ABSTRACT

By combining the data from surveys for H I 21-cm absorption at various impact parameters in near-by galaxies, we report an anti-correlation between the 21-cm absorption strength (velocity integrated optical depth) and the impact parameter. Also, by combining the 21-cm absorption strength with that of the emission, giving the neutral hydrogen column density, \( N_{\text{HI}} \), we find no evidence that the spin temperature of the gas (degenerate with the covering factor) varies significantly across the disc. This is consistent with the uniformity of spin temperature measured across the Galactic disc. Furthermore, comparison with the Galactic \( N_{\text{HI}} \) distribution suggests that intervening 21-cm absorption preferentially arises in discs of high inclinations (near face-on). We also investigate the hypothesis that 21-cm absorption is favourably detected towards compact radio sources. Although there is insufficient data to determine whether there is a higher detection rate towards quasar, rather than radio galaxy, sight-lines, the 21-cm detections intervene objects with a mean turnover frequency of \( \langle \nu_{\text{TO}} \rangle \approx 5 \times 10^8 \) Hz, compared to \( \langle \nu_{\text{TO}} \rangle \approx 1 \times 10^8 \) Hz for the non-detections. Since the turnover frequency is anti-correlated with radio source size, this does indicate a preferential bias for detection towards compact background radio sources.

Key words: galaxies: ISM – quasars: absorption lines – galaxies: structure – radio lines: galaxies.

1 INTRODUCTION

Study of the cool neutral gas over various redshifts gives insight into the evolution of the star forming reservoir and is a science goal of the forthcoming Square Kilometre Array (SKA; Morganti, Sadler & Curran 2015). The distribution of cool neutral hydrogen (H I) with galactocentric radius in external galaxies is crucial in interpreting the data from the forthcoming surveys of H I 21-cm absorption with the SKA and its pathfinders.1 To this end, we (Reeves et al. 2015, 2016) have undertaken a survey of 21-cm absorption of background radio sources at various impact parameters in the discs of intervening, nearby galaxies (\( z < 0.04 \), Fig. 1).

For impact parameters of \( \rho \lesssim 20 \) kpc, the H I detection rate is approximately 50 per cent (Gupta et al. 2010; Borthakur et al. 2011, 2014; Srianand et al. 2013). However, Reeves et al. (2015) find a significantly lower detection rate (4 per cent), which they attribute to the unbiased nature of their sample. That is, no target pre-selection based upon impact parameter nor the nature of the background source. For a given sight-line, a background radio galaxy could result in a lower covering factor, reducing the observed optical depth in comparison to a quasar (see Section 2.2).

Although the gas density in a galaxy is known to decrease with galactocentric radius (e.g. Toomre 1963), none of the previous surveys have found convincing evidence of a decrease in 21-cm absorption strength with impact parameter (Gupta et al. 2010, 2013; Borthakur et al. 2011; Zwaan et al. 2015). This is despite evidence of an anti-correlation between the Lyman \( \alpha \) and C IV equivalent widths and the impact parameter being well established in the optical/UV bands (e.g. Lanzetta et al. 1995; Tripp, Lu & Savage 1998; Chen et al. 2001; Rao et al. 2011; Borthakur et al. 2015). By adding the latest results (Reeves et al. 2015, 2016; Dutta et al. 2016) to the previously published data and incorporating the limits, obtained

1 For example, the First Large Absorption Survey in H I (FLASH) on the Australian Square Kilometre Array Pathfinder (ASKAF), of which the Boolardy Engineering Test Array has already detected redshifted H I 21-cm (at \( z = 0.44 \); Allison et al. 2015).
from the non-detections, here we report the first clear evidence of an anti-correlation between the 21-cm absorption strength and the impact parameter.

