(Dated: February 5, 2019)

We use density matrix renormalization group to study the first-order quantum phase transition induced by a magnetic field \( h \) in a frustrated ferrimagnetic chain. The magnetization \( m \) curve as a function of \( h \) presents a macroscopic jump and the energy curve as a function of \( m \) has two global minima. We characterize the two competing phases and study the phase-separated states in the coexistence region. Also, we observe that the transition is accompanied by an increase in the number of itinerant singlet pairs between sites in the unit cells of the chain. Finally, we identify the critical point at the end of the first-order transition line and a crossover line.

I. INTRODUCTION

Systems made of interacting magnetic units, ions or atoms, can exhibit interesting collective and local quantum modes as control parameters vary. The quantum transitions among these phases or states occur at zero temperature as doping, pressure or an applied magnetic field change. In a first-order transition, the first derivative of the energy as a function of the control parameter is discontinuous, giving rise to a discontinuous change (a jump) in the conjugate variable, and interesting phenomena like phase separation and hysteresis. The physics of first-order quantum phase transitions is observed in strongly correlated electronic materials and atomic gases in optical lattices. In magnetic systems with exchange anisotropy, the metamagnetic transition is typically first order but can be continuous if quantum fluctuations are sufficiently strong.

Geometrically frustrated magnetic systems have exchange coupling patterns favoring the existence of competing ground states. Quantum phase transitions can occur as the couplings change in response to pressure variations, or by changing an applied magnetic field \( h \). In a first-order phase transition with \( h \), the magnetization \( m \) as a function of \( h \) presents a macroscopic jump. In two dimensions, macroscopic magnetization jumps were observed in the frustrated magnet \( \text{SrCu}_2(\text{BO}_3)_2 \), the orthogonal-dimer antiferromagnet, which is modeled by the Shastry-Sutherland lattice, and in kagomé lattices. Recently it was evidenced that a ferrimagnetic ludwigite compound presents metamagnetic transitions with phase coexistence due to magnetic ions in a frustrated state.

In one dimension, geometrically frustrated chains are more accessible to numerical or theoretical investigations and offer plenty of interesting physics. In zero magnetic field, first-order phase transitions induced by changes in the exchange parameters were identified in models of this type. Under a magnetic field, macroscopic magnetization jumps were observed in frustrated chains, including spin tubes, ladder models, and systems with localized magnon states, as frustrated molecules.

The phenomenon of phase separation, in which the two competing states are observed in spatially separated regions, is a remarkable feature of first-order phase transitions. While magnetization jumps in the magnetization curves were observed in a variety of frustrated magnetic systems, the discussion of the phase-separated states of these quantum systems is less common.

Here we use the density matrix renormalization group (DMRG) to study the first-order transition induced by a magnetic field in a frustrated ferrimagnetic chain, particularly its phase-separated states. In Sec. II we present the Hamiltonian of the system and the details of the DMRG calculations. In Sec. III, we show the magnetization curve of the model and the magnetization jump for \( J = 0.7 \), where \( J \) is the frustration parameter. The associated energy curves for fixed values of the magnetic field, with the presence of metastable states, is also exhibited in this Section. In Sec. IV we characterize the two competing states in the transition by calculating average local magnetizations, transverse correlation functions, and local correlations. In particular, we show that the two competing states have a distinct density of itinerant singlet pairs between two sites of a unit cell. Further, we present a detailed analysis of the states inside the jump and show that the two phases coexist in spatially separated regions of the chain. Also in this Section, by changing \( J \) we determine the critical point at which the jump closes. Finally, in Sec. V we summarize our results.

II. MODEL AND METHOD

The Hamiltonian of the system is schematically presented in Fig. [I] and is given by:

\[
H = \sum_l \mathbf{A}_l \cdot (\mathbf{T}_l + \mathbf{T}_{l+1}) + J \sum_l \left[ \frac{(T_l^2 - s_l^2)}{4} \right] + \frac{1}{2} \left( \mathbf{T}_l \cdot \mathbf{T}_{l+1} + s_l^z s_{l+1} \right) - h S^z, \tag{1}
\]

