” is under the event horizon. In classical general relativity, for an external observer, the degrees of freedom of a particle under the event horizon disappear. The only one degree of freedom of a Schwarzschild black hole is its mass. Everything happens as if the particle was absorbed by the singularity.

We have the same thing for our model of quantum black hole, except that due the quantum effects (quantum superpositions, fuzziness of the event horizon) this process is not instantaneous nor necessarily complete. $|\psi(\tau)|^2$ is then the survival probability of the test particle, or in other words, $1 - |\psi(\tau)|^2$ is the probability of absorption of the particle by the black hole singularity.

C. Time observables

The fermionic string state is solution of the Dirac equation

$$i|\dot{\psi}\rangle = \slashed{D}_{\alpha(\tau)}|\psi(\tau)\rangle$$

for the transport of the probe D0-brane $\tau \rightarrow \alpha(\tau)$, $\tau$ being the clock of an observer comoving with the probe brane. We denote by $t$ the clock of an observer at infinity. We extend the Hilbert space as $\mathcal{H}^+ = C^2 \otimes \mathcal{F} \otimes L^2(\mathbb{R}, dt')$, where $\mathcal{F} \sim NC L^2(\mathbb{R}, dX \otimes dY)$ is the space of space wave functions, $L^2(\mathbb{R}, dt')$ is the space of time wave functions and we introduce the operator

$$\hat{t} = \hat{t}(\hat{r}) = \epsilon \sum_{n=1}^{\infty} \frac{1}{1 - \frac{r_s}{\sqrt{n}}} |n\rangle\langle n|$$

The replacement of $\dot{t}$ by $\hat{t}$ takes into account that the other end of the fermionic string does not follow a classical trajectory but is a quantum “wave packet” smeared in the embedding space (because of the fuzziness of the quantum Schwarzschild slice $\mathcal{M}$ on which this end is attached). $E = -i\hat{t} \otimes \partial_{t'}$ plays in this toy model the role of an energy observable. Since $e^{i\omega t'}$ is eigenvector of $-i\partial_{t'}$, we can choose without loss of generality $|\psi(\tau)\rangle \otimes |e^{i\omega t'}\rangle$ and then

$$i\frac{\partial|\psi\rangle}{\partial \tau} = \left(\slashed{D}_{\alpha(\tau)} + \omega \hat{t}\right)|\psi\rangle$$

We can view $\omega$ as a mass parameter, and then the true parameter of the extended model $\omega t'$ is the total energy of the end of the string attached on $\mathcal{M}$. Note that if $r_3^2 \in \mathbb{N}$, $\hat{t}$ is singular with an infinite eigenvalue for $|n = \sqrt{n}\rangle$ (this implies that $\langle n = \sqrt{n}|\psi\rangle = 0$ ($\forall n$) becomes a forbidden state). In order to avoid the mathematical and numerical difficulties due to the singular value, we suppose that $r_3^2 \notin \mathbb{N}$ in the rest of this paper.

By construction the time dilation observable $\hat{t}$ plays the role of a barrier in the neighborhood of the event horizon. In classical general relativity, the time measured by the clock of the observer at infinity is dilated with respect to the proper time when the observed particle approaches the event horizon (and becomes infinite at the even horizon). The observer never sees the particle cross the event horizon. This effect is reproduced for the observation of the “wave packet” of the end of the string attached to $\mathcal{M}$ by the barrier of $\hat{t}$.

We make the hypothesis than the movement of the other end is geodesic, and then that

$$t' = \frac{\epsilon'}{1 - \frac{r_s}{r}}$$

where $\epsilon'$ is the constant of motion of a Schwarzschild geodesic (total energy by mass unit). Now we want to modify the model to have a quantized time for the other end which is a quantum system. We extend the Hilbert space as $\mathcal{H} = C^2 \otimes \mathcal{F} \otimes L^2(\mathbb{R}, dt')$, where $\mathcal{F} \sim NC L^2(\mathbb{R}, dX \otimes dY)$ is the space of space wave functions, $L^2(\mathbb{R}, dt')$ is the space of time wave functions and we introduce the operator

$$\hat{t} = \hat{t}(\hat{r}) = \epsilon \sum_{n=1}^{\infty} \frac{1}{1 - \frac{r_s}{\sqrt{n}}} |n\rangle\langle n|$$

the Dirac equation in the extended Hilbert space being

$$i\frac{\partial|\psi\rangle}{\partial \tau} = \left(\slashed{D}_{\alpha(\tau)} + \omega \hat{t}\right)|\psi\rangle$$

We can view $\omega$ as a mass parameter, and then the true parameter of the extended model $\omega t'$ is the total energy of the end of the string attached on $\mathcal{M}$. Note that if $r_3^2 \in \mathbb{N}$, $\hat{t}$ is singular with an infinite eigenvalue for $|n = \sqrt{n}\rangle$ (this implies that $\langle n = \sqrt{n}|\psi\rangle = 0$ ($\forall n$) becomes a forbidden state). In order to avoid the mathematical and numerical difficulties due to the singular value, we suppose that $r_3^2 \notin \mathbb{N}$ in the rest of this paper.

By construction the time dilation observable $\hat{t}$ plays the role of a barrier in the neighborhood of the event horizon. In classical general relativity, the time measured by the clock of the observer at infinity is dilated with respect to the proper time when the observed particle approaches the event horizon (and becomes infinite at the even horizon). The observer never sees the particle cross the event horizon. This effect is reproduced for the observation of the “wave packet” of the end of the string attached to $\mathcal{M}$ by the barrier of $\hat{t}$.

