Amyloid-\( \beta_{1-42} \) oligomer accelerates senescence in adult hippocampal neural stem/progenitor cells via formylpeptide receptor 2

N He\(^1,2\), W-L Jin\(^3,4\), K-H Lok\(^1\), Y Wang\(^2\), M Yin\(^*1\) and Z-J Wang\(^*1\)

The failure of adult hippocampal neurogenesis is increasingly considered as an important factor in the pathological correlates for memory decline in Alzheimer’s disease (AD). Loss of adult-born neurons and abnormalities of neural stem/progenitor cells (NSPCs) within the dentate gyrus (DG) of adult hippocampus might contribute to this process. In this study, we showed that amyloid-\( \beta_{1-42} \) (A\( \beta_{42} \)) oligomer triggers senescent phenotype of NSPCs in vitro. Oligomerized A\( \beta_{42} \) induced the production of senescence-associated biomarkers p16 and senescence-associated \( \beta \)-galactosidase (SA-\( \beta \)-gal) in adult mouse hippocampal NSPCs, as well as inhibited cells proliferation and differentiation. In the DG of amyloid precursor protein/presenilin1 (APP/PS1) transgenic mice, the number of senescent NSPCs was significantly increased and senescence-associated protein p16 was upregulated. Formylpeptide receptor 2 (FPR2), one of A\( \beta_{42} \) functional receptors, may be involved in NSPCs senescence. The FPR2 antagonist WRW4 significantly inhibited NSPCs senescence induced by A\( \beta_{42} \). In addition, the activation of p38 mitogen-activated protein kinase (MAPK) in response to the accumulation of reactive oxygen species (ROS) was involved in NSPCs senescence induced by A\( \beta_{42} \). WRW4 inhibited the accumulation of ROS and the activation of p38 MAPK in NSPCs. Our data suggest that A\( \beta_{42} \) accelerates NSPCs senescence via FPR2-dependent activation of its downstream ROS-p38 MAPK signaling, which limits the function of NSPCs and contributes to failure of neurogenesis. This is the first demonstration of NSPCs senescence response to A\( \beta_{42} \).

Subject Category: Neuroscience

In the mammalian brain, neurogenesis persists throughout adulthood in the subgranular zone (SGZ) of the dentate gyrus (DG) of the hippocampus and in the subventricular zone (SVZ) of the lateral ventricles.\(^1\) In the SGZ, adult neurogenesis involves activation of quiescent neural stem/progenitor cells (NSPCs) to yield proliferative progenitors, migration of neuroblasts and ultimately differentiation into granule cells that synaptically integrate into the existing neural network. Each of these stages is regulated by microenvironmental cues. Both the number of NSPCs and neurogenesis decline within SGZ has been involved in cognitive impairments linked with ageing and neurodegenerative diseases, and it was suggested to have an important role in Alzheimer’s disease (AD).\(^2\)

AD is an age-related, progressive and irreversible neurodegenerative disease. The disease is characterized by extracellular deposition of \( \beta \)-amyloid (A\( \beta \)) peptides and intracellular hyperphosphorylation of tau protein, which result in progressive loss of memory and other cognitive functions.\(^3\) Over the past decade, researchers and clinicians have not made substantial progress in treating AD, due to the complexity of the disease.\(^4\) Recently, strategy for stem cell therapy has received considerable attention as an alternative treatment for neurodegenerative diseases. Accumulating studies showed that transplantation of NSPCs can reduce neuronal loss, improve cognition and memory in animal models of AD.\(^5-7\) However, up to now, stem cell therapy obtained limited benefits in AD, because hostile microenvironments of AD brain may impair the function of NSPCs, as it contains A\( \beta \).

Considerable evidence, obtained from studies of patient, cell culture and animals models, suggests that A\( \beta \) is the key trigger of AD pathogenesis, and oligomeric amyloid-\( \beta_{1-42} \) (A\( \beta_{42} \)) is thought to be the most toxic form of A\( \beta \).\(^8\) Early works showed that A\( \beta \) impairs proliferation and neuronal differentiation of NSPCs.\(^8,9\) Overproduction and consequent aggregation of A\( \beta \) in amyloid precursor protein/presenilin1 (APP/PS1) transgenic mice severely reduced the number of adult-generated hippocampal neurons.\(^10\) Some studies also showed that A\( \beta \) was directly associated with the reduction in...
hippocampal neurogenesis in AD animal models. Hippocampal neurogenesis decline in neurogenic capacity has been suggested to underlie cognitive impairments that accompany senescence. However, little is currently known about how Aβ affects hippocampal neurogenesis. Recently, Aβ has been described to be involved in senescent responses of neurons and astrocytes. In addition, Aβ peptides caused endothelial cells and retinal pigment epithelial cells to enter senescence. However, these responses have yet to be determined in NSPCs.