2 DATA, RESULTS AND ANALYSIS

2.1 H i 21-cm absorption strength and impact parameter

2.1.1 Raw impact parameters

There are now 90 spectral line observations of radio source sight-lines through the discs of galaxies (summarized in Table 1). In order to fully utilize these data, we include the upper limits to the optical depths (from the non-detections), via the Astronomy SURVival Analysis (ASURV) package (Isobe, Feigelson & Nelson 1986). These are added to the 16 detected sight-lines as censored data points. For the bivariate data, a generalized non-parametric Kendall-tau test gives a probability of \( P(\tau) = 9.39 \times 10^{-4} \) of the observed \( \int \tau d\rho \) anti-correlation correlation arising by chance, which is significant at \( \sigma(\tau) = 3.31 \sigma \), assuming Gaussian statistics (Fig. 2, top panel).

As seen from Table 1, only 14 of the 90 sight-lines were originally targeted as known metal-line absorbers, although these drive the correlation giving a \( \sigma(\tau) = 1.94 \sigma \) significance from just 14 data points. However, this is due to the metal-line absorbers constituting 11 of the 16 detections, which define the parent population against which the limits are quantified, thus requiring their inclusion.

The limits may also be included in the binned univariate data to give the mean \( \int \tau d\rho \) value of each bin, via the Kaplan–Meier estimator which gives a maximum-likelihood estimate based upon the parent population (Feigelson & Nelson 1985). Presenting the data thus, it is visually apparent that the absorption strength does decrease with increasing impact parameter (Fig. 2, bottom panel).

In addition to the generalized Kendall-tau test and the Kaplan–Meier estimates, we split the data in half via the median impact parameter: At \( \rho < 16.2 \) kpc, there are 14 detections and 31 non-detections, that is a 31.1 per cent detection rate. Applying this to the \( \rho > 16.2 \) kpc bin, gives a binomial probability of \( 1.16 \times 10^{-5} \) of obtaining two detections or fewer out of 45 sight-lines, which is significant at \( 4.37 \sigma \).

2.1.2 Normalised impact parameters

Although by the inclusion of the limits, we see a decrease in absorption strength with impact parameter, the sample is heterogeneous, comprising a variety of background source classifications (discussed in Section 2.2), in addition to potential differences in the foreground absorbing galaxies. These may arise from the search strategy of each individual survey, whether an unbiased survey towards galaxy–quasar pairs or the selection of known metal-line absorbers.\(^2\) The detection rate of the former is just 7 per cent, compared to 79 per cent for the latter, with these also tending to be at low impact parameters (Fig. 2). Such metal-line absorbers also comprise the foreground galaxies in the optical surveys which exhibit an equivalent width–impact parameter anticorrelation (Section 1).

Until all of the sample is observed and their metallicities quantified, this possible bias cannot be directly removed. However, both metallicity and equivalent width appear to be correlated with galaxy size (Ellison 2006; Curran et al. 2007; Murphy et al. 2007) and so a potentially wide range of metallicities is expected to reflect a large range of galaxy sizes. This could have the effect of a given impact parameter, which lies well within the disc for an \( L^* \) (high metallicity) galaxy, being located well outside the disc of a dwarf galaxy. In order to account for this, we normalize each impact parameter by the luminosity of the galaxy: As described in Curran et al. (2013a), for each galaxy we obtain the photometry from NASA/IPAC Extragalactic Database (NED), the Wide-Field

\(^2\) Although this does not preclude any of the 76 designated as pairs as being potentially metal-rich – 11 have been detected in Can absorption (see Carilli & van Gorkom 1992; Hwang & Chiou 2004; Gupta et al. 2010), although a further nine have been searched and not detected (see Corbelli & Schneider 1990; Borthakur et al. 2010; Gupta et al. 2010).
Table 1. Summary of the searches for H\(_\alpha\) 21-cm absorption at various impact parameters in external galaxies. In the interest of consistency we quote the NED name of the galaxy, followed by its redshift. ‘Type’ designates whether the search targeted quasar–galaxy pairs (P) or metal-line systems (M). For ease of matching, the sight-line is named as in the reference, followed by its NED classification — galaxy (G), QSO (Q) or unclassified radio source (U). This is followed by the velocity integrated optical depth (or the 3\(\sigma\) limit) of the 21-cm absorption, the impact parameter, the search reference and finally the blue and far-infrared luminosities as obtained from the photometry (see main text).