where \( h \) is an applied magnetic field in the \( z \)-direction, with \( g u_B \equiv 1 \), \( l \) indexes unit cells, \( S^z \) is the \( z \)-component of the total spin, \( \mathbf{A}_l \) is a spin-1/2 operator at
the sublattice \( A \) at cell \( l \), and we use the symmetrical and the anti-symmetrical composition of the spin-1/2 at \( B \) sites in the same unit cell: \( S_i^T = B_{i,l} + B_{i,l} \) and \( s_i = B_{i,l} - B_{i,l} \), respectively. This Hamiltonian is in the class of diamond chain models\(^{50–53}\). These were used to understand the interesting low-temperature properties of the mineral Azurite\(^{54–58}\) and compounds of formula \( \text{A}_2\text{Cu}_3\text{AlO}_2(\text{SO}_4)_4 \) (with \( \text{A} = \text{K}, \text{Rb}, \text{Cs} \))\(^{59–61}\). The superexchange coupling between \( A \) and \( B \) spins is taken as the energy unit in this investigation, while \( J \) is the coupling between \( B \) spins. The \( A-B \) couplings have an \( AB_2 \) pattern\(^{62}\), favoring a ferrimagnetic ordering for \( h = 0 \), and a triplet state between \( B \) sites at the same unit cell. The \( J \) couplings, with a ladder arrangement\(^{63–65}\), introduce frustration in the system since they favor a singlet pairing between \( B \) sites at the same unit cell for \( h = 0 \).

We use DMRG to characterize the zero temperature state of chains with \( N_c \) unit cells and open boundary conditions. \( A \) sites at the two extremes. We kept from 364 to 500 states per block in the DMRG calculations, and the typical discarded weight was \( 10^{-10} \), with a maximum of \( 10^{-8} \).

![FIG. 1. Schematic representation of the Hamiltonian. The model has a sublattice with \( B_1 \) and \( B_2 \) sites in a ladder arrangement; and an \( A \) sublattice, with a spin-1/2 in each site. The coupling between \( A \) and \( B \) spins defines the unit of energy; and \( J \) is the coupling between \( B \) spins. A magnetic field \( h \) is applied in the \( z \)-direction. In the density matrix renormalization group (DMRG) calculations we use open boundary conditions, with \( A \) sites at the left and the right extremes of a chain with \( N_c \) unit cells.](image)

**III. THE FIRST-ORDER PHASE TRANSITION AND ITS ENERGY CURVES**

We present in Fig. 2(a) the magnetization per unit cell \( m(h) \) as a function of \( h \) for \( J = 0.7 \) and \( N_c = 67 \). A magnetization jump of size \( \Delta m = 0.07 \) is observed for \( h = 2.83 \); in fact, due to the finite size of the system, the \( m(h) \) curve is made of finite size steps of size \( 1/N_c = 1/67 = 0.015 \), lower than \( \Delta m \). This jump reveals the first-order transition between two competing phases, which we identify as I, before the jump, and II, after the jump, for increasing values of \( h \). In Fig. 2(b) we show that this jump is robust to the thermodynamic limit by comparing the \( h(m) \) curves for \( N_c = 33, 67 \), and 133. For \( N_c = 133 \) the jump occurs between states with \( S^z_1 = 147 \) \( (m = 1.105) \) and \( S^z_2 = 156 \) \( (m = 1.173) \) at \( h = 2.828241 \equiv h_1(J) \), the transition field for \( J = 0.7 \).

![FIG. 2. First-order transition induced by a magnetic field \( h \), \( J = 0.7 \). (a) Magnetization per unit cell \( m \) as a function of \( h \) for a chain with \( N_c = 67 \). The finite size implies a minimum magnetization step \( \Delta m_{\text{min}} = 1/N_c = 1/67 = 0.015 \). A jump of size \( \Delta m = 0.07 \) at \( B = 2.83 \) separates two competing quantum phases, I and II. (b) \( h \) as a function of \( m \) for \( N_c = 33, 67, 133 \) in the vicinity of the jump. For \( N_c = 133 \), the jump occurs between \( S^z_1 = 147 \) \( (m = 1.105) \) and \( S^z_2 = 156 \) \( (m = 1.173) \), where \( S^z \) is the \( z \) component of the total spin. (c-e) \( h \) fixed: the difference between the total energy \( E_h(m) \) for a given \( m \) and the lowest energy value \( E_h(m_{\text{min}}, \text{II}) \), with \( N_c = 133 \). A single global minimum is observed for \( h \) below \( h = 2.8275 \), phase I) or (e) above \( (h = 2.8289 \), phase II\) the jump. (d) There are two local minima for \( h \) at the jump \( (h = 2.828241) \). We kept a maximum of 364 states per block in the calculations.](image)
is determined after the use of Maxwell construction.\footnote{17,18}