The model includes the time dilation operator $\hat{t}$ and not directly the observable of the quantized time coordinate. Let $\langle t' \rangle$ be the mean value of the time measured
by the observer at infinity when this one watches a clock “attached" to the end of the string on \( \mathcal{M} \) (and so when the observer compares its clock with the quantized time). Heuristically we can set that

\[
\langle t' \rangle = \int_0^T \frac{\langle \psi | \hat{t} | \psi \rangle}{\|\psi\|^2} d\tau \tag{26}
\]

Indeed, if it had existed, an observable \( t' \) would have satisfied \( \frac{d\langle \psi | t' | \psi \rangle}{d\tau} = \iota \langle \{ \hat{D}_\alpha + E, t' \} \rangle \). If we substitute \( t' \) (as the operator multiplying by the quantum variable \( t' \)) to \( \hat{t} \), we have \( [\hat{D}_\alpha + E, t'] \sim [\hat{D}_\alpha + E, \hat{t}] = [E, t'] = \hat{t} \). In the same way we can set the following estimation

\[
\Delta t^2 \sim \int_0^T \Delta \hat{t}^2 d\tau = \int_0^T (\langle \hat{t}^2 \rangle - \langle \hat{t} \rangle^2) d\tau \tag{27}
\]

\section{Schwarzschild Quasi-Coherent State}

We search the quasi-coherent states of the fuzzy Schwarzschild slice \( \mathcal{M} \) (defined by \( (a, a^+, Z) \)) and the associated eigenmanifold \( M_\Lambda \) (classical manifold closest to the \( \mathcal{M} \) in the sense that its points are the mean values of the coordinate observables of \( \mathcal{M} \) with minimal quantum dispersion). Since \( \hat{D}_\alpha \) is not self-adjoint, the associated eigenvalue \( \lambda_\alpha(a) \) is not zero, but is purely imaginary:

\[
\hat{D}_\alpha |\Lambda(\alpha)\rangle = \lambda_\alpha(a) |\Lambda(\alpha)\rangle, \quad \text{Re} \lambda_\alpha = 0 \tag{28}
\]

This definition is consistent with the interpretation of non-hermitian quantum mechanics \[18\]. \( \hat{D}_\alpha \) plays the role of an Hamiltonian in eq. (19) which has the structure of a Schrödinger equation. The interpretation of the complex number \( \lambda_\alpha \in \text{Sp}(\hat{D}_\alpha) \) is the following:

- \( \text{Re} \lambda_\alpha \) is the “energy" measured by \( \hat{D}_\alpha \) when the system is in the state \( |\Lambda\rangle \) (in fact it is the square root of the displacement energy – see [3] – the displacement energy observable being \( \hat{D}_\alpha^2 \) in the self-adjoint cases);

- \( -\text{Im} \lambda_\alpha \) is the inverse of the characteristic time of dissipation in the state \( |\Lambda\rangle \).

We can see this by considering the solution of eq. (19) when \( \alpha \) is frozen and with \( |\psi(0)\rangle = |\Lambda(\alpha)\rangle \):

\[
|\psi(\tau)\rangle = e^{-i\text{Re} \lambda_\alpha(\alpha) \tau} e^{i\text{Im} \lambda_\alpha(\alpha) \tau} |\Lambda(\alpha)\rangle \tag{29}
\]

\( |\psi\rangle \) has an oscillating phase of frequency \( \text{Re} \lambda_\alpha(\alpha) \) (which will generate Rabi oscillations if we choose \( |\psi(0)\rangle \) has a superposition of two different eigenvectors). The norm exponentially decreases as \( \|\psi(\tau)\|^2 = e^{2\text{Im} \lambda_\alpha(\alpha) \tau} \) (\( \text{Im} \lambda_\alpha < 0 \)). The survival time of the particle is then \( \tau_{\text{surv}}(\alpha) = \frac{1}{\text{Im} \lambda_\alpha(\alpha)} \) (after a duration \( \tau_{\text{surv}} \) the probability for which the particle be absorbed by the singularity is larger than 85%). The quasi-coherent states being defined as being the states minimizing the displacement energy, we must have \( \text{Re} \lambda_\alpha = 0 \). But \( \text{Im} \lambda_\alpha \neq 0 \) because of the process of absorption by the black hole singularity. Nevertheless, we expect that \( \text{Im} \lambda_\alpha(\alpha) \simeq 0 \) for \( |\alpha| > r_S \).

The eigenmanifold is then defined as

\[
M_\Lambda = \{(\alpha, z(\alpha)) \in \mathbb{C} \times \mathbb{R}, \text{ s.t. } \text{Sp}(\hat{D}_\alpha) \cap i\mathbb{R} \neq \emptyset \} \tag{30}
\]

The solving of eq. (28) needs to find the three quantities:

\( |\Lambda(\alpha)\rangle \in \mathcal{H}, \lambda_\alpha(\alpha) \in i\mathbb{R} \) and \( z(\alpha) \in \mathbb{R} \). Appendix \[B\] presents the numerical method used to this.

\subsection{Emergent geometry}

The functions \( \alpha \mapsto \text{Im} \lambda_\alpha(\alpha) \) and \( \alpha \mapsto z(\alpha) \) are drawn fig. (2). As expected \( \text{Im} \lambda_\alpha(\alpha) \simeq 0 \) for \( \alpha > r_S \) and roughly follows the imaginary part of \( f(|\alpha|) \). As expected \( z(\alpha) \) presents the profile of the classical Schwarzschild slice except that the decreasing in the neighborhood of \( r_S \) is softened (in accordance with the fuzziness of the quantum event horizon \( \langle r_S \rangle \pm \Delta r_S \simeq 1.36 \pm 0.61 \) when the classical parameter is \( r_S = 1.5 \)). The embedding of \( M_\Lambda \) in \( \mathbb{R}^3 \) is represented fig. \[3\]. For the aspects concerning the time, we have drawn the mean value of \( \hat{t} \) in the quasi-coherent state fig. \[4\]. In \( \alpha \)-representation \( \hat{t} \) plays then well the role of an potential barrier in front of the event horizon (a small barrier in average, more important by taking
into account the quantum uncertainty), preventing the crossing of the event horizon by the particle observed by an observer at infinity comoving with the quantum black hole (the observable of time dilation governing the quantum end of the string attached on $\mathcal{M}$ measured by the observer’s clock). We see also a potential well behind the event horizon trapping the particle inside the black hole.