**Figure 3.** The distribution of the blue-band luminosities of the absorbing galaxies, where sufficient photometry is available. The hatched histogram shows the metal-line searches and the open the galaxy–quasar pair searches.

**Infrared Survey Explorer (WISE) and the Two Micron All Sky Survey (2MASS), correcting each value for Galactic extinction (Wilhelm 2013) before fitting to the required wavelength in the galaxy rest frame.**

We summarize the derived blue-band luminosities in Fig. 3. Using these to normalize the impact parameter, via the same

\[ n(h) \propto L_B \left( \frac{L_B}{L_B^*} \right)^{-0.46} \]

We correct as Chen et al. (2001), we find the absorption strength–impact parameter anti-correlation retains a similar significance, although with 16 fewer data points (Fig. 4). As before, we can also compare detection rates above and below the median (normalized) impact parameter: At \( n(h) \propto L_B \left( \frac{L_B}{L_B^*} \right)^{-0.46} \), there are 9 detections and 28 non-detections, that is a 24.3 per cent detection rate. Applying this to the >18.7 kpc...
As Fig. 4 but with the impact parameter normalized by the $K$-band luminosity (cf. Chen et al. 2001).

Figure 5. As Fig. 3 but for the near-infrared luminosity.

Figure 6. As Fig. 3, but for the near-infrared luminosity.

bin, gives a binomial probability of $4.28 \times 10^{-4}$ of obtaining two or fewer detections out of 37 sight-lines, which is significant at 3.52σ.

Chen et al. (2001) also normalize the impact parameter by the near-infrared luminosity (Fig. 5), since this is less susceptible to extinction and irregularities caused by star formation, providing a better tracer of the total stellar mass. Normalizing the impact parameter, the significance of the anti-correlation increases (Fig. 6) and, again comparing detection rates above and below the median (normalized) impact parameter: At $(\rho/h) \times (L_K/L_K^*)^{-0.28} < 22.2$ kpc, there are 10 detections and 21 non-detections, that is a 30.5 per cent detection rate. Applying this to the $>22.2$ kpc bin, gives a binomial probability of $3.05 \times 10^{-4}$ of obtaining one detection or fewer out of 33 sight-lines, which is significant at 4.17σ.

Since we have both the blue and near-infrared luminosities for many of the galaxies, we can verify that the observed decrease in $\int f\,d\tau$ with impact parameter is not dominated by a colour bias, where the redder (and presumably, dustier) galaxies are more hospitable to the presence of cool gas.\(^{3}\) In Fig. 7 we plot the 21-cm absorption strength against the $B-K$ colour, where no correlation is apparent, leaving the decrease in gas density with impact parameter the major most likely cause. We also note that the known metal-line systems do exhibit some reddening ($B - K > 0$), which is consistent with the metallicity–dust (and molecular fraction) relation (see Curran et al. 2004 and references therein).

### 2.2 The effect of the background source size

As mentioned in Section 1, in addition to the impact parameter, it is believed that the extent of the background source can have an effect on the 21-cm detection rate. Specifically, for a given absorption cross-section\(^4\) different background source sizes will have different observed optical depths, $\tau_{\text{obs}}$, according to

$$\tau = - \ln \left( 1 - \frac{\tau_{\text{obs}}}{f} \right) \approx \frac{\tau_{\text{obs}}}{f} \text{ for } \tau_{\text{obs}} \lesssim 0.3 \Rightarrow \tau_{\text{obs}} \approx f \tau, \quad (1)$$

in the optically thin regime\(^5\), where the observed optical depth is defined as the ratio of the line depth to the continuum ($\tau_{\text{obs}} \approx \Delta S/\delta$). Given that the covering factor ranges over $0 \leq f \leq 1$ for zero to full coverage of the background flux, larger background sources could give systematically lower observed optical depths. That is, we may expect the more compact quasar sight-lines to give a higher detection rate than those of radio galaxies.\(^6\)