IV. COMPETING STATES AND PHASE SEPARATION

In Fig. 3 (a) we illustrate the magnetic orientation of phases I and II, as suggested by the data shown in Figs. 3(b)-(g), to help in the discussion. The magnetization profile of A spins ($\langle A_l \rangle$) is homogeneous in the two phases if we discard sites near the boundaries, with $A$ spins approximately fully polarized in phase II, as shown in Fig. 3(b). The magnetization profile of the $B$ spins is presented in Fig. 3(c) through the sum

$$\langle T^z_l \rangle = \langle B^z_{1,l} \rangle + \langle B^z_{2,l} \rangle.$$  \hspace{1cm} (2)

Considering the bulk, the profiles are also homogeneous, but the average magnetization of $B$ spins decreases from phase I to phase II. Also, the order parameters of $A$ and $B$ sublattices become uncoupled after the transition.

We also calculate the transverse spin correlation functions

$$C_T(r) = \langle \langle S^z_m S^z_n + S^y_m S^y_n \rangle \rangle,$$  \hspace{1cm} (3)

with $|m-n|=r$, along the $A$ sublattice and along the $B_1$ sublattice, averaging the correlations among all pair of cells $m$ and $n$ such that $|m-n|=r$. In phase I, Fig. 3(d), $C_T(r)$ shows a behavior consistent with a uniform ferromagnetic critical power-law behavior along each sublattice; while the correlation between spins in one sublattice with spins in the other, inset of Fig. 3(d), is critical and alternating. These results show that in phase I the spin-flop transition occurs with a canting orientation between $A$ and $B$ spins, as illustrated in Fig. 3(a). In phase II, Fig. 3(e), the transverse correlation between $A$ spins is negligible, while $B_1$ spins have an alternating critical correlation, as shown in the inset of Fig. 3(c). So, in phase II, the spin-flop transition occurs by a canting orientation between $B$ spins at the same sublattice, as illustrated in Fig. 3(a).

The correlation between $B$ spins at the same cell, $\langle B_{1,l} \cdot B_{2,l} \rangle$, is shown in Fig. 3(f) and evidence that in phase I these spins are in a superposition of triplet states: $|↓↓\rangle_l$, $(|↑↑\rangle_l + |↓↓\rangle_l)/\sqrt{2}$, and $|↑↑\rangle_l$, since $\langle B_{1,l} \cdot B_{2,l} \rangle = 0.25$ for these states. In particular, the component $|↑↑\rangle_l$ is the most relevant because $\langle T^z_1 \rangle \approx 0.8$, as shown in Fig. 3(c). In phase II, $\langle B_{1,l} \cdot B_{2,l} \rangle \neq 0.25$ and $B_1$ and $B_2$ spins at the same cell are canting, one related to the other, as illustrated in Fig. 3(a). To figure out an approximate picture of the quantum state, we remember that the four quantum states of the pair are the three triplet states and the singlet state, $(|↓↓\rangle_l - |↑↑\rangle_l)/\sqrt{2}$, with $\langle B_{1,l} \cdot B_{2,l} \rangle = -0.75$. Thus we expect that the quantum state in phase II has a large number of components in which the $B$ spins at the same cell are in a singlet state.

We define the average local singlet density as

$$\eta_l \equiv 0.25 - \langle B_{1,l} \cdot B_{2,l} \rangle$$  \hspace{1cm} (4)

and present it in Fig. 3(g). In phase II, $\eta_l$ has an average value of 0.25, one singlet spin pair for every four cells, and is homogeneous throughout the chain; while in phase I, also homogeneous, $\eta_l$ has a much lower value. We illustrate the quantum state in phase II in Fig. 3(h). In fact, we attribute the oscillations in the magnetizations shown in Figs. 3(b) and (c) to the itinerancy of these singlet pairs throughout the chain, with a low singlet density in phase I and a high singlet density in phase II.
we present the local properties of the low magnetization, $S^z = 152$, $N_c = 133$ and $J = 0.7$. We present the data for $S^z = 147$ and $S^z = 156$ as a reference. The open boundaries of the chain dominate the averages in boundary layers, while transition layers exhibit a mixed phase. We present the schematic magnetic orientation in the two coexisting regions and a cartoon of the quantum state in phase II. (a) Average local spin of $S^z$ sites, $\langle S^z \rangle_\text{local}$. (b) Average singlet density $\eta_l = 0.25 - (B_{1,l} + B_{2,l})$ at cell $l$. To stabilize the state with $S^z = 152$, the calculation required 48 sweeps, keeping 500 states in the last 6. (c) Global averages as a function of magnetization, $N_c = 133$ and $J = 0.7$: $\langle T^z \rangle = \frac{1}{L} \sum_l \langle T^z_l \rangle$, $\langle A^z \rangle = \frac{1}{L} \sum_l \langle A^z_l \rangle$, and $\langle \eta \rangle = \frac{1}{L} \sum_l \langle \eta_l \rangle$, where $l = [8, 125]$ and $L = 118$. We kept a maximum of 364 states per block in the DMRG calculations shown in (c).