**B. Structure of the quasi-coherent state**

Let $(|n\rangle)_{n \in \mathbb{N}}$ be the (local) orthonormal basis of $\mathcal{F}$ defined by

$$|n\rangle = (a^+ - \bar{a})^n |\alpha\rangle$$

(31)

$|\alpha\rangle$ being the Perelomov coherent state of the harmonic oscillator algebra. This basis is “local” in the sense that it is defined for a point $\alpha$ and is associated with an harmonic oscillator re-centred on $\alpha$ (we can interpret $|n\rangle\alpha$ as a quantum state with a local excitation of amplitude $n$ at $\alpha$). Let $(|\lambda_{n\pm}(\alpha)\rangle)$ be the local basis of $\mathcal{H} = \mathbb{C}^2 \otimes \mathcal{F}$ defined by

$$|\lambda_0\rangle = |0\rangle \otimes |0\rangle\alpha$$

(32)

$$|\lambda_{n\pm}(\alpha)\rangle = \frac{1}{\sqrt{2}} (|0\rangle \otimes |n\rangle\alpha \pm |1\rangle \otimes |n-1\rangle\alpha)$$

(33)

This is the eigenbasis of the Dirac operator in the case of the noncommutative plane ($Z = 0$) (see appendix A). $|\lambda_0\rangle$ is the quasi-coherent state of the noncommutative plane whereas $|\lambda_{n\pm}\rangle$ (with $n > 0$) are states for which the displacement energy is $n$. Since our model of fuzzy Schwarzschild slice is a deformation of the noncommutative plane, this basis is pertinent to study the quasi-coherent state. We expect in particular that the quasi-coherent state. We expect in particular that

$$\langle \alpha|\lambda_{n\pm}(\alpha)\rangle = \frac{1}{\sqrt{2}} (|0\rangle \otimes |n\rangle\alpha \pm |1\rangle \otimes |n-1\rangle\alpha)$$

(33)

This is the eigenbasis of the Dirac operator in the case of the noncommutative plane ($Z = 0$) (see appendix A). $|\lambda_0\rangle$ is the quasi-coherent state of the noncommutative plane whereas $|\lambda_{n\pm}\rangle$ (with $n > 0$) are states for which the displacement energy is $n$. Since our model of fuzzy Schwarzschild slice is a deformation of the noncommutative plane, this basis is pertinent to study the quasi-coherent state. We expect in particular that the quasi-coherent state. We expect in particular that

$$\langle \alpha|\lambda_{n\pm}(\alpha)\rangle = \frac{1}{\sqrt{2}} (|0\rangle \otimes |n\rangle\alpha \pm |1\rangle \otimes |n-1\rangle\alpha)$$

(33)

This is the eigenbasis of the Dirac operator in the case of the noncommutative plane ($Z = 0$) (see appendix A). $|\lambda_0\rangle$ is the quasi-coherent state of the noncommutative plane whereas $|\lambda_{n\pm}\rangle$ (with $n > 0$) are states for which the displacement energy is $n$. Since our model of fuzzy Schwarzschild slice is a deformation of the noncommutative plane, this basis is pertinent to study the quasi-coherent state. We expect in particular that the quasi-coherent state. We expect in particular that

$$\langle \alpha|\lambda_{n\pm}(\alpha)\rangle = \frac{1}{\sqrt{2}} (|0\rangle \otimes |n\rangle\alpha \pm |1\rangle \otimes |n-1\rangle\alpha)$$

(33)

This is the eigenbasis of the Dirac operator in the case of the noncommutative plane ($Z = 0$) (see appendix A). $|\lambda_0\rangle$ is the quasi-coherent state of the noncommutative plane whereas $|\lambda_{n\pm}\rangle$ (with $n > 0$) are states for which the displacement energy is $n$. Since our model of fuzzy Schwarzschild slice is a deformation of the noncommutative plane, this basis is pertinent to study the quasi-coherent state. We expect in particular that the quasi-coherent state. We expect in particular that

$$\langle \alpha|\lambda_{n\pm}(\alpha)\rangle = \frac{1}{\sqrt{2}} (|0\rangle \otimes |n\rangle\alpha \pm |1\rangle \otimes |n-1\rangle\alpha)$$

(33)

This is the eigenbasis of the Dirac operator in the case of the noncommutative plane ($Z = 0$) (see appendix A). $|\lambda_0\rangle$ is the quasi-coherent state of the noncommutative plane whereas $|\lambda_{n\pm}\rangle$ (with $n > 0$) are states for which the displacement energy is $n$. Since our model of fuzzy Schwarzschild slice is a deformation of the noncommutative plane, this basis is pertinent to study the quasi-coherent state. We expect in particular that the quasi-coherent state. We expect in particular that

$$\langle \alpha|\lambda_{n\pm}(\alpha)\rangle = \frac{1}{\sqrt{2}} (|0\rangle \otimes |n\rangle\alpha \pm |1\rangle \otimes |n-1\rangle\alpha)$$

(33)
A coherent state is entangled in the neighborhood of the fuzzy event horizon and also in a region around $|\alpha| \simeq 0.7$ independently of $r_S$. The interpretation of this second peak of entropy is not clear, but due to its position (which is independent of the black hole parameter), we can think that it is related to the border of the fuzzy singularity.

V. QUANTUM DYNAMICS

Now we want study the dynamics governed by eq. \ref{eq:25} with $|\psi(0)\rangle = |\Lambda(\alpha(0))\rangle$ for different worldlines $\tau \mapsto (t(\tau), \alpha(\tau))$ of the probe D0-brane. We control the probe D0-brane to drive the fermionic string (if the state remains a quasi-coherent state during the whole of the dynamics, the probe D0-brane drives the point-like particle defined by a gaussian wave packet with minimal width in the $\alpha$-representation). The regime of the dynamics is then essentially governed by $|\alpha|$. In the case of the transport of a D0-brane in a noncommutative plane (appendix A), we have two extremal regimes: an adiabatic regime for small velocities of the probe D0-brane where the state remains an instantaneous quasi-coherent state; and a sudden regime for large velocities. The interest of the sudden regime is low, the probe D0-brane being transported at a velocity close to the speed of light, the “wave packet” of the other end of the string in the $\alpha$-representation cannot follow it and remains at its initial position. In the case of the fuzzy Schwarzschild spacetime, we expect similar behaviors with respect to the magnitude of $|\alpha|$, but due to the irregularity of the event horizon in the Schwarzschild coordinates, the dynamical behavior will be strongly affected in the neighborhood of the fuzzy event horizon.