Addressing this, from the NED classifications, contrary to our expectations, we find a higher (50–100 per cent) detection rate towards radio galaxies compared to the quasars (20–37 per cent, Fig. 8). Performing a Pearson $\chi^2$–statistic test and applying Yates’s correction for continuity gives a significance of $p = 0.25$. Thus, the null hypothesis that the detection rates are the equal for radio galaxies and quasars cannot be rejected.

It is generally accepted that the turnover frequency of a radio source is anti-correlated with its extent (e.g. Fanil et al. 1990), with flat spectral indices arising from radio emission projected along our line of sight, thus also appearing more compact. Therefore, in the absence of high resolution radio images, we can use any clustering

\(^{3}\)As is seen for both H i (Curran & Whiting 2010) and H$_2$ (Curran et al. 2011) at high redshift.

\(^{4}\)H i 21-cm absorbing clouds in external galaxies are believed to have 1.4 GHz cross-sections of $\sim 100$ pc (Braun 2012; Curran et al. 2013b).

\(^{5}\)The maximum of the sample is $\tau_{\text{obs}} = 0.24$ (Zwaan et al. 2006).

\(^{6}\)Curran et al. (2013b) have shown that the observed anti-correlation between the atomic hydrogen column density and the projected linear size of the background radio emission (Pilbröm, Conway & Vermeulen 2003; Gupta & Saikia 2006a,b; Gupta et al. 2006; Orienti, Morganti & Dallacasa 2006; Chandola, Sirolitha & Saikia 2011) is most likely driven by the observed optical depth resulting from the coverage of the radio source.
generally varies with galactocentric radius, which is the spin temperature of the gas and \( I \) with the nor-

\( T_\text{30 kpc} \geq 100 \, \text{kpc}, \) \( 10 \lesssim T \) with redshift, possibly due to the geometry effects of an 

\( \approx N_1 \times R_1 \) (Kalberla et al. 2014). However, the effect can adequately be accounted for by a decrease in \( f \) with redshift, due to the geometry effects of an expanding Universe (Curran 2012).

For this near-by sample we have the opportunity to determine whether \( T_{\text{spin}}/f \) generally varies with galactocentric radius, which could possibly introduce a beam-filling effect, where the mean value of \( T_{\text{spin}}/f \) within the beam could also contribute to a redshift dependence. Given that the gas is optically thin, for the low redshifts of the sample (Fig. 1), where 21-cm emission can be detected (\( z \lesssim 0.2 \), Catinella & Cortese 2015), the column density can be obtained directly from the brightness temperature of the line emission, \( T_b \) [K], via

\[ N_{\text{HI}} \approx 1.8 \times 10^{18} \int T_b \, dv, \tag{3} \]

which in conjunction with equation (2) yields \( T_{\text{spin}}/f \). Plotting this (Fig. 10), we see no evidence of a variation in \( T_{\text{spin}}/f \) with the normalized impact parameter over \( (\rho/h) \times (L_\text{K}/L_\text{K}^{0.28}) \lesssim 100 \, \text{kpc} \), which corresponds to the inner \( r \approx 30 \, \text{kpc} \) of galactocentric radius.