In Fig. 4 we present the local properties of the low energy state in the $S^z = 152$ sector, which has a value of magnetization $m = 1.143$ between $m_{14}$ and $m_{11}$. The magnetization profiles shown in Fig. 4(a) are compared with the ones in states just before the jump, with $S^z = 147$ ($m = m_{14}$), and just after the jump, with $S^z = 156$ ($m = m_{11}$). In the profile of $S^z = 152$, we identify the magnetizations of phases I and II in spatially separated regions. The transition layers between the two phases, the interface between then, have a mixed state with the coexistence of the two phases in the same spatial region and is relatively large. Further, boundary layers are spatial regions strongly dominated by the boundaries of the system, in which the magnetizations do not change appreciably among the three states. In Fig. 4(b) we show that the singlet density $\eta_l$ enforce these conclusions. In fact, the singlet density profile at the center of the chain in the state with $S^z = 152$ coincides with that of phase II ($S^z = 156$), while the profile changes to that of phase I after the transition layers.

In Fig. 4(c), we show the global average of the magnetizations of $A$ and of $B$ sites, as well as that of the singlet density:

$$\langle A^z \rangle = \frac{1}{L} \sum_l \langle A^z_l \rangle,$$  \hspace{1cm} (5)

$$\langle T^z \rangle = \frac{1}{L} \sum_l \langle T^z_l \rangle,$$  \hspace{1cm} (6)

$$\langle \eta \rangle = \frac{1}{L} \sum_l \langle \eta_l \rangle,$$  \hspace{1cm} (7)

respectively, as a function of the magnetization from below the jump up to the saturation magnetization. To discard the cells in the boundary layers, we consider $l = [8, 125]$, such that $L = 118$. The behavior of these averages is approximately linear for magnetizations inside the jump. However, this behavior depends on the range of sites chosen to calculate these quantities due to the inhomogeneous nature of the states inside the jump. Further, we observe that the average singlet density monotonically decreases with $h$ after the transition field, with the magnetization of $B$ spins increasing in accord, and the $A$ spins remaining fully polarized up to the saturation field. Using the singlet density, we can make a direct comparison of this transition with a thermal liquid-gas transition by identifying the low-density phase, phase I, as the gas phase and the high-density phase, phase II, as the liquid phase.

We attribute the origin of the transition to the competition between the $A - B$ superexchange pattern and $J$ couplings, ladder superexchange pattern, in the Hamiltonian \[diagram\], and the magnetic field. In phase I, the magnetization of $A$ spins is less than $1/2$ due to the antiferromagnetic coupling with $B$ spins, which have the triplet $|\uparrow\uparrow\rangle$ as the most relevant component. Notice that $J$ coupling between these spins does not favor this component. In phase II, $A$ spins are fully polarized, thanks to the magnetic field, and the dynamics of the system is governed by the ladder $J$ couplings, with a larger singlet density. The energy of these two phases becomes equal at the transition field, with a discontinuity in the first derivative at the transition. The order of the transition and phase separation can be better understood by considering the dynamics of the singlets, which act like holes in a doped system. The ladder pattern in Hamiltonian \[diagram\] is related to the itinerancy of the singlets, which are hard-core bosons, and a repulsion between singlets in nearest neighbor cells. Consider a fixed
FIG. 5. Closing of the magnetization jump and the critical point, \( N_c = 67 \). (a) \( h \) as a function of \( m \). We present the central value of \( h \) in the magnetization finite-size plateaus, except for the plateaus bounding the jump. We applied an arbitrary translation \( \Delta h \) to \( h \) for better visualization. The magnetization jump decreases to the minimum attainable value for \( N_c = 67 \), \( \Delta m_{\text{min}} = 0.015 \), at \( J \approx 0.712 \equiv J(N_c) \). In the Inset we present the transition line \( h_J(J) \) (first-order transition points, the critical point, and the crossover line (triangles)).

