Classification of stable three-dimensional Dirac semimetals with nontrivial topology

Bohm-Jung Yang\(^1\) & Naoto Nagaosa\(^{1,2}\)

A three-dimensional (3D) Dirac semimetal (SM) is the 3D analogue of graphene having linear energy dispersion around Fermi points. Owing to the nontrivial topology of electronic wave functions, the 3D Dirac SM shows nontrivial physical properties and hosts various exotic quantum states such as Weyl SMs and topological insulators under proper external conditions. There are several kinds of Dirac SMs proposed theoretically and partly confirmed experimentally, but its unified picture is still missing. Here we propose a general framework to classify stable 3D Dirac SMs in systems having the time-reversal, inversion and uniaxial rotational symmetries. We show that there are two distinct classes of 3D Dirac SMs. In one class, the Dirac SM possesses a single Dirac point (DP) at a time-reversal invariant momentum on the rotation axis. Whereas the other class of Dirac SMs have a pair of DPs created by band inversion, and carry a quantized topological invariant.
Dirac semimetal (SM) indicates a phase whose low-energy excitations can be described by pseudorelativistic Dirac fermions with linear energy dispersion. Before the discovery of three-dimensional (3D) topological insulators, graphene has been considered as the unique system where the intriguing properties of two-dimensional (2D) Dirac fermions can be observed. However, the recent progress in the field of topological insulators has shown that stable 2D Dirac fermions exist ubiquitously on the surface of 3D topological insulators. Moreover, through the careful studies on the topological phase transition between a 3D topological insulator and a normal insulator, it is demonstrated that even the 3D Dirac fermions with the linear dispersion in all three momentum directions can be observed in the same material if we can reach the quantum critical point. As the 3D Dirac point (DP) with fourfold degeneracy does not carry a Chern number, the degeneracy at the gap-closing point can be easily lifted by small external perturbations, hence, the 3D Dirac fermions can be observed only at the single quantum critical point. However, the approach to the quantum critical point requires the intricate fine-tuning of the alloy chemical compositions, which limits the accessibility to the fascinating physics of 3D Dirac fermions in experiments.

The breakthrough in the search for stable 3D Dirac SMs is achieved in the recent series of studies on Na₃Bi (refs 9,10) and Cd₃As₂ (refs 11–14) compounds, where a pair of 3D DPs stably exist on the kₚ axis. The stability of the 3D DP in these materials stems from the fact that the system has additional crystalline symmetries other than the time-reversal symmetry (TRS) and inversion symmetry (IS). For instance, Young et al. have proposed that particular space groups allow 3D DPs as symmetry protected degeneracies. Also, Wang et al. have shown the symmetry protection of the 3D DPs through the detailed symmetry analysis of Na₃Bi (ref. 17) and Cd₃As₂ (ref. 18).

In the present paper, we propose a general framework to classify stable 3D Dirac SMs in systems with TRS, IS and uniaxial rotation symmetry, which are the most common symmetries of crystalline solids. Through the careful examination of the condition for the accidental band crossing (ABC), we have accomplished the complete classification of stable 3D Dirac SMs, and uncovered that there are two broad classes of 3D Dirac SMs. The Dirac SMs belonging to the first class are created via a band inversion, and have a pair of DPs on the rotation axis away from the time-reversal invariant momentum (TRIM). On the other hand, the second class of Dirac SMs have a single DP at a TRIM on the rotation axis where the band crossing is ensured by the lattice symmetry. In particular, we find that the first class of 3D Dirac SMs have nontrivial topological properties. We have clarified the fundamental relationship between the crystalline symmetries and the topological property of 3D Dirac SMs, and demonstrated that the 3D topological Dirac SM generally mediates the topological quantum phase transition between a normal insulator and a 3D weak topological insulator (or a topological crystalline insulator). In fact, the 3D topological Dirac SM itself is a parent state of 3D topological insulators, which turns into either a 3D strong topological insulator or a 3D topological crystalline insulator when the 3D DP acquires a mass gap because of symmetry breaking.

Results

Basic principles to create 3D Dirac semimetals. Our strategy to synthesize a 3D Dirac SM is as follows. Let us consider a system having both the TRS and IS. In general, the TRS requires $E_{\sigma,n}(k) = E_{\sigma,n}(-k)$, where $E_{\sigma,n}(k)$ indicates the energy eigenvalue of the n-th band with the spin $\sigma = \uparrow, \downarrow$ at the momentum k. On the other hand, the IS requires $E_{\sigma,n}(k) = E_{\sigma,n}(-k)$. Therefore, under the combined operation of TRS and IS, $E_{\sigma,n}(k) = E_{\sigma,n}(k)$, hence, the energy band is doubly degenerate locally at each k. Under this condition, whenever an ABC occurs between the valence and conduction bands, a 3D DP with fourfold degeneracy can be generated. According to Murakami et al. and Wang et al., such an ABC can be achieved only under certain limited conditions because of the strong repulsion between degenerate bands. Namely, only when the valence and conduction bands have the opposite parities, an ABC can occur at a TRIM by tuning an external parameter m. In this case, a 3D DP appears at the quantum critical point $(m = m_0)$ between a normal insulator and a $Z_2$ topological insulator (see Fig. 1a). As a band gap opens immediately once $m \neq m_0$, the DP is unstable. However, in many crystals, the rotational symmetry as well as TRS and IS presents ubiquitously and constrains the physical properties of materials. Surprisingly, as we will describe in detail below, the additional uniaxial rotational symmetry strongly modifies the condition for ABC, which allows the 3D Dirac SM to emerge as a stable phase. This is possible because when the valence and conduction bands have different topological invariants, the level repulsion between them can be significantly relaxed as pointed out by Wang et al., which eventually leads to the emergence of a stable 3D Dirac SM phase in the wide range of the parameter space (see Fig. 1b, c).