In this study, we showed that Aβ oligomer can promote the senescence of cultured adult mouse hippocampal NSPCs. Compared with wild-type mice, more senescent NSPCs were observed in the DG of APP/PS1 transgenic mice. Furthermore, we provided evidence suggesting that Aβ induces NSPCs senescence via the activation of formylpeptide receptor 2 (FPR2) and its downstream reactive oxygen species p38 mitogen-activated protein kinase (ROS-p38 MAPK) signaling pathways. These results therefore represent, to the best of our knowledge, the first study of the relationship between Aβ and NSPCs senescence. This finding may provide us new insights into the potential therapy of stem cell for neurodegeneration including AD.

**Results**

Aβ inhibits NSPCs proliferation and high-dose also induces apoptosis. To begin our study of the effects of Aβ on the adult hippocampal neurogenesis, we first isolated NSPCs from the hippocampus of adult mouse brain. NSPCs form clonal spheres called neurospheres, which are composed of NSPCs and more committed neural progenitors. Immunostaining experiments revealed that NSPCs markers Nestin and Sox2 were expressed on our cultured neurospheres or dissociated NSPCs (data not shown).

We then tested the effect of Aβ on cell viability. Cells were treated with Aβ (2.5, 5 or 10 μM) for 1, 3 and 5 days. Then, cell viability was determined by CCK-8 assay. We found that at 3 days, the significant inhibitory effect of Aβ was detectable only at 10 μM. However, at 5 days, Aβ significantly inhibited the viability of NSPCs in concentration-dependent manners (Figure 1a), which led us to choose 5 days of incubation to detect the following experiments. These data indicate that Aβ decreases NSPCs viability in dose-dependent and time-dependent manners.

To investigate the effect of Aβ on the biology of NSPCs, we used the neurospheres proliferation assay to detect the number and diameter of neurospheres. The number of newly formed neurospheres and the size of newly formed neurospheres were reduced significantly in Aβ-treated NSPCs. Further, the decrease of neurosphere diameter was also found in Aβ-treated cells. However, there was no significant difference among these treatment conditions (Figure 1c).

To identify whether the proliferation-inhibitory effect of Aβ was due to NSPCs apoptosis, we further examined the effect of Aβ on apoptosis. The data showed that incubation with low-dose Aβ (2.5 or 5 μM) did not alter the percentage of apoptotic cell (Figure 1e). However, high-dose Aβ (10 μM) increased the percentage of apoptotic cell by 1.3-fold in

**Figure 1** Aβ inhibits NSPCs proliferation and high-dose induces NSPCs apoptosis. (a) Cell viability assay (CCK-8) showed that Aβ suppressed NSPCs viability in dose- and time-dependent manners. The number of newly formed neurospheres (b) and the size of newly formed neurospheres (c) were reduced significantly in Aβ-treated NSPCs. (d) NSPCs were treated with the indicated concentrations of Aβ for 5 days, apoptotic cells were analyzed with Annexin V-FITC kit by flow cytometry. The effects of Aβ (0 or 10 μM) on the NSPCs apoptosis are shown. (e) The percentage of apoptotic cells was calculated by Annexin V+/PI− and Annexin V+/PI+ together. The mean ± S.D. of three independent experiments is shown. *P<0.05, **P<0.01 compared with control.
comparison with control (Figures 1d and e). Taken together, these data indicate that low-dose Aβ42 inhibits NSPCs proliferation and resists to apoptosis, whereas, in addition to inhibition proliferation, high-dose Aβ42 also induces NSPCs apoptosis.

**Aβ42 treatment results in morphological and differentiated changes in NSPCs.** Morphologically, in suspension culture conditions, NSPCs appeared as cell clusters with a smooth and well-defined border. However, NSPCs treated with 10 μM Aβ42 displayed smaller in size and less in number than control, and usually had an uneven border (Figure 2a). In monolayer cultivation conditions, untreated cells grew in clusters with tight cell-cell contacts. In contrast, Aβ42-treated cells exhibited obvious reduction in total cell number, which was accompanied by a unique flattened and enlarged morphology, and tended to grow disjointed (Figure 2b). These morphological changes in Aβ42-induced NSPCs confirm to cellular senescence phenotype.