(b-d) Difference between the total energy \( E_h(m) \) for a fixed \( h \) and its lowest value \( E_{h_{\text{min}}} \) for the same \( h \) and \( J \). The curves are shown for (b) \( J = 0.675 \), (c) \( J = 0.705 \), and (d) \( J = 0.713 \), with the respective \( h = h_J(J) \). The double minima observed for \( J \) below the critical value \( J < J_c(N_c) \), as in (b) and (c), change to a single minimum for \( J > J_c(N_c) \), as shown in (d). We kept a maximum of 364 states per block in the calculations.

value of singlet density, \( \langle \eta \rangle \), between its value in phase I, \( \langle \eta \rangle_{I} \), and in phase II, \( \langle \eta \rangle_{II} \), for which the phase-separated state has lower energy. If \( \langle \eta \rangle \gtrsim \langle \eta \rangle_{I} \), a nucleation process of phase I takes place by the expelling of some singlets from a region of the chain, lowering the singlet density in this region, thereby increasing the density in the complementary region of the chain. This process can be understood as an effective attraction between the singlets. This transfer of singlets stops when the first portion of the chain has a density \( \langle \eta \rangle_{I} \) and the second portion \( \langle \eta \rangle_{II} \). The specific value of \( \langle \eta \rangle_{II} \) is due to the hard-core constraint and the repulsion between the singlets in neighboring cells.

At a critical value of \( J \), a continuous second-order transition occurs between the two phases. In Fig. 5a we present \( h(m) \) curves for values of \( J \) near \( J = 0.7 \) and \( N_c = 67 \), with an arbitrary translation in \( h \) at each curve for a better visualization. The magnetization jump exhibits a little increase as \( J \) increases from \( J = 0.675 \) to \( J = 0.700 \), and starts to decrease at \( J = 0.705 \). The jump closes between \( J = 0.710 \) and \( J = 0.713 \), implying a critical point at \( J_c(N_c=67) = 0.712 \); since energies curves with a double minima, Figs. 5b and (c), changes to a single minimum curve in the critical point, Fig. 5d. In the inset of Fig. 5a we draw the \( h-J \) phase diagram. The first-order transitions are defined by the value of \( h \) at which the jump occurs, for which \( \partial h/\partial m = 0 \). At the critical point, the same condition \( \partial h/\partial m = 0 \); while for \( J > J_c(N_c=67) \) the crossover line between the two phases is defined by the minimum in the \( \partial h/\partial m \) curve.

V. SUMMARY

We studied the first-order quantum transition induced by a magnetic field in a quantum frustrated ferrimagnetic chain through the density matrix renormalization group. The first-order transition gives rise to a magnetization jump in the magnetization curve of the system. In particular, we did a detailed analysis of the phase-separated states inside the jump for a frustration parameter \( J = 0.7 \). The Hamiltonian of the system has three spins per unit cell and is in the class of diamond chain or frustrated AB2 chain models. The energy curves as a function of the magnetization present a double global minimum in the transition field, with unstable and metastable states. The first-order transition occurs between states with different densities of itinerant singlet paired spins, from a state with a lower singlet density (“gas” phase) to a higher one (“liquid phase”), as evidenced by the local averages of the magnetization, local correlations and transverse correlation functions along the chain. These quantities show that in the “liquid phase”, two spins in the unit cell are canted, and present evidence of a power-law alternating transverse correlation along the chain, while the third spin is approximately fully polarized. Local averages of the magnetization and the singlet density show that the states inside the jump are phase separated with the two phases observed in distinct spatial regions. The interface between the two spatially separated phases is in a mixed phase with the two phases coexisting in the same spatial region. Further, the global averages of the same quantities have an approximately linear behavior with the magnetization inside the jump. In particular, the singlet density increases with magnetization, while the magnetization of the third site increases. For higher magnetizations, above the jump, the singlet density decreases monotonically to zero up to the saturation magnetization. In the \( h-J \) phase diagram, the first-order transition line ends at a critical point beyond which a crossover between the two phases takes place. The competition between the superexchange couplings, frustration, is an essential ingredient to the first- and second-order transitions.

Some interesting questions can be addressed by future research on this model. In particular, we mention the study of the hysteresis loops induced by the metastable states, including their dynamical and thermodynamical aspects, as well as a detailed analysis of the critical region.