To describe an ABC of two bands, each of which is doubly degenerate because of the simultaneous presence of TRS and IS, a 4 × 4 matrix Hamiltonian can be used as a minimal Hamiltonian, which in general has the following form,

$$
- \sum_{ij=0}^{3} \begin{pmatrix} a_{ij}(k) \sigma_i \tau_j = \begin{pmatrix} h_{ij1}(k) & h_{ij2}(k) \\
 h_{ij2}(k) & h_{ij1}(k) \end{pmatrix}
$$

where the Pauli matrix $\sigma_{1,2,3}$ ($\tau_{1,2,3}$) indicates the spin (orbital) degrees of freedom and $s_0$ and $t_0$ are the 2 × 2 identity matrices. $h_{\sigma'\sigma}(\sigma' = \sigma, \sigma')$ indicates a 2 × 2 matrix, which can be spanned by $\tau_{0,1,2,3}$ and $a_{ij}(k)$ are real functions of k. The invariance of the system under the rotation in the 3D space 21.

In such a basis, the Hamiltonian can be written as

$$
H(k) = \begin{pmatrix} d_0 + d_1 \tau_3 + d_2 \tau_1 \tau_3 + d_3 \tau_1,
\end{pmatrix}
$$

where $d_{0,1,2,3}(k,m)$ are real functions. As the simultaneous presence of TRS and IS requires the double degeneracy of each state, among $d_{1,2,3}$ only one function can be non-zero. Also, as the degenerate bands should have the opposite spin directions, $d_0 = 0$. Hence, the Hamiltonian becomes

$$
H(k) = \begin{pmatrix} d_0 + d(k, m) \Gamma, \end{pmatrix}
$$

where $\Gamma$ is either $\tau_1$ or $\tau_3$. Then, as the energy gap is given by $|d(k,m)|$, an ABC can be achieved if and only if $d(k,m) = 0$. Here the number of variables (two) is larger than the number of equations (one) to be satisfied for the band crossing, hence, the Dirac SM can always be created via an ABC.

Moreover, owing to the TRS and IS, $d(k)$ has a definite parity under the sign reversal of $k_z$ as shown in Methods. In fact, the parity of $d(k)$ can be simply determined by the matrix representation P of the IS. Namely, when P has a diagonal form such as $P = \pm \tau_0$ or $\pm \tau_z$, $d(k)$ is even, whereas it is odd if P has an off-diagonal form $P = \pm \tau_x$. At first, when $d(k)$ is even, $d(k) \approx M + \frac{1}{2} \tau_z k_z^2$ in the leading order with constants $M$ and $\tau_z$. In this case, the system is a gapped insulator (a Dirac SM) when $M \tau_z > 0$ ($M \tau_z < 0$). Namely, by taking M as a tunable parameter...
when a single control parameter $m$ is varied in systems with the TRS and IS but lacking the rotation symmetry. The 3D Dirac fermion appears only at the critical point $m = m_0$, and the ABC mediates the transition between a normal insulator and a strong topological insulator (TI). When an additional uniaxial rotational symmetry is included, two different phase diagrams can be obtained as shown in b and c. Here we choose the $k_x$ axis as the axis for the $n$-fold rotation. (c) The Dirac SM persists irrespective of $m$. The Dirac point locates at a TRIM on the rotation axis. The Dirac SM in Table 2 corresponds to this case. At the quantum critical points ($m = m_{c1}$ or $m = m_{c2}$), the energy dispersion along the $k_x$ direction is quadratic while the dispersion along the $k_y$ and $k_z$ directions is linear (linear Dirac SM) or quadratic (quadratic Dirac SM) or cubic (cubic Dirac SM).

**Table 1 | Classification table for 3D topological Dirac semimetals.**

| $C_6$ | $|P|$ | $(u_A, u_B, 1)$ | $g(k_y, k_z)$ | $2D$ topological invariant | $H_{Dirac}(q)$ | Materials |
|---|---|---|---|---|---|---|
| $C_2$ | $t_2$ | $-e^{i\theta}$ | $\beta k_x + \gamma k_y$ | $n_{m} = \pm 1$ | Not allowed | Na$_3$Bi$^{17}$ |
| $C_2$ | $t_0$ | $0$ | $0$ | $2D\text{ }V = 1$ | Linear Dirac | Cd$_3$As$_2$$^{18}$ |

| $C_6$ | $t_0$ | $0$ | $0$ | $2D\text{ }V = 0$ | Linear Dirac | Na$_3$Bi$^{17}$ |

2D, two-dimensional; 3D, three-dimensional.

Classification table for 3D topological Dirac semimetals obtained by an accidental band crossing in systems having $C_6$ rotational symmetry with respect to the $z$ axis. Here $C_6 = \text{diag}(u_A, u_A, -u_B, -u_B)$, and $u_A$ and $u_B$ are arranged in a way that $0 < \arg(u_A) > |\arg(u_A)| < \frac{\pi}{2} (\text{mod } 2\pi)$. The $2 \times 2$ Hamiltonian $H_{Dirac}(q)$ describes the effective Hamiltonian near the bulk Dirac point, which is either $H_{Dirac}(q) = \pm \beta_0 k_x + \gamma_0 k_y$ (Linear Dirac) or $H_{Dirac}(q) = \pm \beta_0 k_x + \gamma_0 k_y + \frac{1}{2}(\alpha_0 k_z^2 + \gamma_0 k_y^2)$ (Quadratic Dirac), where $\beta_0, \gamma_0, \alpha_0, \eta, \lambda$ are real constants. The momentum $q$ is measured with respect to the bulk Dirac point.

and assuming $t_2 < 0$, the transition from an insulator ($M < 0$) to a 3D Dirac SM ($M > 0$) can be achieved across the sign reversal of $M$ (or the band inversion). In particular, the 3D Dirac SM phase possesses two DPs, which are symmetrically located with respect to the centre of the rotation axis at $k_x = \pm \sqrt{2M/t_2}$. The Dirac SMs realized in Cd$_3$As$_2$ and Na$_3$Bi belong to this class$^{17,18}$. 
On the other hand, when \( d(k_z) \) is odd, \( d(k_z) \approx v k_z \) in the leading order with a constant \( v \). In this case, there is a single 3D DP at \( k_z = 0 \). Then the system is nothing but a stable 3D Dirac SM with a single DP at the centre of the rotation axis. Considering the full periodic structure of the Brillouin zone (BZ), both \( k_x = 0 \) and \( k_z = \pi \), that is, the TRIMs on the rotation axis, are the possible locations of the DP. The candidate Dirac SM systems such as \( \beta \)-cristobalite \( \mathrm{BiO}_2 \) (ref. 15) and distorted spinels\(^{16} \) proposed by the recent theoretical studies belong to this class. In these systems, \( P = \pm \sigma_z \) representation is realized due to the non-symmetric shape group symmetry the system with two sublattice degrees of freedom. Namely, the system is invariant under the inversion with respect to a lattice site followed by a partial translation between sublattice sites. As the sublattices are interchanged throughout the symmetry operation, \( P \) can have an off-diagonal form of \( P = \pm \sigma_z \). In distorted spinels, the compound IS combined with additional twofold rotation and time-reversal symmetries gives rise to a single DP at the T point of the BZ\(^{16} \). On the other hand, there are three bulk DPs in \( \beta \)-cristobalite \( \mathrm{BiO}_2 \) at the three symmetry-related \( X \) points\(^{15} \). At each \( X \) point, the system has a uniaxial fourfold rotation symmetry with the compound IS \( P \) consistent with our theory.