Multipotency is an important characteristic of NSPCs, which can differentiate into the neuron, astrocyte or oligodendrocyte. As shown in Figure 2c, in normal conditions, NSPCs rapidly spread out from the center to the periphery in the differentiation media and were mainly consisted of both β-III-tubulin-positive and GFAP-positive cells. In Aβ42-treated conditions, NSPCs began to differentiate much later (data not shown), displayed sphere morphology with little process extension and reduced expressions of neural phenotype β-III-tubulin and GFAP. To rule out the possibility that smaller neurosphere has lower differentiation capacity than bigger one, untreated and Aβ42-treated NSPCs were dissociated to single cells and then grown onto glass coverslips coated with poly-D-lysine hydrobromide (PDL) at the same cell density in differentiation media. After 5 days of differentiation, we stained the cells for lineage markers. Quantitative analysis showed that there were decrease of β-III-tubulin-positive cells (1.2-fold) and GFAP-positive cells (3.1-fold) (Figure 2d). These results suggest that Aβ42 suppresses NSPCs differentiation capacity, which leads to neurogenesis impairment.

**Aβ42 induces NSPCs senescence in vitro.** One possible explanation to Aβ42 suppresses neurogenesis could be that Aβ42 induces NSPCs senescence. To test this hypothesis, we assessed the number of senescence-associated β-galactosidase (SA-β-gal)-positive cells, because of SA-β-gal staining as a marker of cellular senescence.20 Our results showed that the number of SA-β-gal-positive cells was significantly increased by Aβ42 (5 or 10 μM) compared with that in the control (Figures 3c and d). These data suggest that Aβ42 results in NSPCs senescence.

To further confirm that Aβ42 induces NSPCs senescence, we also monitored the expressions of prosenescence molecules p16 and pRb. The p16-Rb axis maintains the growth arrest, which is known to induce cellular senescence.21 An inverse relationship was observed between p16 and pRb in that as p16 expression increased, pRb levels decreased correspondingly in Aβ42-treated NSPCs compared with the control (Figures 3c and d). These effects exhibit a concentration-dependent manner; therefore, these results further indicate that Aβ42 accelerates NSPCs senescence.

The number of senescent NSPCs has a significant increase in APP/PS1 transgenic mice. Having established that Aβ can induce NSPCs senescence in vitro, we examined the brain tissue from a transgenic mouse model of AD. Transgenic mouse that carries an APP andPS1 mutated gene shows AD-like pathology and memory impairment, and is useful for studying AD and testing possible treatments.22–24 It had been reported that Aβ is deposited in the DG of the hippocampus of APP/PS1 transgenic mice at 9 months and impaired adult hippocampus neurogenesis.11 Therefore, 9-month-old APP/PS1 transgenic mice and age-matched wild-type control allowed us to test whether
Aβ was associated with NSPCs senescence in vivo. As confirmed by Aβ immunohistochemistry, only APP/PS1 mice harbored Aβ deposits in the cerebral cortex and hippocampus, including the DG, whereas no such was found in the wild-type mice (Figure 4a). Interestingly, we also found that compared with wild-type control, the number of SA-β-gal-positive cells was increased in the DG of APP/PS1 mice (1.7-fold) (Figure 4b). Furthermore, brain sections were screened for p16-positive NSPCs using double immunofluorescence for cellular senescent biomarker p16 and NSPCs marker Nestin (Figure 4c). APP/PS1 transgenic mice exhibited a 1.3-fold increase in the number of p16-positive NSPCs within the DG compared with wild-type counterparts (Figure 4d). These results indicate that the number of senescent NSPCs is increased in APP/PS1 transgenic mice.

FPR2 involves in Aβ42-induced NSPCs senescence. Recent evidence suggested that FPR2, a G protein-coupled receptor (GPCR), mediates a range of inflammatory responses to Aβ in AD.25 To gain insight into the molecular mechanisms by which Aβ42 induced NSPCs senescence, we investigated whether FPR2 is involved in this process. First, brain sections of 9-month-old APP/PS1 transgenic mice and age-corresponding wild-type mice were stained with FPR2 antibody. We found that FPR2 is expressed in the DG of the hippocampus with higher (3.4-fold) expression in transgenic mice (Figure 5a). DG niches contain NSPCs, committed progenitor and differentiated progeny. To confirm that FPR2 is expressed in the DG of the hippocampus, we performed FPR2 immunohistochemistry in transgenic mice (Figure 5b). FPR2 is expressed in the DG of the hippocampus, whereas no such was found in the wild-type mice (Figure 5c).