A. Decoherence processes

Three quantities must be particularly monitored during the dynamics:

- $\|\psi\|^2$ the survival probability of the fermion.
• The fidelity to a quasi-coherent state:
  \[ F(\Lambda|\psi) = \sup_{\alpha} \frac{\langle \Lambda(\alpha)|\psi \rangle^2}{\|\psi\|^2} \tag{36} \]
  which is equal to 1 if \(|\psi\rangle\) is proportional to a quasi-coherent state for some \(\alpha\) and 0 if \(|\psi\rangle\) is orthogonal to the quasi-coherent states for all \(\alpha\). \(F(\Lambda|\psi)\) measures then the sustain of \(|\psi\rangle\) as a quasi-coherent state corresponding to a classical point particle (gaussian wave packet in \(\alpha\)-representation with minimal Heisenberg uncertainties). We can then consider \(F(\Lambda|\psi)\) as a measure of the spatial coherence. Moreover, since in adiabatic regimes \(|\psi(\tau)\rangle \propto |\Lambda(\alpha(\tau))\rangle\), \(F(\Lambda|\psi(\tau))\) is also a measure of the adiabaticity of the dynamics.

• The purity:
  \[ P(\rho) = \text{tr}(\rho^2) \quad \text{with} \quad \rho = \text{tr}_\mathcal{F} \frac{|\psi\rangle \langle \psi|}{\|\psi\|^2} \tag{37} \]
  which is equal to 1 if \(|\psi\rangle\) is separable and 0 if \(|\psi\rangle\) is maximally entangled. The purity is then a measure of the entanglement between the spin degree of freedom and the space degree of freedom described by \(\mathcal{F}\). In classical general relativity, the transport of an angular momentum in a curved spacetime involves rotation of this one (with Thomas and de Sitter precession phenomena for example). In quantum gravity, we can expect that the transport of a spin in a fuzzy spacetime involves not only a precession but also a loss of purity: the spin state becomes a statistical mixture of spin pure states. We can see the decreasing of one of these three quantities as a decoherence process: a fall of the survival probability characterizes the disappearance of the fermion by absorption by the black hole singularity; a fall of the fidelity to a quasi-coherent state characterizes the decreasing of the spatial coherence (the state can no longer be correctly described by a gaussian wave packet in the \(\alpha\)-representation), a fall of the purity characterizes the increasing of the entanglement between the spin and the quantum spacetime.

\section*{B. Fall on a quantum black hole}

We consider first an uniform radial transport of the probe D0-brane to the singularity with \(\dot{r} = -u\) (with \(u > 0\) constant), corresponding to \(t = \frac{\sqrt{\left(1 - \frac{\omega\tau}{v}\right)^{-1} + \left(1 - \frac{\omega\tau}{v}\right)^{-2}u^2}}{\sqrt{1 - \omega}}\) (with \(v\) the velocity of the D0-brane). For a small value of \(u\), the evolutions of the coherences are drawn fig.8. As could be expected, strong decoherences occur at the event horizon. In particular, the spatial decoherence falls (the speed at the neighborhood of \(r_S\) becomes equal to the speed of light, involving a strong non-adiabaticity) and the survival probability falls (inside the black hole the fermion is absorbed by the singularity). The mean values of \(\omega\) and \(t\) are drawn fig.9. The other end of the string follows the probe D0-brane, but it seems to bounce on the event horizon and to stagnate in its neighborhood. This can be confirmed by examining the wave packet of the \(\alpha\)-representation of the end of the string:

\[ \psi(\alpha, \tau) = \langle \Lambda(\alpha)|\tilde{\psi}(\tau)\rangle \tag{38} \]

where \(|\tilde{\psi}(\tau)\rangle = \frac{|\psi(\tau)\rangle}{\sup_{\alpha} \langle \Lambda(\alpha)|\psi(\tau)\rangle}\) is the renormalized state in order to normalize its spatial coherence at 1 at each time (this permits to examine the evolution of the spatially coherent part of \(|\psi\rangle\)). \(\psi(\alpha, \tau)\) is represented fig.10. We have considered the case \(\omega' = 0\), so the particle is not submitted to the barrier generated by \(t\). We can interpret the behavior at the event horizon as being similar to the reflection of a wave packet by a rough potential well. A part of the wave packet is reflected by the black hole (which can be viewed as a potential well in \(\alpha\)-representation fig.2). But driven by the probe D0-brane, this wave packet part returns on event horizon and bounces again and again (fig.10). But note that in fig.9-10 the state \(|\psi\rangle\) is renormalized. In fact, as we can see it fig.8 the most of the state is transmitted by the event horizon and is quickly dissipated (absorbed by the singularity). So the mean position in fig.9-10 after the arrival at the event horizon corresponds to the position of the tiny part which survives by reflection. The transmitted part does not contribute to the mean position since this one disappears quickly.

The situation differs if we consider the case where \(\omega' > 0\), fig.11. The barrier on the event horizon induced by \(\omega'\) (fig.4) reflects a large part of the wave packet, inducing that the dissipation (which concerns the transmitted part) is not complete. The rebounds on the event horizon (now induced by the barrier) concerns...
now a particle with a non-negligible survival probability. These ones imply strong oscillations of the spatial coherences. It can be counterintuitive that a quantum black hole has more difficulties for absorbing a heavy particle $\omega' \gg 0$ than a light one $\omega' \approx 0$. But note that black hole mass is $M = \frac{r_S}{\omega'}$. In the example fig.11 where the particle essentially bounces on the event horizon, we have $M = 0.75$ and $\omega' = 0.5$. It is not surprising that the quantum black hole has difficulties to absorb a particle almost as big as it. With $\omega' = 1 > M$, the survival probability rests equal to 1 during the whole dynamics, the reflection by the event horizon is then total. The quantum black hole cannot absorb a particle bigger than itself.