In conclusion, when the material has the TRS, IS and uniaxial rotation symmetry simultaneously, there are two different ways to obtain a stable Dirac SM phase. One is through an ABC (or a band inversion), which gives rise to a stable 3D Dirac SM with a pair of 3D DPs on the axis of the rotation (see Fig. 1c). This class of Dirac SMs appears when the IS is represented by \( P = \pm \sigma_z \) or \( \pm \sigma_x \). The other case is when the system naturally supports a 3D DP at a TRIM on the rotation axis due to the symmetry of the system (see Fig. 1b). Such a Dirac SM can exist when the IS is represented by \( P = \pm \sigma_x \). The intrinsic properties of the relevant 3D Dirac SM phases are summarized in Tables 1 and 2, respectively. Up to now, we have considered only the leading order terms of \( d(k_z) \). However, when the higher order terms are included, the number of DPs can be increased as a pair of DPs can always be created whenever an additional ABC happens. However, independent of the total number of DPs, the Dirac SM with \( P = \pm \sigma_x \) always has an even number of DPs away from the TRIM, whereas the Dirac SM with \( P = \pm \sigma_z \), having an odd number of DPs always possesses a single DP at a TRIM.

**Classification table.** The classification of the 3D Dirac SM phases can be performed rigorously by imposing the TRS, IS and \( C_n \) rotation symmetry to the minimal \( 4 \times 4 \) Hamiltonian \( H(k) \). In the simultaneous presence of the TRS and IS, the Hamiltonian can always be written as \( H(k) = \sum_{i=1}^{3} a_i(k) \Gamma_i \), where \( \Gamma_i \) indicates 4 × 4 hermitian matrices satisfying \( \{ \Gamma_i, \Gamma_j \} = 2 \delta_{ij} \), which guarantees the double degeneracy of eigenstates at each \( k \) (see Methods). The precise functional form of \( a_i(k) \) can be fixed by imposing the \( C_n \) rotational symmetry using the basis under which both \( C_n \) and \( H(k) \) are diagonal along the \( k_z \) direction\(^{21} \). The results of the complete classification are concisely summarized in Tables 1 and 2. Because of the TRS, the rotation operator becomes \( C_n = \text{diag}(u_{A_1}, u_{B_1}, u_{A_2}, u_{B_2}) \), where each component \( u \) can be written as \( u = \exp \left( i \frac{\pi}{n} (p + \frac{1}{2}) \right) \) with \( p = 0, 1, \ldots, n-1 \) and \( A, B \) indicate the orbital degrees of freedom. Hence, only two components of \( C_n \) are independent.

The properties of the 3D Dirac SM generated via ABCs are shown in Table 1. In general, the ABC requires the valence and conduction bands to have different \( C_n \) eigenvalues. Namely, \( \{ u_{A_1}, u_{A_2} \} \) and \( \{ u_{B_1}, u_{B_2} \} \) should not have common elements to avoid interband hybridization. However, in the case of \( C_n \) invariant systems, \( \{ u_{A_1}, u_{A_2} \} = \{ u_{B_1}, u_{B_2} \} = \{ i, -i \} \), hence, the ABC is not allowed. On the other hand, the systems with \( C_3 \), \( C_4 \) and \( C_6 \) symmetries can support 3D Dirac SM phases. Although the detailed structure of the Hamiltonian \( H(k) \) depends on the specific symmetries of the corresponding system, there are only two different types of low-energy effective Hamiltonians near the bulk gap-closing point. In the first case, after some suitable unitary transformations, the effective Hamiltonian near each of the bulk DP can be written as

\[
H_{\text{Dirac}}(q) \sim \begin{pmatrix}
q_x \tau_x + q_y \tau_y + q_z \tau_z & 0 \\
0 & -q_x \tau_x - q_y \tau_y - q_z \tau_z
\end{pmatrix},
\]

where the momentum \( q \) is measured with respect to the DP. This is the Hamiltonian for the conventional Dirac fermion (the linear Dirac fermion), which is composed of two Weyl fermions having the Chern number +1 or −1, respectively. Whereas in the case of \( C_4 \) invariant system with the \( \{ u_{A_1}, u_{B_1} \} = \{ e^{i \pi/3}, e^{i \pi/2} \} \), the effective Hamiltonian is given by

\[
H_{\text{Dirac}}(q) \sim \begin{pmatrix}
(q_x^2 - q_y^2) \tau_x + 2 q_x q_y \tau_y + q_z \tau_z & 0 \\
0 & -(q_x^2 - q_y^2) \tau_x - 2 q_x q_y \tau_y - q_z \tau_z
\end{pmatrix}.
\]

Note that this DP is composed of two double-Weyl fermions, which have the Chern number +2 or −2, respectively\(^{21,22} \). Hence, we call this gapless fermions as the quadratic Dirac fermions.

The physical properties of the 3D Dirac SM with a DP at the centre of the rotation axis are summarized in Table 2. As the IS flips the orbitals in this case \( P = \pm \sigma_x \), the doubly degenerate states at each momentum on the \( k_z \) axis have different orbitals.