This is consistent the result of Dickey et al. (2009), who find remarkably little variation in the spin temperature over radii of 8–25 kpc in the Milky Way, despite both the 21-cm emission and absorption strengths varying by two orders of magnitudes.

of either or both the turnover frequency/spectral index to gauge whether an unclassified background source is likely to be a quasar or a radio galaxy. We therefore compiled the photometry of each background source and, using the methods described in Curran et al. (2013a), determined the rest-frame turnover frequency, \( v_{10} \), and spectral index at a rest frequency of 1.4 GHz, \( \alpha \). From this (Fig. 9), we see that both the radio galaxies and unclassified sources, for which both \( v_{10} \) and \( \alpha \) could be determined, are too few in number to exhibit any clustering, which is absent from the sources classified as QSOs in any case. Thus, at least at present, this method is of little use in predicting the nature of the background source. Based upon this limited sample, however, we see that, while there is a large overlap in the spectral indices (although the detections are more ‘flat’, \( |\alpha| < 0.5 \), the detections and non-detections have distinct mean turnover frequencies \( \langle v_{10} \rangle = 10^{6.60 \pm 0.32} \) and \( 10^{6.03 \pm 0.21} \) Hz, respectively). Since the turnover frequency is anti-correlated with the source size (e.g. O’Dea 1998; Fanti 2000; Orienti et al. 2006), this is consistent with a detection bias towards the more compact radio sources, indicating that the covering factor is important.

2.3 Spin temperature and impact parameter

In the optically thin regime (equation 1), the neutral hydrogen column density, \( N_{\text{HI}} \) [cm\(^{-2}\)], is related to the absorption strength via

\[ N_{\text{HI}} \approx 1.8 \times 10^{18} \int T_b \, dv, \tag{2} \]

where \( T_{\text{spin}} \) [K] is the spin temperature of the gas and \( \int T_b \, dv \) [km s\(^{-1}\)] the velocity integrated optical depth of the absorption. The comparison of \( \int T_b \, dv \) with \( N_{\text{HI}} \), from Lyman \( \alpha \) (\( \lambda = 1216 \) Å) observations, has shown an increase in \( T_{\text{spin}}/f \) with redshift, possibly suggesting an evolution in the spin temperature (e.g. Kanekar et al. 2014). However, the effect can adequately be accounted for by a decrease in \( f \) with redshift, due to the geometry effects of an expanding Universe (Curran 2012).

Figure 8. Breakdown of the various sight-line types, from NED (where quasars are classified as QSOs), for the whole sample (top panel) and for impact parameters less than the median value (bottom). The solid histogram shows the 21-cm detections and the open the non-detections.

Figure 9. The rest-frame turnover frequency versus the spectral index for the background sources for which these could be determined. If no turnover is apparent in the radio SED we assume that this occurs below the lowest observed frequency (typically \(~10 \) MHz) and use this to assign an upper limit to \( v_{10} \). Again, the solid symbols represent the detections and the open the non-detections with shapes representing the classification of the background source. In the bottom panel, the binned values of the detections and non-detections are shown.

2.4 Disc inclination

By assuming the known H \( I \) column density distribution of the Milky Way, we can estimate the approximate orientation of the average H \( I \) absorbing disc, based upon the \( f \, dv \sim \rho \) relationship: The Galactic volume density of the neutral gas exhibits an exponential decrease with galactocentric radius according to \( n = n_0 \exp^{-r/R} \), where \( n_0 = 13.4 \, \text{cm}^{-3} \) and the scale-length \( R = 3 \, \text{kpc} \) (Kalberla et al. 2007). The column density at each value of \( \rho \) is obtained from the volume density via \( N_{\text{HI}} \approx \int n \, dv \), where \( N_{\text{HI}} = n \, h = n_0 \exp^{-r/R} \, h \).
smaller absorbing cross-section. We thus suggest that the targeted galaxies tend to have face-on inclinations, which is consistent with the observations of Reeves et al. (2015), who, from the azimuthal profiles of the H I emission, suggest that the intervening galaxies could be highly inclined (or highly asymmetric).