For a large value of $u$, we have a sudden regime for which the end of the string attached on $\mathcal{M}$ cannot fol-

low the too rapid probe D0-brane, see fig.12. Since the particle never arrives at the event horizon, no dissipation occurs. On the contrary, the too rapid drive induces a strong non-adiabaticity in the dynamics and so a rapid fall of the spatial coherence. This one can be associated in the $\alpha$-representation to the oscillations in the driving direction of the spatially coherent part of the state.
It can be more natural to consider a geodesic fall of the probe D0-brane (considering that the probe brane is not transported but moves under the effect of the gravity). We suppose that the probe D0-brane follows a radial timelike geodesic of the Schwarzschild geometry:

\[
\begin{align*}
\dot{r}^2 + 1 - \frac{r_S}{r} &= \epsilon^2 \\
\left(1 - \frac{r_S}{r}\right) \dot{t} &= \epsilon
\end{align*}
\]  

(39)

where \(\epsilon\) is the constant of motion (total energy by mass unit). The coherences are drawn fig.13. As for an uniform transport, we observe decoherence when the probe brane arrives at the event horizon. We have also a small fall of the spatial coherence at the beginning of the dynamics due to a non-adiabatic start. The mean values of \(\hat{r}\) and \(\hat{t}'\) are plotted fig.14 and the wave packet \(\psi(\alpha, \tau)\) are plotted fig.15. The other end of the string follows a path similar to a geodesic close to the probe D0-brane by the classical event horizon) and \(\omega' = 0\).

C. Geodesic fall

FIG. 12. Same as fig.8 (up left), fig.9 (up right and down left) and fig.10 (down right), but with \(u = 1\) (\(v(0) \approx 0.84\)).

FIG. 13. Evolutions of the survival probability, of the spatial coherence and of the purity of the fermionic state for a radial geodesic fall of the probe D0-brane with \(\epsilon \approx 0.85\) (corresponding to an initial speed \(v(0) \approx 0.56\)). \(r_S = 1.5\) (the vertical line corresponds to the passage of the probe D0-brane by the classical event horizon) and \(\omega' = 0\).

D. Particle extraction from the black hole

We can try to extract a particle from the black hole by transporting the D0-brane from the singularity to outside of the event horizon with \(\dot{r} = u\) (constant). Fig.16 shows the evolution of the corresponding wave packet \(\psi(\alpha, \tau)\) and of the survival probability of the particle. The particle seems to can be extracted from the quasi-coherent point of view, but as expected the dissipation process by reabsorption by the singularity drastically re-
FIG. 15. Wave packet $\psi(\alpha,t)$ representing the spatially coherent part of the end of the string state compared to the geodesic of the probe D0-brane (green path) with $\varepsilon \simeq 0.85$. The white dashed lines represent the classical event horizon $r_S = 1.5$ and the fuzzy event horizon $\langle r_S \rangle \pm \Delta r_S$. $\omega' = 0$.

stricts this possibility, the probability of success being of $\lim_{t \to +\infty} p_{\text{surv}} \simeq 6.3 \times 10^{-7}$ with the parameters used here (in particular $\omega' = 0$). With massive particle ($\omega' \neq 0$) the situation is even less favorable because of the well and the barrier at the event horizon induced by $\omega \dot{t}$ (fig. 4). With $\omega' = 0$, we have now $\lim_{t \to +\infty} p_{\text{surv}} \simeq 1.6 \times 10^{-10}$.

VI. WHITE HOLE AND WORMHOLE

At the construction of the model, we have decide to define $f$ on the Riemann sheet such that $\sqrt{-t} = -i\sqrt{t}$ (with $r > 0$), in order to the anti-selfadjoint part of $Z$ ($-i\text{Im } Z$) be a dissipator. If we choose now the other Riemann sheet ($\sqrt{-t} = +i\sqrt{t}$), the anti-selfadjoint part of $Z$ ($+i\text{Im } Z$) becomes a quantum flux generator (it increases the state norm with the time). In place of absorbing particles, the singularity now “emits particles”. We can then assimilate this case to a toy model of white hole. The Dirac operator for this white hole is simply $\slashed{D}_\alpha$ (with $\slashed{D}_\alpha$ still defined by eq. 13). This is well the operator governing a quantum dynamics of a time reversed black hole, in accordance with the classical definition of a white hole.

Consider the decomposition between selfadjoint and anti-selfadjoint parts of the Dirac operator:

$$\slashed{D}_\alpha = \begin{pmatrix} \text{Re } Z - z(\alpha) & a^+ - \bar{\alpha} \\ a - \bar{\alpha} & -\text{Re } Z + z(\alpha) \end{pmatrix} = \text{Re } \slashed{D}_\alpha - i\text{Im } \slashed{D}_\alpha$$ (40)

We see that $\slashed{D}_\alpha^\dagger = \text{Re } \slashed{D}_\alpha + i\text{Im } \slashed{D}$ whereas $\overline{\slashed{D}_\alpha} = \text{Re } \slashed{D}_\alpha + i\text{Im } \slashed{D}$ and so

$$\slashed{D}_\alpha^\dagger = \overline{\slashed{D}_\alpha}$$ (41)

and then

$$\slashed{D}_\alpha |\Lambda_{BH}(\alpha)\rangle = \lambda_0(\alpha)|\Lambda_{BH}(\alpha)\rangle$$ (42)

$$\Rightarrow \slashed{D}_\alpha |\Lambda_{BH}(\bar{\alpha})\rangle = -\lambda_0(\bar{\alpha})|\Lambda_{BH}(\bar{\alpha})\rangle$$ (43)

$$\Rightarrow \slashed{D}_\alpha^\dagger |\Lambda_{BH}(\alpha)\rangle = -\lambda_0(\alpha)|\Lambda_{BH}(\alpha)\rangle$$ (44)

$$\Rightarrow \slashed{D}_\alpha^\dagger |\Lambda_{WH}(\alpha)\rangle = -\lambda_0(\bar{\alpha})|\Lambda_{WH}(\alpha)\rangle$$ (45)
with the quasi-coherent state of the white hole defined by

$$|\Lambda_{WH}(\alpha)\rangle = |\Lambda_{BH}(\bar{\alpha})\rangle$$

Note that the duality $|\Lambda_{BH}\rangle/|\Lambda_{WH}\rangle$ is the duality between left and right eigenvectors in the non-hermitian quantum dynamics [18].