### Table 2 | Classification table for 3D Dirac SMs with a single Dirac point.

| \( C_n \) | \( |P| \) | \( u_{A_1} \) | \( f(k_z, k_x) \) | \( g(k_x, k_z) \) | \( H_{\text{Dirac}}(q) \) | Material |
|---|---|---|---|---|---|---|
| \( C_2 \) | \( \tau_x \) | \( e^{i \pi/4} \) | \( k_x F_1^{(1)}(k_x) - i k_y F_2^{(1)}(k_x) \) | \( x k_x + i b k_y \) | Linear Dirac | Distorted spinels\(^{16} \) |
| \( C_3 \) | \( \tau_x \) | \( e^{i \pi/4} \) | \( k_x F_1^{(2)}(k_x) - i k_y F_2^{(2)}(k_x) \) | \( 2 k_x \) | Linear Dirac | \( \beta \)-cristobalite \( \mathrm{BiO}_2 \)\(^{15} \) |
| \( C_4 \) | \( \tau_x \) | \( e^{i \pi/4} \) | \( k_x F_1^{(3)}(k_x) + i k_y F_2^{(3)}(k_x) \) | \( 2 k_x \) | Linear Dirac | Cubic Dirac |
| \( C_6 \) | \( \tau_x \) | \( e^{i \pi/4} \) | \( k_x F_1^{(3)}(k_x) + i k_y F_2^{(3)}(k_x) \) | \( F_3^{(1)}(k_x) + i F_4^{(1)}(k_x) \) | Linear Dirac |

3D, three-dimensional; SM, semimetal.

Classification table for 3D topological Dirac SMs in systems having \( C_n \) rotational symmetry with respect to the \( z \) axis when \( P = \pm \sigma_x \). In this Dirac SM phase, the location of the 3D DP is fixed either at the centre or the edge of the rotation axis, that is, at a time-reversal invariant momentum on the rotation axis. Here \( C_n = \text{diag}(u_1, u_2, u_3, u_4) = \text{diag}(u_1, u_2, u_3, -u_4) \) and \( \alpha, \beta \) are complex numbers. For compact presentation, \( \text{arg}(u_\alpha) \rangle \rightarrow k_x \rangle \) is fixed to be \(-\frac{\pi}{2} \leq \text{arg}(u_\alpha) \rangle \leq \frac{\pi}{2} \). But the same result holds even if \( \text{arg}(u_\alpha) \rangle \) is shifted by \( \pi \). The real functions \( F_1^{(1)}(k_x) \), \( F_1^{(2)}(k_x) \) and \( F_1^{(3)}(k_x) \) are real constants. The 2 × 2 Hamiltonian \( \hbar \Gamma_3(k) = \hbar \Gamma_3(k) + g(k) \Gamma_5 \) is shown in the table. \( H_{\text{Dirac}}(q) \) describes the effective Hamiltonian near the bulk Dirac point, which is either \( H_{\text{Dirac}}(q) = i u_1 \Gamma_1 + i u_2 \Gamma_3 + i u_3 \Gamma_5 \) (Linear Dirac) or \( H_{\text{Dirac}}(q) = i (q_x \Gamma_3 + q_y \Gamma_4 + i q_z \Gamma_5) \) (Cubic Dirac), where the momentum \( q \) is measured with respect to the bulk Dirac point with \( q_x = q_y = 0 \). Here \( F_1^{(1)} \rangle \) are mutually anticommuting 4 × 4 Gamma matrices and \( i_{123} \rangle \) are real constants.
and opposite spin directions. Therefore, the band crossing between degenerate bands requires \([u_{A1}, u_{B1}] \cap [u_{A1}, u_{A1}] = \emptyset\) contrary to the previous case. Moreover, owing to the additional constraint of \(u_{A1} = -u_{A1}\), the Dirac SM phase with a single DP cannot exist in the system with \(C_3\) invariance, whereas the systems with \(C_2, C_6, C_6\) symmetries support it (see Methods). One interesting prediction of Table 2 is that when the system has \(C_6\) symmetry with \(u_{A1} = \pm e^{i\pi/2}\), the low-energy Hamiltonian near the DP can be written as

\[H_{\text{Dirac}}(q) \sim \begin{pmatrix}
(q_+^2 + q_0^2) \tau_z + i(q_+^2 - q_0^2) \tau_y + q_0 \tau_x & 0 \\
0 & -(q_+^2 + q_0^2) \tau_z - i(q_+^2 - q_0^2) \tau_y - q_0 \tau_x
\end{pmatrix}\]

Note that this DP is composed of two triple-Weyl fermions, which have the Chern number +3 or -3, respectively. Hence, we can call this gapless fermion as the cubic Dirac fermion. For the other cases in Table 2, the effective Hamiltonian near the DP is simply described by the ordinary linear Dirac fermions.

**Topological properties of the 3D Dirac semimetals.** One important characteristic of the 3D Dirac SM generated by an ABC is that it carries a quantized topological invariant although it is a gapless SM. In fact, the band inversion associated with the ABC is the common origin of the presence of the 2D topological invariant and the emergence of bulk DPs. As shown in Table 1, in each case, a quantized 2D topological invariant can be defined on the \(k_z = 0\) plane where the ABC occurs. First of all, as the \(k_z = 0\) plane can be considered as a 2D system with TRS, a 2D Z2 invariant \(\nu_2\) is well-defined on \(q_{xy}\) plane. Moreover, because of the simultaneous presence of the TRS and IS, \(\nu_2\) can be determined by the parities of the occupied bands at TRIM. Therefore, whenever an ABC happens, it also changes the 2D topological invariant of the corresponding 2D planes. There are two different types of insulators in the phase diagram. One is a normal insulator, which does not carry a topological number, and the other is either a weak topological insulator or a topological crystalline insulator, in which both the \(k_z = 0\) and \(k_z = \pi\) planes have nontrivial 2D topological invariants. The system with \(P = \pm \tau_z\) supports a weak topological insulator, which has the \(Z_2\) topological index of \((0; 0, 0) = 0\) because \(\nu_2 = 1\) in both the \(k_z = 0\) and \(k_z = \pi\) planes. On the other hand, when \(P = \pm \tau_0, \nu_1, 2, 3 = 0\) independent of the band inversion because every band has the same parity. However, it is possible to obtain a topological crystalline insulator, as both the \(k_z = 0\) and \(k_z = \pi\) planes can have the non-zero mirror Chern number of \(\nu_3 = 2\). In fact, it is to note that the weak topological insulator in the system with \(P = \pm \tau_z\) can also have finite mirror Chern numbers. However, for convenience, we mainly focus on the \(Z_2\) invariant to characterize the system with \(P = \pm \tau_z\).