To determine the role of FPR2 on Aβ42-induced NSPCs senescence, NSPCs were pretreated with 10 μM WRW4 (a selective and potent antagonist of FPR2) for 1 h before exposure to 10 μM Aβ42, and then senescence-associated indexes were detected 5 days later. We found that WRW4 significantly decreased the percentage of SA-β-gal-positive cells in NSPCs during Aβ42 incubation (Figure 5d). This was paralleled by an increase of pRb (2.1-fold) and a decrease of p16 (1.5-fold) (Figure 5e). Thus, FPR2 antagonist WRW4 ameliorates Aβ42-induced NSPCs senescent phenotype. Together, these results suggest that FPR2 involves in Aβ42-induced NSPCs senescence.

Elevated intracellular ROS levels and activated p38 MAPK are associated with Aβ42-induced NSPCs senescence. The ROS-p38 MAPK pathway has been shown to induce cellular senescence.26 Furthermore, Aβ increases intracellular ROS production by acting at FPR2 in the brain.27 This led us to hypothesize that the ROS-p38 MAPK pathway might contribute to the Aβ42-mediated induction of NSPCs senescence. To test the hypothesis, NSPCs were pretreated with 10 μM WRW4, 1 mM antioxidant N-acetylcysteine (NAC) or 10 μM p38 MAPK inhibitor SB203580 for 1 h before exposure to 10 μM Aβ42. During the 5-day experimental period, Aβ42 obviously increased intracellular ROS production, which was significantly inhibited by WRW4 or NAC (Figure 6a). Western blot showed that WRW4 or NAC also obviously suppress...
phosphorylation of p38 MAPK induced by Aβ42 (Figure 6b). Moreover, NAC or SB203580 significantly decreased the number of SA-b-gal-positive cells during Aβ42 insult (Figure 6c). And NAC reduced the number of senescent cells to the control level. This was also confirmed by the detection expressions of p16 and pRb proteins (Figure 6d). These findings strongly support that Aβ42 promotes NSPCs senescence through activation of FPR2 and its downstream ROS-p38 MAPK signaling pathway.

Discussion

In this study, we have demonstrated for the first time that Aβ42 induces NSPCs senescence in vitro, and the number of senescent NSPCs is increased in the DG of APP/PS1 double transgenic mice. Furthermore, results from our mechanistic studies suggest that Aβ42 induction of NSPCs senescence is mediated via the activation of FPR2 and its downstream ROS-p38 MAPK signaling pathway as summarized in Figure 7.
Several lines of evidence demonstrated that Aβ42 triggers senescent phenotype of NSPCs in vitro. Aβ42 significantly inhibited proliferation and differentiation capacities of NSPCs. Furthermore, Aβ42 (2.5 or 5 μM) also exhibited resistance to apoptosis. In contrast, Aβ42 (10 μM) significantly induced NSPCs apoptosis. Morphologically, Aβ42-treated neurospheres are smaller in size and less in number than untreated cells. Under the condition of monolayer cultivation, Aβ42-treated cells displayed a unique flattened and enlarged morphology. These features of Aβ42-treated NSPCs displayed typical cellular senescence phenotype. This notion is further supported by the observation that Aβ42 dose-dependently increased the number of SA-β-gal-positive cells and upregulated p16 and decreased pRb phosphorylation. p16 is cyclin-dependent kinase inhibitor, which can maintain downstream Rb protein in a hypophosphorylated and active state. The p16-Rb axis maintains the growth arrest, which is known to induce cellular senescence. Our results support the view that expression of p16 increases in NSPCs of the aged mouse brain, which limits NSPCs proliferation and...
inhibits neurogenesis. All of these results indicate that Aβ42 directly alters the phenotypical features of NSPCs and accelerates NSPCs senescence. Interestingly, it has been reported that at the same concentration, Aβ42 oligomers lead to astrocyte senescence in vitro. Astrocytes, as a crucial component of the neurogenic niche, has an important role for adult hippocampal neurogenesis, and support neuronal homeostasis in NSPCs niche. Therefore, senescent astrocytes may also indirectly induce NSPCs senescence, for example, through secreted interleukin-6 (IL-6).

