Dendritic cell (DC)-based vaccination is a promising strategy for cancer immunotherapy. However, clinical trials have indicated that immunosuppressive microenvironments induced by tumors profoundly suppress antitumor immunity and inhibit vaccine efficacy, resulting in insufficient reduction of tumor burdens. To overcome these obstacles and enhance the efficiency of DC vaccination, we generated interleukin (IL)-12- and granulocyte-macrophage colony-stimulating factor (GM-CSF)-coexpressing oncolytic adenovirus (Ad-ΔB7/IL12/GMCSF) as suitable therapeutic adjuvant to eliminate immune suppression and promote DC function. By treating tumors with Ad-ΔB7/IL12/GMCSF prior to DC vaccination, DCs elicited greater antitumor effects than in response to either treatment alone. DC migration to draining lymph nodes (DLNs) dramatically increased in mice treated with the combination therapy. This result was associated with upregulation of CC-chemokine ligand 21 (CCL21+) lymphatics in tumors treated with Ad-ΔB7/IL12/GMCSF. Moreover, the proportion of CD4+CD25+ T-cells and vascular endothelial growth factor (VEGF) expression was decreased in mice treated with the combination therapy. Furthermore, combination therapy using immature DCs also showed effective antitumor effects when combined with Ad-ΔB7/IL12/GMCSF. The combination therapy had a remarkable therapeutic efficacy on large tumors. Taken together, oncolytic adenovirus coexpressing IL-12 and GM-CSF in combination with DC vaccination has synergistic antitumor effects and can act as a potent adjuvant for promoting and optimizing DC vaccination.

INTRODUCTION

Dendritic cells (DC) are potent antigen-presenting cells (APC) with a unique capability to induce primary immune responses to self or foreign antigens. DC-based vaccines are a promising strategy in cancer immunotherapy. DCs pulsed with tumor-associated antigen can induce protective and therapeutic tumor-specific immune responses to various tumor types. Recently, DC-based vaccine clinical trials have been performed with patients with prostate cancer, melanoma, lymphoma, and renal carcinoma. However, beneficial patient responses were fewer than predicted. Although tumor-specific immune responses were seen in most of the patients, objective clinical responses were only observed in a few patients. DCs have been reported to have significantly impaired biological functions in advanced cancer patients, which might be associated with the failure of the DC vaccination in clinical trials. Emerging evidence indicates that this effect might be mediated by various factors produced by tumor cells. Tumor tissues can produce immunosuppressive molecules, such as vascular endothelial growth factor (VEGF), transforming growth factor-β, and interleukin (IL)-10. These molecules induce an immunosuppressive microenvironment within the tumors. The function of tumor-associated DCs may also be suppressed under these conditions. Therefore, DC vaccination efficacy may be improved by the addition of an adjuvant to reduce or eliminate tumor-induced immunosuppression.

Cytokine therapy has been reported to be an effective strategy for cancer therapy. Ectopic cytokine expression in tumor tissues can induce strong antitumor immune responses, and can also convert the immunosuppressive tumor microenvironment to one with more antitumor characteristics. IL-12 is an important cytokine in innate and adaptive immunity that is able to enhance T-helper 1 cells (Th1) immunity, increase cytotoxic T-lymphocytes cytotoxicity, and inhibit angiogenesis. Preclinical and clinical trials of IL-12-based immunotherapy have demonstrated strong antitumor immune responses. Previous studies reported that immunosuppressive conditions can be reversed by induction of intratumoral IL-12 expression. These results were associated with effector T-cell activation, Treg cell apoptosis induction, and cytotoxic T-lymphocytes infiltration. In addition, IL-12-induced IFN-γ-inducible protein 10 (IP-10) and Mig expression are strong inhibitors of tumor angiogenesis. Granulocyte-macrophage colony-stimulating factor (GM-CSF) is produced by a wide range of cell types and functions to stimulate proliferation, maturation, and function of APCs. Previous studies have demonstrated an
antitumor effect of GM-CSF in cancer immunotherapy, indicating that GM-CSF is a useful therapeutic agent in cancer therapy.\textsuperscript{19,20} Recently, adenovirus (Ad) vectors as efficient gene delivery systems have been widely used in cancer gene therapy. Cytokine gene delivery can induce sustained antitumor effect \textit{via} sustained expression of therapeutic dose of cytokine in the local tumor tissue and that can prolong the antitumor effect and reduce toxicity compared with treatment of recombinant cytokine protein.\textsuperscript{21-23} In an effort to overcome systemic cytokine toxicity, local injection of recombinant cytokine protein has been tried. But it was still not easily amenable in the clinics because it forced the continuous administration of cytokine.\textsuperscript{24} Moreover, Ad vectors can be modified to allow for replication in only cancer cells.\textsuperscript{25} Our previous adjuvant for optimizing DC vaccination. oncolytic Ad coexpressing IL-12 and GM-CSF can act as a potent adjuvant for optimizing DC vaccination.