The 3D Dirac SM phases can also be distinguished in two different ways. At first, when the Dirac SM phase has a non-zero topological invariant in either the \(k_z = 0\) plane or the \(k_z = \pi\) plane, we can call it a topological Dirac SM as the Dirac SM carries stable 2D Dirac cones on the surface. Similarly, a topologically trivial Dirac SM can be defined when the system does not have any topological invariant in both planes. However, in both cases, independent of the presence of the 2D topological invariants, the 3D Dirac SM phase is stable because the symmetry of the system and occupies a finite region in the phase diagram.

Figure 3 shows the evolution of the Fermi surface of the topological Dirac SM system with a slab geometry whose surface normal is parallel to the [100] direction. The translational symmetry of the system in the yz plane is maintained. Here we first pick the states touching the Fermi level \((E_F)\) and then plot the wave function amplitudes of the corresponding state localized on the first five layers from the top surface. The red colour indicates the states localized on the [100] surface, whereas the bright blue colour corresponds to the 3D bulk Dirac states. In the case of the topological Dirac SM with \(\nu_2 = 1\) in the \(k_z = 0\) plane, a 2D Dirac surface cone appears on the \(k_z = 0\) plane at the Fermi energy \((E_F)\) near the bulk DP \((E_F = 0)\) at the DP, the bulk and surface states are decoupled, and the surface states form an isolated closed loop. As \(E_F\) increases, the Fermi surface topography evolves continuously, and when the bulk and surface states start to overlap, the 2D surface state is deformed to the Fermi arc structure. Namely, the Fermi arcs of 3D Dirac SM emerge simply because of the deformation of the 2D Dirac cone, which exists due to the fact that \(\nu_2 = 1\) in the \(k_z = 0\) plane. As such an evolution of the surface spectrum occurs
continuously, the Fermi arc states can appear even when \( E_F = 0 \) if the parameters of the model Hamiltonian are tuned properly.

The energy spectrum of the topological Dirac SM with \( n_M = 2 \) on the \( k_z = 0 \) plane also shows a similar variation as described in Fig. 3b. As \( n_M = 2 \), there are two 2D surface Dirac cones on the \( k_y \) axis. As \( E_F \) increases, the surface Dirac cones evolve to Fermi arcs when the surface and bulk states overlap. As the number of surface Dirac cones is two, the number of surface Fermi arc is also doubled as compared with the case shown in Fig. 3a. It is worth to note that in both cases shown in Fig. 3a,b, the energy dispersion near the bulk 3D DP is basically the same, that is, the bulk state shows the linear dispersion relation in all three momentum directions. This clearly shows that the number of Fermi arcs of the topological Dirac SM is irrespective of the dispersion of the bulk states.

It is worth to stress that the physical origin of the surface Fermi arcs in the 3D Dirac SM is clearly distinct from that of the Weyl SM which has twofold degeneracy at the gap-closing point. In the Weyl SM, the Chern number carried by the bulk gapless point (Weyl point) guarantees the emergence and stability of the Fermi arc states. As the Chern number of the Weyl point is purely determined by the energy dispersion around the Weyl point, the number of Fermi arcs in the system with a fixed number of Weyl points strongly depends on the energy dispersion near the Weyl point. In conventional Weyl SMs with the linear dispersion around the Weyl point, the number of Fermi arcs on one surface of the sample is equal to the number of Weyl point pairs in the first BZ. On the other hand, in the case of Weyl SMs with double (triple)-Weyl fermions whose dispersion is quadratic (cubic) along the two momentum directions but linear in the third direction, the number of Fermi arcs is double (triple) of the number of the Weyl point pairs. However, in contrast to the case of the Weyl SM, the physical origin of the surface states of the 3D Dirac SM is independent of the energy dispersion of the 3D bulk Dirac fermions. Because of the simultaneous presence of the TRS and IS, the Chern number of each 3D DP is zero. Here the number of the Fermi arcs on the surface of the sample is solely determined by the 2D topological invariant on the \( k_z = 0 \) (or \( k_z = \pi \)) plane irrespective of the energy dispersion around the 3D DP. Therefore, although the low-energy Hamiltonian near the 3D bulk DP is the same, the number of Fermi arcs can be different depending on the 2D topological invariant of the system as shown above.

**Discussion**

Up to now, we have considered the system with a uniaxial rotation symmetry together with TRS and IS. As most crystals have a larger symmetry with multiple rotation axes, it is important to understand how our theory can be applied to these systems. First of all, it is worth to note that the location of the two DPs can be anywhere on the rotation axis in the case of the Dirac SMs with \( P = \pm \tau_{0z} \) in Table 1. Therefore, the primary rotation axis should be the line connecting the two DPs in this case. Even if there are multiple pairs of DPs in the BZ, we can easily specify the primary rotation axis for each pair of DPs by using the fact that the centre of the rotation axis locates at a TRIM and the relative orientation of different rotation axes should satisfy the crystalline symmetry. Once the primary rotation axis is specified, we can apply our classification scheme to each pair of DPs. On the other hand, in the case of the Dirac SM with \( P = \pm \tau_x \) in Table 2, the role of the additional crystalline symmetry is more significant because the DP locates at a TRIM where the system generally has a higher crystalline symmetry. At this point, it is important to note that the threefold rotation symmetry prohibits a DP at a TRIM according to Table 2. In fact, this imposes a strong constraint to the allowed position of the DP, and we can rule out the \( \Gamma \) point as a possible location of the DP because the space...
groups allowing the fourfold degeneracy at the Γ point always have a threefold rotation symmetry (see Methods and also ref. 15). Therefore, a DP can locate only at a TRIM on the BZ surface. Even if the point group symmetry of the crystal contains many rotation axes, the symmetry on the BZ surface can be much lower and the system often has a uniaxial rotation symmetry at a TRIM on the BZ surface. For example, in both β-cristobalite BiO$_2$ and distorted spinels, there is a uniaxial rotation symmetry at the momentum where each DP presents. In this situation, it is straightforward to apply our theory. To sum up, although the point group symmetry of the crystal has multiple rotation axes, the local symmetry at the momentum where each DP presents is much lower, hence, our theory can be applied to crystalline solids in general.