However, our results in vitro studies differ from some others showing that Aβ42 has neurogenic effect on NSPCs. The major difference is that we used NSPCs isolated from the hippocampus of adult mice, used much higher concentrations of Aβ42 and much shorter incubation time. Taken together, these results suggest that neurogenic effect of much lower concentrations of Aβ42 may be a compensatory response as one of the endogenous brain repair mechanism. With the accumulation of Aβ42, it drives cellular senescence, ultimately results in neurogenesis dysfunction.

Evidence coming mainly from the APP/PS1 double transgenic mouse model indicates that Aβ first appears between 4 and 5 months of age and worsens with age, and it is abundant.
in the hippocampus and cortex by 9 months of age.\textsuperscript{34} Consistent with these observations, we found that compared with age-corresponding wild-type mice, A\textsubscript{\beta} pathology was specific to APP/PS1 mice at 9 months. In addition, our in vivo data also showed that the number of SA-\textsubscript{\beta}-gal-positive cells and senescent NSPCs was increased in the DG of APP/PS1 transgenic mice. The animal model studies further suggest that A\textsubscript{\beta} possibly associates with adult hippocampal NSPCs senescence.

As a functional receptor of A\textsubscript{\beta}, FPR2 has been suggested to participate in the pathogenesis of AD.\textsuperscript{25} Upon binding to FPR2, A\textsubscript{\beta} generates oxidative stress through activation of microglial cells and mediates these cells migration response to A\textsubscript{\beta}.\textsuperscript{27} FPR2 has also shown to be involved in the endocytosis process of A\textsubscript{\beta} and its cytotoxicity for neuronal cells.\textsuperscript{38} Recent findings demonstrated that FPR2 also regulates cell cycle by inducing p21 and p16 accumulation.\textsuperscript{25,36} In the present paper, we have first observed that the expression of FPR2 was also present in the DG of the hippocampus and purified NSPCs. The expression of FPR2 was significantly increased in the APP/PS1 transgenic mice and A\textsubscript{\beta}\textsubscript{25-35}-treated NSPCs. FPR2 antagonist WRW4 inhibited the increased number of SA-\textsubscript{\beta}-gal-positive cells by A\textsubscript{\beta} and downregulated the expressions of senescent-associated proteins. Therefore, FPR2 antagonist WRW4 ameliorates A\textsubscript{\beta}\textsubscript{25-35}-induced NSPCs senescent phenotype. These results suggest that FPR2 might be a potential target for the regulation of neuron genesis in the process of AD.

Our study also provided evidence suggesting that A\textsubscript{\beta}\textsubscript{25-35}-induced NSPCs senescence via FPR2 is mediated through the ROS-p38 MAPK pathway. Activation of FPR2 initiates the activation of microglial cells and produces ROS.\textsuperscript{27} ROS, one of signal molecules, can regulate a variety of cellular functions, including NSPCs proliferation, differentiation and mobilization at physiological levels.\textsuperscript{37-40} Abnormal increase of ROS production under pathological conditions can inhibit NSPCs self-renewal and adult neurogenesis.\textsuperscript{41} It has been reported that activation of the p38 MAPK pathway by elevated level of ROS results in defective function of NSPCs, which may lead to premature exhaustion of NSPCs and dysfunction of neurogenesis.\textsuperscript{42} Our data showed that A\textsubscript{\beta} increased intracellular ROS levels and p38 kinase phosphorylation, which can be significantly inhibited by WRW4. Antioxidant NAC or p38 MAPK inhibitor SB203580 significantly decreased the number of SA-\textsubscript{\beta}-gal-positive cells and downregulated p16 and upregulated pRb expressions. Therefore, these results further provide strong evidence that A\textsubscript{\beta} induces NSPCs senescence by the activation of FPR2 and its downstream ROS-p38 MAPK signaling pathway.

In conclusion, our study established for the first time a novel link between A\textsubscript{\beta} and NSPCs senescence. Besides inhibiting proliferation and differentiation capacities, A\textsubscript{\beta} induces senescent phenotype of NSPCs through activating FPR2 and its downstream ROS-p38 MAPK pathway. In addition, the number of senescent NSPCs increases in the animal model of AD. These results may be of significance for explanation of AD pathogenesis and also provide valuable information on the potential of stem cell therapy for neurodegeneration.