### A. Quantum transition from black hole to white hole

It can be possible that a black hole can bounce out its proper event horizon via quantum tunneling into a white hole (see for example [19]). It is then interesting to study the probability of transition from a black hole to white hole in our toy model:

$$P_{BH\rightarrow WH}(\alpha) = |\langle \Lambda_{WH}(\alpha)|\Lambda_{BH}(\alpha)\rangle|^2 \quad (47)$$

$$= |\langle \Lambda_{BH}(\bar{\alpha})|\Lambda_{BH}(\alpha)\rangle|^2 \quad (48)$$

This one is plotted fig.17. It is important to well interpret $P_{BH\rightarrow WH}(\alpha)$: this is the probability for an observer comoving with the probe D0-brane at $\alpha$ to see a transition from a black hole fuzzy spacetime to a white hole fuzzy spacetime after a measurement onto the test particle (fermionic string). We note that $P_{BH\rightarrow WH}(\alpha) \simeq 1$ for $|\alpha| \gg r_S$. This is consistent with the fact that the Schwarzschild geometry is asymptotically Minkowskian. In the neighborhood of $\alpha$ with large $|\alpha|$, the spacetime is Minkowskian and there is no difference between black and white holes for the observer. This difference can be seen only in neighborhood of the event horizon. Moreover we have no take into account the time effects, by considering that the observer makes measures onto the test fermionic string immediately after its emission/preparation in a quasi-coherent state. Consider the following change of representation:

$$|\psi\rangle = U_E|\tilde{\psi}\rangle \, \text{with} \, U_E(\tau) = e^{-i\omega_\epsilon \tau} \quad (49)$$

$$\frac{\partial |\tilde{\psi}\rangle}{\partial \tau} = U_E^{-1}(\tau)\hat{D}_{\alpha,\tau}U_E(\tau)|\tilde{\psi}(\tau)\rangle \quad (50)$$

We have then a time-dependent eigenvectors of $\hat{D}_{\alpha,\tau}$ which is $|\Lambda_{BH}(\alpha,\tau)\rangle = U_E(\tau)|\Lambda_{BH}(\alpha)\rangle$ and then a time-dependent probability of transition

$$P_{BH\rightarrow WH}(\alpha,\tau) = |\langle \Lambda_{BH}(\bar{\alpha})|U_E(\tau)|\Lambda_{BH}(\alpha)\rangle|^2 \quad (51)$$

This one is the probability for an observer comoving with the probe D0-brane at $\alpha$ to see a transition from a black hole fuzzy spacetime to a white hole fuzzy spacetime during a measurement after a proper time $\tau$ from the “preparation” of the fermionic string in the quasi-coherent state at the position $\alpha$. The time-dependent transition probability is drawn fig.18. The probability falls to 0 for $|\alpha| \gg r_S$ with sufficiently large $\tau$. For short time, the observer cannot have the time to receive information from the event horizon and cannot then distinguish a white hole from a black hole by a local measure onto the test particle. But with $\tau$ sufficiently large, this confusion disappears and it becomes impossible to realize a transition from a black to a white hole by a measurement far from the event horizon. In contrast, the probability of this transition rests possible at the neighborhood of the event horizon (but it is submitted to fast oscillations).

### B. Einstein-Rosen like bridge

Isolated fuzzy white hole causes a problem in the presented model, because the normalization of the state $|\psi\rangle$ exponentially increases during the dynamics. As
in other approaches of black hole physics, it is more consistent to consider white holes as partners of black holes within wormholes as Einstein-Rosen bridges. The present formalism is not adapted to quantize a Schwarzschild spacetime in Kruskal-Szekeres coordinates for which the extension of a black hole with white hole is natural. But we can propose a modification of our toy model in Schwarzschild coordinates to built an Einstein-Rosen like bridge.

We consider two spacetime regions denoted by $\mathcal{M}_+$ (corresponding to a black hole) and $\mathcal{M}_-$ (corresponding to a white hole), in which the fuzzy Schwarzschild manifold $\mathcal{M}$ is embedded, in the sense that $\mathcal{M}_+ \cup (0,0) \mathcal{M}_-$ (the surgery of the two manifolds gluing at $\alpha = 0$) is the new configuration space of the probe D0-brane. Let $(|+\rangle, |−\rangle)$ be the quantum states of occupation of these regions. We consider then now, the Hilbert space $\mathcal{H} = \mathbb{C}^2 \otimes \mathbb{C}^2 \otimes \mathcal{F}$ (spacetime region states $\otimes$ spin states $\otimes$ noncommutative space wavefunctions). The dissipator $-i\text{Im} Z$ of the black hole Dirac operator must now make the particle disappear in the region $\mathcal{M}_+$ to make it reappear in the region $\mathcal{M}_-$ (and conversely for the generator $+i\text{Im} Z$ of the white hole Dirac operator). $\pm i\text{Im} Z$ must be then now couplings between the states $\pm\rangle$. We propose then the following Dirac operator for the wormhole:

$$\hat{D}_\alpha = \begin{cases} \Re \hat{D}_0 -i\text{Im} Z & \text{if } \bullet \in \mathcal{M}_+ \\ -i\text{Im} Z \Re \hat{D}_0 & \text{if } \bullet \in \mathcal{M}_- \end{cases}$$ (52)

$\bullet$ denoting the probe D0-brane. $\hat{D}_\alpha^\infty$ is self-adjoint because now the quantum flux disappearing in $\mathcal{M}_+$ reappears in $\mathcal{M}_-$. The quasi-coherent state is extended as

$$|\Lambda^\infty(\alpha)\rangle = \begin{cases} |+\rangle \otimes |\Lambda_{BH}(\alpha)\rangle & \text{if } \bullet \in \mathcal{M}_+ \\ |−\rangle \otimes |\Lambda_{BH}(\alpha)\rangle & \text{if } \bullet \in \mathcal{M}_- \end{cases}$$ (53)