We conclude with a discussion about the stability of the 3D Dirac SM under the influence of the Coulomb interaction and disorder. Simple power counting shows that the long-range Coulomb interaction is a marginally irrelevant perturbation to the 3D Dirac fermions with the linear dispersion $\mathcal{H} = \pm \delta$. Hence, various physical properties of the 3D Dirac SM can receive logarithmic corrections because of the long-range Coulomb interaction similar to the cases of 3D Weyl SM$^{35-37}$ and graphene$^{38-40}$. On the other hand, as the disorder is irrelevant according to the power counting, we expect the Dirac SM state can be stable at least against weak disorder effect. However, as the crystalline symmetry is important for the protection of the DP, strong disorder can induce nontrivial physical consequences to 3D Dirac SM phase, especially when the interaction and disorder effect are considered simultaneously$^{34}$. Moreover, in the case of the quadratic Dirac SM and the cubic Dirac SM, the effect of the interaction and disorder can be more significant. As the in-plane dispersion becomes either quadratic or cubic in the momentum space, which strongly enhances the low energy density of states, it is expected that the interaction and disorder can even bring about new exotic quantum phases. For instance, according to a recent theoretical study, an exotic non-Fermi liquid state can appear in a 3D SM having quadratic energy dispersion in the momentum space$^{41}$. As the interplay between the long-range Coulomb interaction and nontrivial screening because of the enhanced low energy density of states is the fundamental origin leading to the non-Fermi liquid phase, the quadratic Dirac SM and the cubic Dirac SM are also promising systems to observe novel quantum critical states.

Finally, let us note that the quantum critical point in Fig. 1c where the pair creation or pair annihilation of bulk DPs happens is another interesting venue to observe a new types of quantum critical phenomena. At the quantum critical point, as the energy dispersion along the rotation axis is always quadratic, the low-energy excitation can show highly anisotropic dispersion relations in the linear Dirac SM and cubic Dirac SM. According to the recent theoretical study$^{42,43}$, it is shown that such an anisotropic dispersion can induce a novel screening phenomenon, which can induce anomalous distribution of the screening charge around a charged impurity. To reveal the fascinating physical properties of the linear Dirac SM and the triple Dirac SM at the critical point would be another interesting topic for future studies.

**Figure 3 | Evolution of the Fermi surface of a [100] film varying the Fermi energy.** The wave function amplitudes confined within the first five layers from the top surface are plotted for the states touching the Fermi level ($E_F$). To obtain the Fermi surface we have solved numerically the lattice Hamiltonian in equations (16) and (19). (a) For a topological Dirac semimetal with $C_4$ symmetry, which has $\gamma_{2D} = 1$ on the $k_z = 0$ plane. The closed loop at the centre of the surface BZ is from a 2D surface Dirac point at the Γ point. Two 3D bulk Dirac cones also produce finite intensity symmetrically on the $k_z$ axis. As $E_F$ increase, the closed loop due to the 2D Dirac point deforms to a pair of Fermi arcs connected to the bulk states. (b) For a topological Dirac semimetal with $C_4$ symmetry, which has $n_{\text{sym}} = 2$ on the $k_z = 0$ plane. The two closed loops on the $k_z$ axis are due to two 2D Dirac points localized on the surface. As $E_F$ increases, the closed loops due to 2D Dirac cones turn into four Fermi arcs. In both a and b, the 3D bulk Dirac fermions show the linear dispersion in the momentum space. Hence, the number of surface Fermi arcs is solely determined by the 2D topological invariant on the $k_z = 0$ plane independent of the dispersion of the bulk Dirac fermions.
Methods

The classification procedure. The classification of the minimal 4 × 4 matrix Hamiltonian \(H(k)\) can be performed as follows. At first, let us impose the TRS on \(H(k)\). The TRS can be represented by the operator \(\Theta = \Theta(k)\), where \(\Theta(k)\) is a Pauli matrix. All matrices for spin degrees of freedom and \(k\) stands for complex conjugation. The invariance of the Hamiltonian under TRS, that is, \(H(-k) = \Theta(k)H(k)\Theta(-k)\), gives rise to the relations \(h_n(k) = \Theta(k)h_n(-k)\) and \(h_i(k) = \Theta(k)h_i(-k)\), where the superscript \(T\) indicates the transposition. Then, the resulting Hamiltonian with the TRS can be written in the following way.

\[
H(k) = \begin{pmatrix}
 h_1(k) & h_2(k) \\
 -h_2^T(-k) & h_1^T(-k)
\end{pmatrix},
\]

where the superscript \(\ast\) indicates the complex conjugate. Second, to impose the IS on the Hamiltonian \(H(k)\), we have to determine the matrix representation \(P\) of the IS. As the IS is independent of the spin rotation, in general, \(P = \Theta(k)P\Theta(-k)\). To determine \(\Theta(k)P\), the following three relations can be used: (i) \(\Theta(k)P = \Theta(k)\), (ii) \(PP = 1\) and (iii) \((\Theta(k)P)^2 = 1\). Then, the general solution for \(P\) is given by \(P = \pm e^{i\theta}\) or \(P = e^{i\theta}P^{-1}\) with \(\theta \in [0, 2\pi]\). The invariance of the Hamiltonian under \(P\), that is, \(H(-k) = \Theta(k)H(k)\Theta(-k)\), combined with the TRS constraints gives the set of the Hamiltonian, which can be summarized as the following way.

(i) When \(P = \pm e^{i\theta}\), \(H(k) = a_0(k) + \sum_{\gamma = 1}^5 a_{\gamma}(k)\Gamma_\gamma\), where \(\Gamma_\gamma = \gamma\Gamma_0\), \(\Gamma_1 = \tau_y\), and \(\Gamma_2 = \tau_x\). All \(a_\gamma(k)\) are real and even under the sign of the k. 
(ii) When \(P = e^{i\theta}P^{-1}\), \(H(k) = a_0(k) + \sum_{\gamma = 1}^5 a_{\gamma}(k)\Gamma_\gamma\), where \(\Gamma_\gamma = \gamma\Gamma_0\), \(\Gamma_1 = \tau_y\), and \(\Gamma_2 = \tau_x\). All \(a_\gamma(k)\) are real functions.