### Materials and Methods

**Animals.** Eight-week-old male C57BL/6 mice were purchased from Slaccas Experimental Animal Company. Nine-month-old APP/PS1 transgenic mice and age-corresponding wild-type C57BL/6 mice were purchased from The Jackson Laboratory (B6C3-Tg (APPswe, PSEN1dE9) 85DboJ; stock no. 004462). The experimental protocol used in this study was approved by the Ethics Committee for Animal Experimentation and was conducted in strict accordance with the Guidelines for Animal Experimentation of Shanghai Jiao Tong University.

**Mouse NSPCs cultures.** NSPCs were isolated from the hippocampus of 8-week-old male C57BL/6 mice and were cultured as described previously in detail.\textsuperscript{43} Briefly, hippocampal tissues were dissociated in 0.1% Papan mixture (Worthington, Lakewood, NJ, USA). For neurosphere cultures, cells were plated in serum-free neurosphere medium containing DMEM/F12, 2% B27 supplement, 20 ng/ml bFGF and 10 ng/ml EGF (Invitrogen, Carlsbad, CA, USA). For adherent monolayer cultivation, the methods have been previously described in detail.\textsuperscript{44} Cells were grown on dishes precoated with PDL and laminin (both from Sigma, St. Louis, MO, USA) containing the above mentioned medium. Cells were incubated at 37°C in an atmosphere of 5% CO\textsubscript{2}.

**Oligomeric A\textsubscript{\beta} preparation.** Oligomeric A\textsubscript{\beta} peptide was prepared as described previously.\textsuperscript{35} A\textsubscript{\beta} peptide (Invitrogen) was first dissolved to 1 mM in 100% hexafluoroisopropanol (HFIP), and then HFIP was removed under vacuum. The peptide was resuspended in dimethyl sulfoxide (DMSO) to 5 mM. F12 (without phenol red) culture medium (Invitrogen) was added to bring the peptide to a final concentration of 100 μM and incubated at 4°C for 24 h. The solution was centrifuged at 13,000 r.p.m. for 20 min, and the supernatant was stored at −20°C before use.

**Cell viability assays.** For cell viability assay, after trypsinizing neurospheres, single NSPCs were resuspended in proliferation medium. The cells were seeded into 96-well plates at a density of 10\textsuperscript{4} cells per well. The compounds under study were added when the cells were seeded. After incubation for indicated time, cell viability was determined by a commercial Cell Counting Kit (CCK-8, Dojindo, Japan). CCK-8 reagent was added to each well and incubated at 4°C for 1 h. Absorbance was measured at 450 nm in a spectrophotometer. Each experiment was performed in triplicate wells and repeated at least three times.

**Cell proliferation assays.** For neurosphere proliferation assay, single neurospheres were plated in 24-well plates at a density of 1800 cells per well. After incubation for indicated time, the numbers of newly formed neurospheres per well were counted using phase contrast microscopy, and the neurosphere sizes were estimated using a micromass measurement system from Olympus IX51 inverted microscope (Olympus, Tokyo, Japan).

**Neurosphere differentiation assays.** After the 7-day culture period described previously, neurospheres treated with A\textsubscript{\beta} (0 or 10 μM) were grown on glass coverslips coated with PDL and laminin within 24-well tissue culture plates containing growth factor-free medium and 1% fetal bovine serum (FBS). Neurospheres were differentiated for 5 days before assessment by immunocytochemistry.

**Immunocytochemistry.** Animals received an overdose of sodium pentobarbital and were transcardially perfused with saline followed by ice-cold 4% paraformaldehyde (PFA) in 0.1 M KBPS. Brains were removed, postfixed overnight and placed in 20% sucrose in 0.1 M phosphate buffer for 24 h. Coronal sections (30 μm) were cut on a freezing microtome and stored in cryoprotective solution. Free-floating sections were preincubated in 0.25% Triton X-100 in KBPS containing 5% normal goat serum for 1 h. Sections were then incubated with primary antibodies overnight at 4°C. Primary antibodies included the following: rabbit anti-A\textsubscript{\beta} (Cell Signaling Technology, Danvers, MA, USA; 1:250), mouse anti-Nestin (Cell Signaling Technology; 1:200), rabbit anti-p16 (Santa Cruz, Dallas, TX, USA; 1:200) and rabbit anti-FPR2 (Proteintech, Chicago, IL, USA; 1:50).