We consider an uniform radial transport of the D0-brane traveling through $\mathcal{M}_+$ to $\mathcal{M}_-$, with $|r| = u$ (constant). For a small value of $u$, the coherences are plotted fig[19] The coherences fall during the transport on $\mathcal{M}_+$ but increase during the transport on $\mathcal{M}_-$, in accordance with the “anti-symmetric” role of the white hole. The mean observables during the transport are drawn fig[20] The particle passes through the wormhole, the process starting with a small probability which strongly increases when the D0-brane is between the two event horizons. The mean value of $\hat{r}$ follows the probe D0-brane. $(\tau')$ is meaningless in that case, since it corresponds to a measure by a distant observer in $\mathcal{M}_+$ which formally counts negatively the elapsed time between the two horizons. But the average value $\hat{r}$ hides an important phenomenon which can be revealed by drawing the wave packet $\psi(\alpha, \tau) = \langle \Lambda^\infty(\alpha) | \hat{\psi}(\tau) \rangle$, fig[21] The quasi-coherent wave packet does not come in the wormhole. As observed for the fall into a quantum black hole, the wave packet bounces on the event horizon and stagnates in its neighborhood. The part which is transmitted by the event horizon (which not absorbed now), directly reappears in the neighborhood of the second horizon. The quasi-coherent wave packet does not travel through the wormhole but passes through it by quantum tunneling. This is in accordance with the fact that the Einstein-Rosen bridges are classically non-traversable. With large values of $\omega'$, the tunneling process is tone off and the particle remains stuck in front of the first event horizon (for $\langle \hat{r} \rangle$ and for the wave packet) because of the large barrier introduced by $\hat{\omega}$ (as in the previous examples, if $\omega' > M$, the wormhole cannot transfer a particle bigger than itself). In contrast, a small non-zero value of $\omega'$ increases the quantum tunneling through the wormhole, see fig[22] This can be understand by regarding fig[4] With reasonable value of $\omega'$ the wave packet can overcome the small barrier ahead the event horizon but can be trapped by the deep well behind the horizon. The wave packet can be then easily passes by tunneling from the deep well of the first horizon to the one of the second. This can be confirmed by fig[22] down right, where we see wave packet trapped behind the event horizons.

**VII. CONCLUSION**

A toy model representing the quantization of a $(r, \theta)$ Schwarzschild slice is proposed as a fuzzy manifold. This model permits to describe a fuzzy event horizon by a purely quantum model (in contrast with previous works as [12,13] where a classical geometry is computed from a delocalized singularity viewed as a smeared mass). The Dirac operator is not self-adjoint, the dissipator being interpreted as the effect of particle absorption by the black
FIG. 20. Up: probability to find in the spacetime region $\mathcal{M}_-$ the end of the string attached on $\mathcal{M}$. Middle: $\langle \hat{r} \rangle = \frac{\langle \hat{r} \psi | \psi \rangle}{\| \psi \|^2}$ (mean value of the radial coordinate of the end of the string attached on $\mathcal{M}$) compared to the radial coordinate of the probe D0-brane (the vertical axis is graduated positively for $\mathcal{M}_+$ and negatively for $\mathcal{M}_-$). Down: $\langle t' \rangle = \int_0^\infty \frac{\langle \hat{t} \psi | \psi \rangle}{\| \psi \|^2} d\tau$ (mean value of the time of the end of the string measured by the clock of an observer at infinity in $\mathcal{M}_+$ comoving with the black hole) compared to the time coordinate of the probe D0-brane. The light blue clouds correspond to the quantum uncertainties. The parameters are $|\hat{r}| = u = 0.05$, $r_S = 1.5$ and $\omega' = 0$. The dashed horizontal lines are the classical event horizons (the light green cloud corresponds to fuzzy event horizon $\langle r_S \rangle \pm \Delta r_S$); the dashed vertical line indicates the time where the probe D0-brane crosses a classical event horizon or the singularity.

FIG. 21. Wave packet $\psi(\alpha, \tau)$ representing the spatially coherent part of the end of the string state compared to the radial coordinate of the probe D0-brane (green path) passing through a wormhole when $|\hat{r}| = u = 0.05$. The white dashed lines represent the classical event horizons $r_S = 1.5$ and the fuzzy event horizons $\langle r_S \rangle \pm \Delta r_S$. $\omega' = 0$. The horizontal axis is graduated positively for $\mathcal{M}_+$ and negatively for $\mathcal{M}_-$.

FIG. 22. Same as fig.19 (up left), fig.20 (up right and down left) and fig.21 (down right), but with $\omega' = 0.09$.
in $\mathbb{R}^7$ (with Eddington-Finkelstein coordinates) but with the noncommutative manifold obtained as a “semiclassical manifold” by using a Moyal-type star product. An interesting question is the possibility to find intermediate models of noncommutative manifold related to the Schwarzschild geometry. In particular, since quantum event horizons can be described by fuzzy spheres [10, 12], a future work could consist to built a composite model from the fuzzy sphere and the fuzzy Schwarzschild slice. Another question is the signature of the noncommutativity at the emergent geometry in the quasi-coherent representation. In ref. [20] it is proved that at the semiclassical limit, a non-zero torsion is a signature of the noncommutativity of the quantum spacetime. Moreover a general framework based on the geometric phases of the adiabatic transport to define such non-zero torsion with fuzzy geometries has proposed in [21]. This method is not applicable here because of the strong non-adiabaticity of the model in the neighborhood of the fuzzy event horizon. Maybe with a fuzzy manifold obtained by quantization of a different coordinate system regular at the horizon (as Kruskal-Szekeres coordinates) could avoid this problem and permits to study a torsion induced by the spacetime noncommutativity.

Appendix A: The noncommutative plane

The noncommutative plane is defined by eq. (1). The associated Dirac operator is then

$$\hat{D}_\alpha = \begin{pmatrix} 0 & a^+ - \alpha \\ a - \alpha & 0 \end{pmatrix} \quad (A1)$$

The quasi-coherent state, solution of $\hat{D}_\alpha |\lambda_0(\alpha)\rangle = 0$, is simply

$$|\lambda_0(\alpha)\rangle = |0\rangle \otimes |\alpha\rangle \quad (A2)$$

where

$$|\alpha\rangle = e^{-|\alpha|^2/2} \sum_{n=0}^{\infty} \frac{\alpha^n}{\sqrt{n!}} |n\rangle \quad (A3)$$

is the Perelomov coherent state [17] of the quantum harmonic oscillator algebra: $a|\alpha\rangle = \alpha|\alpha\rangle$. Coherent states are not orthogonal:

$$|\langle \beta | \alpha \rangle|^2 = e^{-|\alpha - \beta|^2} \quad (A4)$$

and correspond then to gaussian localizations around $\alpha \in \mathbb{C}$ minimizing the quantum uncertainties. More generally, we have (for $n > 0$)

$$\hat{D}_\alpha |\lambda_{n\pm}(\alpha)\rangle = \pm \sqrt{n} |\lambda_{n\pm}(\alpha)\rangle \quad (A5)$$

$$|\lambda_{n\pm}(\alpha)\rangle = \frac{1}{\sqrt{2}} (|0\rangle \otimes |n\rangle_{\alpha} \pm |1\rangle \otimes |n-1\rangle_{\alpha}) \quad (A6)$$

where

$$|n\rangle_{\alpha} = \frac{(a^+ - \alpha)^n}{\sqrt{n!}} |\alpha\rangle \quad (A7)$$