Hence, \(a_1 = a_3/2, a_0 = a_4/2, a_2 = a_5/2, a_4 = a_5/2\), and \(a_5 = a_4/2\). Here \(a_0\) and \(a_5\) are real and \(a_1, a_2, a_3, a_4\) are real functions.

In both cases, an ABC is possible only if the first five equations are satisfied simultaneously. Here each function \(a_i\) has four variables including the three momentum components \(k_x, k_y, k_z\), and one external control parameter \(m\), that is, \(a_i = a_i(k_x, k_y, k_z, m)\). As the number of equations to be satisfied is five, whereas the number of variables is four, the condition for the ABC cannot be satisfied in general at a generic momentum \(k\). However, it is worth to note that the above consideration does not rule out the ABC at non-generic points in the momentum space with high symmetry. For instance, as pointed out by Murakami\(^1\), the time-reversal invariant momentum \(k = (0, 0, \pi)\). Hence, \(h_{\pm}(k_x, k_y, k_z)\) and \(h_{\pm}(k_x, k_y, k_z)\) are equivalent, all odd functions in \(k\) vanish. In the case of (ii) with \(P = e^{i\theta}P^{-1}\), \(a_{1,2,3,4}(k_x, k_y, k_z, m) = 0\). Therefore, an ABC is possible if and only if one condition \(a_{1,2,3,4}(k_x, k_y, k_z, m) = 0\) is satisfied, which can be achieved by tuning one external control parameter \(m\). This is the reason why the topological phase transition between two insulators on the same ABC at a time-reversal invariant momentum.

Now let us show how the condition for ABC is modified by the presence of the additional rotation symmetry \(C_\alpha\) with respect to the z axis. Here \(\alpha\) is restricted to be \(n = 2, 3, 4, 6, 7\) in periodic lattice systems. Using a basis in which both \(h_i(k)_{k_x, k_y, k_z} = 0\) and \(C_\alpha\) diagonal, \(C_\alpha\) can be represented by a diagonal matrix

\[
C_\alpha = \text{diag}(u_{\alpha,1}, u_{\alpha,2}, u_{\alpha,3}, u_{\alpha,4}) = \text{diag}(\{x, y, a, b, c, d\}^{-1})
\]

with \(p = 0, 1, \ldots, n - 1\) (ref. 21). For convenience, we express \(C_\alpha\) in the following way:

\[
C_\alpha = \begin{pmatrix}
 e^{\frac{\pi i}{n}} & 0 \\
 0 & e^{\frac{-\pi i}{n}}
\end{pmatrix}
\]

The invariance of the Hamiltonian under \(C_\alpha\) leads to

\[
C_\alpha H(k_x, k_y, k_z) C_\alpha^{-1} = H(k_x, e^{2\pi i/n}k_y, e^{-2\pi i/n}k_z),
\]

where \(k_x = k_x \pm \Delta k\). From equation (1), we can obtain

\[
e^{\frac{2\pi i}{n} [\gamma (q + s + 1)]} = 1 = \text{diag} (x_2, x_3, x_4, x_5).
\]

The above equations can be further simplified by considering the condition \(C_\alpha\) because of the TRS. Namely, as \(\{x, y, a, b, c, d\} = 0\), we can show that \(e^{i\pi \frac{(p + r + 1)}{n}} = 1\), \(e^{i\pi \frac{(q + s + 1)}{n}} = 1\), and \(e^{i\pi \frac{(q + s + 1)}{n}} = 1\). Then equation (2) becomes

\[
e^{i\pi \frac{\gamma (q + s + 1)}{n}} e^{i\pi \frac{\gamma (q + s + 1)}{n}} = 1 = e^{i\pi \frac{\gamma (q + s + 1)}{n}} = 1.
\]

In general, \(h_1(k)\) and \(h_2(k)\) can be represented by

\[
h_1(k) = h_1(k_x, k_y, k_z) + f_1(k_x, k_y, k_z) \tau_+ + f_2(k_x, k_y, k_z) \tau_-
\]

\[
h_2(k) = g_0(k_x, k_y, k_z) \tau_+ + g_1(k_x, k_y, k_z) \tau_+ + g_2(k_x, k_y, k_z) \tau_-
\]

where \(f_\alpha, g_\alpha\) are real functions, whereas \(f_\alpha, g_\alpha\) are complex functions. Also \(\tau_\alpha = \tau_+ \pm \tau_\tau\). As \(f_\alpha, g_\alpha\) does not affect the gap-closing, we can neglect it in the forthcoming discussion. Equation (3) gives the following relations:

\[
e^{i\pi \frac{\gamma (q + s + 1)}{n}} e^{i\pi \frac{\gamma (q + s + 1)}{n}} = 1 = e^{i\pi \frac{\gamma (q + s + 1)}{n}} = 1.
\]

The physical meaning of these two conditions is as follows. First of all, as the IS flips the orbits in this case \((P = \pm 1)\), \(C_\alpha H(k_x, k_y, k_z) C_\alpha^{-1}\). Then, the combined flips of the TRS and IS ensures \(E_x(k_x, k_y, k_z) = E_x(k_x, k_y, k_z)\) for \(k_x = (0, 0, \pi)\). Note that the angular momentum is a good quantum number in this case, because the angular momentum is a good quantum number on the \(k_x\) axis. Then, the crossing between two degenerate bands requires \(u_{\alpha,1} = u_{\alpha,2}\) or \(u_{\alpha,3} = u_{\alpha,4}\). Moreover, as \((C_\alpha P)^2 = (C_\alpha P)^2\) on the \(k_x\) axis, \(C_\alpha P = \pm C_\alpha P\). However, as the equation (12) is violated if \(u_{\alpha,1} = u_{\alpha,2}\), we obtain \(u_{\alpha,1} = u_{\alpha,2}\), which immediately leads to the equation (12). In fact, the condition \(\alpha = \gamma\) means

\[
e^{i\pi \frac{\gamma (q + s + 1)}{n}} = 1 = e^{i\pi \frac{\gamma (q + s + 1)}{n}} = 1
\]