Cells grown on PDL/laminin-coated coverslips were fixed with 4% PFA for 30 min at room temperature (RT) and rinsed with PBS three times before being permeabilized in 1% Triton X-100 for 10 min. Nonspecific antibody binding sites were blocked by incubating with normal goat serum for 2 h at RT before labeling with primary antibodies overnight at 4°C. Primary antibodies included the following: mouse anti-\beta-III-tubulin (Cell Signaling Technology; 1:50), rabbit anti-GFAP (Epitomics, Burlingame, CA, USA; 1:100) and rabbit anti-FPR2 (Proteintech; 1:50).
After washing three times in PBS for 5 min, sections were reacted for 1 h at 37 °C in the dark with second antibodies. The second antibodies included AlexaFluor 488 goat anti-mouse IgG and DyLight 594 goat anti-rabbit IgG (1:500). Nuclei were stained with 4',6-diamidino-2-phenylindole (DAPI). After final washing, the stained slides were mounted with Olympus DP control and DP software.

**Determination of NSPCs apoptosis.** For apoptosis analysis, cells were assessed with the Annexin V-FITC kit (BD Biosciences, San Jose, CA, USA) according to the manufacturer’s instructions. The percentage of early apoptotic cells (Annexin V+/propidium iodide−) and late-stage apoptotic cells (Annexin V+/propidium iodide+) together were considered total apoptotic cells. The apoptotic index was analyzed by flow cytometry.

**Analysis of intracellular ROS.** Intracellular ROS levels were monitored by using 2',7'-dichlorofluorescein diacetate (DCFH-DA), which forms the fluorescent compound dichlorofluorescein on oxidation with ROS. After NSPCs were incubated with 10 μM DCFH-DA at 37 °C for 30 min, the fluorescence was monitored by scanning the whole well using a fluorescent plate reader at excitation and emission wavelengths of 465 and 525 nm.

**SA-β-gal labeling assays.** SA-β-gal labeling assays were used to identify senescent cells in tissues and NSPCs. In brief, frozen sections or cells were washed three times with PBS and fixed for 30 min at RT with fixative solution. After incubation with the staining solution overnight at 37 °C, slides were viewed with a compound microscope and scored for the SA-β-gal label as indicated by blue/green reactivation product over the cell soma. SA-β-gal-positive cells were quantified by counting six random fields per slides.

**Quantitative analysis of immunopositive cells densities in the DG.** Quantification of Nestin+ or β16+, FPR2+ or SA-β-gal+ cells in the DG were conducted using unbiased stereological methods, as described previously. Briefly, this analysis was quantified from a one-in-six series of peroxidase-labeled sections spaced at 240 μm spanning the full rostrocaudal extent of the hippocampus. The number of Nestin+/β16+, FPR2+ or SA-β-gal+ cells in the DG region were estimated using a computerized stereology system (Stereologer; Systems Planning and Analysis, Alexandria, VA, USA). Every 10th section was selected and generated 10–15 sections per reference system (Stereologer; Systems Planning and Analysis, Alexandria, VA, USA).

**Western blot.** Cells were lysed with RIPA lysis buffer. Insoluble material was removed by centrifugation at 13,000 r.p.m. for 20 min at 4 °C. Total proteins from cell lysates were denatured at 100 °C for 5 min and 50 μg proteins were electrophoresed on 6–12% SDS-PAGE and transferred to a PVDF membrane. The membrane was blocked with 5% nonfat milk at RT for 1 h and incubated overnight with primary antibodies at 4 °C. The membrane was washed and then incubated with secondary antibody at RT for 1 h. The primary antibodies included polyclonal-pRb (Assaybiotech, Los Angeles, CA, USA; 1:500), polyclonal-p16 (Santa Cruz; 1:500), polyclonal-pFPR2 (1:500), polyclonal-p38 (Cell Signaling Technology; 1:1000), polyclonal-p38 (Cell Signaling Technology; 1:800) and monoclonal-GAPDH (Proteintech; 1:2000). Detection was carried out using an enhanced chemiluminescence detection kit (Pierce, Rockford, IL, USA). The optical density of each band was quantified using image analysis software.

**Statistical analysis.** All data are presented as mean ± S.D. Quantitative data were analyzed by one-way analysis of variance (ANOVA), followed by the Student-Newman-Keuls test and the Dunnett’s test. Differences were considered significant when P < 0.05.