(with the identification $|\alpha\rangle = |0\rangle_\alpha$). $(|n\rangle_\alpha)_{n \in \mathbb{N}}$ constitutes an orthonormal basis of the Fock space $\mathcal{F}$ as the canonical basis of the representation of the quantum harmonic oscillator operators $b_\alpha = a - \alpha$ and $b_\alpha^+ = a^+ - \alpha \ (b_\alpha, b_\alpha^+ = 1)$: $b_\alpha^+ |n\rangle_\alpha = \sqrt{n+1} |n+1\rangle_\alpha$ and $b_\alpha |n\rangle_\alpha = \sqrt{n} |n-1\rangle_\alpha$. We can then view $(|n\rangle_\alpha)_{n \in \mathbb{N}}$ as the local basis of $\mathcal{F}$ (“local” in the meaning of the $\alpha$-representation).

Let $r(\tau) = r_0 - \gamma \tau r$ (with $\gamma = 1/\sqrt{1 - v^2}$) be a geodesic transport of the probe D0-brane ($\alpha(\tau) = r(\tau)e^{i\theta}$). We consider the Dirac equation:

$$i|\dot{\psi}\rangle = \hat{D}_\alpha |\lambda_0(\alpha)\rangle \quad (A8)$$

$$|\psi(0)\rangle = |\lambda_0(\alpha(0))\rangle \quad (A9)$$

where the dot denotes the derivative with respect to the proper time $\tau$. Since $\hat{D}_\alpha = r \begin{pmatrix} 0 & e^{i\theta} \\ e^{-i\theta} & 0 \end{pmatrix}$, the dynamical behavior is governed by $|\dot{\psi}\rangle = \gamma v$:

- **For** $v \ll 1 \iff |\dot{\psi}| \ll 1$, the dynamics is adiabatic and then

$$|\psi(\tau)\rangle \simeq e^{i\varepsilon v(\tau)} |\lambda_0(\alpha(\tau))\rangle \quad (A10)$$

where $e^{i\varepsilon v(\tau)}$ is the dynamical and geometric phases. The mean value of the “wave packet” $\langle \psi(\alpha, \tau) = \langle 0, \alpha | \psi(\tau) \rangle \rangle$ follows then the classical geodesic of the probe D0-brane and the spatial coherence (fidelity to a quasi-coherent state) remains 1 during the whole dynamics. Numerical simulations show that this regime is valid until $v \simeq 0.3$ ($\gamma v \simeq 0.3$).

- **For** $v \sim 1 \iff |\dot{\psi}| \sim +\infty$, the dynamics is sudden and then

$$|\psi(\tau)\rangle \simeq |\lambda_0(\alpha(\tau))\rangle \quad (A11)$$

The wave packet remains at $\alpha(0)$ with a strong loss of coherence (the quantum state cannot follow the too rapid D0-brane). Numerical simulations show that this regime starts to dominate from $v \simeq 0.6$ ($\gamma v \simeq 0.75$).

With $v \in [0.3, 0.6]$ the dynamics is a mix of the adiabatic and sudden regimes.

Appendix B: About numerical computations

In numerical computations we work with the truncated Fock space $\mathcal{F}_N = \text{Lin} \{|n\rangle, n \in \{0, ..., N\}\}$. The operators of the quantum harmonic oscillator algebra are then represented by

$$a_N = \sum_{n=0}^{N} \sqrt{n} |n-1\rangle \langle n| \quad (B1)$$

$$a_N^+ = \sum_{n=0}^{N-1} \sqrt{n+1} |n+1\rangle \langle n| \quad (B2)$$
The value of $r_{\text{max}}$ (maximal value for which the numerical representation is correct) depends on the truncation value $N$ and the expected accuracy $\epsilon$. Fig. 23 shows this relation. In the computations presented in this paper, we have chosen $N = 50$ involving than $r_{\text{max}} = 5$ (with $\epsilon = 10^{-2}$).

To solve the equation $\mathcal{D}_\alpha |\Lambda(\alpha)\rangle = \lambda_0(\alpha) |\Lambda(\alpha)\rangle$ with $\text{Re}\lambda_0 = 0$, we consider a lattice $\mathcal{X} = \{r_i e^{i\theta_j}, r_i = \frac{\lambda_{\text{max}}}{N_\alpha}, \theta_j = \frac{2\pi j}{N_\alpha}, i = 0, \ldots, N_\alpha - 1\}$ of the disk $|\alpha| \leq r_{\text{max}}$. We consider also a partition $\mathcal{X}_z = \{k f(r_{\text{max}}/N_\alpha)\}_{k = 0, \ldots, N_z}$. For each point $(\alpha_{ij}, z_k) \in \mathcal{X} \times \mathcal{X}_z$, we diagonalize $\mathcal{D}_\alpha_{ij, z_k, N}$ (Dirac operator built with the truncated creation and annihilation operators) and we select the eigenvalue $\lambda_{ij}$ with minimal real part. $z_{ij}$ such that $\text{Re}\lambda_{ij} = \min_k \text{Re}\lambda_{ij}$, is a first approximation of $z(\alpha_{ij})$. Next we improve the approximation by dichotomy: we compute $\lambda_{ij, k_{ij} \pm 1/2}$ (with $z_{kl} \pm \frac{1}{2}$) and redefine $z_{ij}$ with $k_{ij}$ corresponding to the minimal value of $\{\text{Re}\lambda_{ij} - \text{Re}\lambda_{ij, k_{ij} \pm 1/2}\}$. And we iterate the process until we find an eigenvalue with real part equal to zero with the expected accuracy ($\epsilon = 10^{-2}$ in the computations presented in this paper). For computations needed only results on a single radial axis ($\theta = 0$ for example), we can only consider a 1D lattice $\mathcal{X}_r = \{r_i = \frac{\lambda_{\text{max}}}{N_\alpha}\}_{i = 0, \ldots, N_\alpha}$.