with integers \(p\) and \(q\). But this relation cannot be satisfied if \(n = 3\). Therefore, the 3D Dirac SM with a single DP cannot exist in systems with \(C_\alpha\) invariance.
Absence of the symmetry-protected Dirac point at the Γ point. Let us explain why the symmetry-protected DP cannot exist at the Γ point in the first BZ. Here we only consider the fourfold degenerate DP, which splits into two doubly degenerate states away from the band crossing point. At the Γ point, the representation of the space group is equivalent to the representation of the point group, which is true for both the non-symmetric and symmorphic space groups. As the symmetry-protected DP can appear when the space group symmetry at a given momentum allows a four-dimensional irreducible representation, what we have to do is to check the presence of the four-dimensional irreducible representation in the double-valued representation of the relevant point group. It is straightforward to confirm that among the 32-point groups, only the cubic groups Td, O, Oh support a four-dimensional irreducible representation in their double-valued representation. All, however, these cubic groups contain threfold rotation axes. According to Table 2, an isolated symmetry-protected DP locating at a TRIM is forbidden if the system has a threefold rotation symmetry. Therefore, we conclude that the symmetry-protected DP cannot present at the Γ point in 3D periodic electronic systems. A similar conclusion is also obtained in ref. 15.

The emergence of the mirror symmetry in the Hamiltonian. Let us briefly describe how the mirror symmetry manifests in the effective Hamiltonian $H(k) = \sum f_i a_i^\dagger(k) \Gamma f_i$. As shown in Table 1, in systems with the C4 or Cs symmetry, either $|f\rangle$ or $|g\rangle$ becomes zero in the $k_x = 0$ plane. Although only the lowest order terms are shown in Table 1, we can show that the same result holds in all orders. This means that the effective Hamiltonian can be written as $H(k) = \sum f_i a_i^\dagger(k) \Gamma f_i$ in the $k_x = 0$ plane. Here $\Gamma_f$ are three mutually anti-commuting Gamma matrices. As only three Gamma matrices appear in the Hamiltonian, we can define a conserved quantity $\Gamma^T \Gamma_f$ satisfying $\{H(k), \Gamma^T \Gamma_f\} = 0$. It is straightforward to show that $\Gamma^T \Gamma_f$ is equivalent to the mirror operator $M$ in all cases, hence, the system has the mirror symmetry in the $k_x = 0$ plane.

The lattice Hamiltonians. We can construct the lattice Hamiltonians straightforwardly by using the information in Tables 1 and 2. For instance, for the C4 invariant system with $P = \pm \tau$, that is, 6th row of Table 1, we can use
\[
\begin{align*}
\eta &= \sin k_x + \sin k_y, \\
g &= \sin k_z \{(\beta + \gamma) \cos k_x - \cos k_z\} + i(\beta - \gamma) \sin k_x \sin k_y,
\end{align*}
\]
where $\beta, \gamma, M, \tau_x, \tau_y$ are real constants. More explicitly,
\[
H = \sum_k \left[ \eta \sin k_x |1\rangle \langle 1| + \sin k_y |2\rangle \langle 2| + \sin k_z |3\rangle \langle 3| \right] + \sum_k \left[ (\beta + \gamma) \cos k_x |2\rangle \langle 3| + (\beta - \gamma) \sin k_x |3\rangle \langle 2| \right] + \sum_k \left[ -M - \tau_y (\cos k_x + \cos k_z) - \tau_x \cos k_z \right] |4\rangle \langle 4|
\]
where $|1\rangle$ and $|4\rangle$ are the two nearest-neighbour hopping amplitudes in the $xy$ plane and $(\beta + \gamma)$ denotes the next nearest neighbour hopping amplitudes in the $yz$ and $zx$ planes. $M$, $\tau_x$, $\tau_y$ have the same meaning as above. In both cases, we have chosen $\eta = 1$, $\beta = 2$, $\gamma = 1$, $\tau_x = 1$ while varying $M$ and $\tau_y$ for the numerical computation.

More explicitly,
\[
H = \sum_k \left[ \sin k_x \sin k_z |1\rangle \langle 1| + \sin k_y \sin k_z |2\rangle \langle 2| + \sin k_x |3\rangle \langle 3| \right] + \sum_k \left[ (\beta + \gamma) \cos k_x |2\rangle \langle 3| + (\beta - \gamma) \sin k_x |3\rangle \langle 2| \right] + \sum_k \left[ -M - \tau_y (\cos k_x + \cos k_z) - \tau_x \cos k_z \right] |4\rangle \langle 4|
\]
In real space, the Hamiltonian becomes
\[
H = \sum_k \left[ \eta \sin k_x |1\rangle \langle 1| + \sin k_y |2\rangle \langle 2| + \sin k_z |3\rangle \langle 3| \right] + \sum_k \left[ (\beta + \gamma) \cos k_x |2\rangle \langle 3| + (\beta - \gamma) \sin k_x |3\rangle \langle 2| \right] + \sum_k \left[ -M - \tau_y (\cos k_x + \cos k_z) - \tau_x \cos k_z \right] |4\rangle \langle 4|
\]
where $(\beta + \gamma)$ indicates the nearest neighbour hopping amplitudes in the $xy$ plane, $\{H(k), \Gamma^T \Gamma_f\}$ denotes the next nearest neighbour hopping amplitudes in the $yz$ and $zx$ planes, and $(\beta - \gamma)$ indicates the hopping process along the body-diagonal direction of the cubic lattice. $M$ indicates the on-site potential difference between the A and B orbitals, and $\tau_y$ describes the hopping amplitude difference in different orbitals along the $x$, $y$ directions (in the $z$ direction).

Similarly, for the C4 invariant system with $P = \pm \tau$, that is, the 7th row of Table 1, we use
\[
\begin{align*}
\eta &= \sin k_x + i \sin k_y, \\
g &= \{(\beta + \gamma) \cos k_x - \cos k_z\} + i(\beta - \gamma) \sin k_x \sin k_y,
\end{align*}
\]
where $\eta$ indicates the unit lattice vectors along $x, y, z$ directions. $\eta$ indicates the nearest neighbour hopping amplitudes in the $xy$ plane, $(\beta + \gamma)$ denotes the next nearest neighbour hopping amplitudes in the $yz$ and $zx$ planes, and $(\beta - \gamma)$ indicates the hopping process along the body-diagonal direction of the cubic lattice. $M$ indicates the on-site potential difference between the A and B orbitals, and $\tau_y$ describes the hopping amplitude difference in different orbitals along the $x, y$ directions (in the $z$ direction) respectively.