3 CONCLUSIONS

One of the goals of current surveys for H I 21-cm absorption at various impact parameters is to determine the expected detection rate of cool, neutral gas in distant galaxies with the next generation of large radio telescopes. An important aspect of this is the determination of the expected detection rate of 21-cm absorption at redshifts where the detection of 21-cm emission will not be possible. Here we demonstrate a clear anti-correlation between the integrated optical depth and the impact parameter, where previously only weak correlations were apparent at best (significance levels of \( \lesssim 0.81\sigma \); Gupta et al. 2010, 2013; Borthakur et al. 2011; Zwaan et al. 2015).

Also, investigating the hypothesis that 21-cm absorption is more readily detected towards quasars in comparison to radio galaxies, we find that the statistics are insufficient to draw any conclusions. However, we do find that the mean detection occurs towards a radio source with a higher turnover frequency than a non-detection. Since the turnover frequency is anti-correlated with source size, this suggests that the coverage of the background emission is important and thus we would expect a higher detection rate towards quasars in comparison to radio galaxies.

Lastly, using the neutral hydrogen column density obtained from the 21-cm emission, we find no statistical evidence for a variation of the spin temperature (degenerate with the covering factor) over the inner \( \approx 30 \) kpc of the disc, similar to the consistency in spin temperature observed across the Milky Way (Dickey et al. 2009). By using \( N_{\text{HI}} \) obtained from the H I distribution of the Milky Way, the observed \( f \tau d\nu / \rho \) correlation may suggest that the intervening galactic discs have high inclinations (close to face-on). This is consistent with the H I emission maps of Reeves et al. (2015), who suggest that galaxies which intercept background sources may be highly inclined.

ACKNOWLEDGEMENTS

We wish to thank the anonymous referee for their helpful and detailed comments and the Radio Galaxy Morning Tea group at the University of Sydney for useful discussion. This research has made use of the NASA/IPAC Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration and NASA’s Astrophysics Data System Bibliographic Service. This research has also made use of NASA’s Astrophysics Data System Bibliographic Service and ASURV Rev 1.2 (Lavalley, Isobe & Feigelson 1992), which implements the methods presented in Isobe et al. (1986).

\(^7\)Where the height of the disc, \( h \), is given by the flare factor, \( f_{\text{FL}} = \rho / h \), which describes the flaring of the H I gas with galactocentric radius (Kalberla et al. 2007).

Figure 10. The spin temperature–covering factor degeneracy versus the normalized impact parameter for all of the published searches where a measure of the column density is available. In the top panel, the symbols are as per Fig. 2 and in the bottom panel the grey boxes show the range in the outer Milky Way \((T_{\text{spin}} = 250–400 \text{ K}, \text{Dickey et al. 2009})\). Since \( f \leq 1 \), this places a lower limit on \( T_{\text{spin}}/f \).

Figure 11. Top: the binned 21-cm absorption strength (left ordinate axis, \( i = 90^\circ \) disc) and \( N_{\text{HI}} = n_0 \int_0^\rho e^{-\rho / R} d\rho = n_0 R e^{-\rho / R} \) for an edge-on \(( i = 0^\circ \) disc \( (\text{Fig. 11}) \). From this, the face-on galactic disc appears to better trace the binned integrated optical depth values, again with \( T_{\text{spin}}/f \sim 10^3 \) K remaining approximately consistent with galactocentric radius out to \( (\rho / h) \times \left( L_K / L_K^* \right)^{0.28} \sim 20 \) kpc, beyond which this falls to \( T_{\text{spin}}/f = 40 \) K \( (\text{Fig. 10}) \). Applying the edge-on Galactic disc would give much larger values of \( T_{\text{spin}}/f \) due either to very high spin temperatures and/or very low covering factors, the latter of which would be expected from a low inclination disc presenting a much smaller absorbing cross-section. We thus suggest that the targeted galaxies tend to have face-on inclinations, which is consistent with the observations of Reeves et al. (2015), who, from the azimuthal profiles of the H I emission, suggest that the intervening galaxies could be highly inclined (or highly asymmetric).