**RESULTS**

**Oncolytic Ad-mediated IL-12 and GM-CSF expression**

Ad-\textit{ΔB7}, an oncolytic Ad, was mutated in the retinoblastoma binding sites of E1A and had the E1B region deleted, as shown in Figure 1a. The cancer-specific viral replication and cytotoxicity of Ad-\textit{ΔB7} has been previously confirmed.\textsuperscript{26} To generate the Ad-\textit{ΔB7/IL12/GMCSF} oncolytic Ad, murine IL-12 and GM-CSF genes were inserted into the E1 and E3 regions of the Ad-\textit{ΔB7} viral genome, respectively. Cultured murine melanoma B16-F10 cells were infected with Ad-\textit{ΔB7/IL12/GMCSF} at multiplicity of infection (MOIs) of 50, 100, and 500. As shown in Figure 1b,c a dose-dependent increase in secreted IL-12 and GM-CSF was observed in cells infected with Ad-\textit{ΔB7/IL12/GMCSF} after 48 hour.

**Characterization of cultured DCs**

To evaluate DC quality and phenotype, \textit{in vitro} cultures of bone marrow-derived mature and immature DCs were assayed by flow cytometry. After the 8-day culture regimen, the cultures consisted of >80% DCs (Supplementary Figure S1a). After antigen-pulsing and activation by lipopolysaccharide, the mature DCs showed markedly increased cell-surface expression of the costimulatory molecules CD40, CD80, CD86, and CC-chemokine receptor 7 (CCR7), as compared with immature DCs (Supplementary Figure S1b,c).

**Therapeutic efficacy of Ad-\textit{ΔB7/IL12/GMCSF} combined with DCs in an established murine melanoma model**

To evaluate the therapeutic efficacy of Ad-\textit{ΔB7/IL12/GMCSF} in combination with DCs in vivo, established B16-F10 melanoma tumors in C57BL/6 mice were intratumorally injected with three doses of Ad-\textit{ΔB7/IL12/GMCSF} on days 0–2, followed by three injections of DCs on days 3–5. Treatment groups included phosphate-buffered saline (PBS)-only control, Ad-\textit{ΔB7/IL12/GMCSF} only (5 × 10\textsuperscript{9} viral particle (VP)/injection), DCs only (1 × 10\textsuperscript{6}/injection), or a combination of DCs and Ad-\textit{ΔB7/IL12/GMCSF}, referred to as the combination therapy. In parallel, one group of mice was given a treatment regimen of a high dose of Ad-\textit{ΔB7/IL12/GMCSF} and GM-CSF.
survival of mice treated with Ad-B7/IL12/GMCSF alone, DCs

was 18, 18, 28, and over 90 days, respectively. All treatment groups
alone, the combination therapy, or high-dose combination therapy
even greater antitumor effect than combination therapy (on day
24, and 177 ± 19 mm3, respectively. These data correlate to 63, 85,
high-dose combination therapy were 1,031 ± 443, 410 ± 170, 210 ±

tumor volumes in mice treated with DCs alone, or DCs alone showed significant inhibition of tumor growth. On
day 8, the mean tumor volumes in mice treated with DCs alone,
Ad-B7/IL12/GMCSF alone, the combination therapy, or the
high-dose combination therapy were 1,031 ± 443, 410 ± 170, 210 ±
and 177 ± 19 mm3, respectively. These data correlate to 63, 85,
92, and 93% tumor growth inhibition, respectively, as compared to
PBS alone controls. Tumor growth inhibition was statistically sig-
nificant in mice treated with the combination therapy as compared
with individual treatment groups (P < 0.05 versus DCs or Ad-B7/
ILI2/IL12/GMCSF). The high-dose combination therapy showed an
even greater antitumor effect than combination therapy (on day
26, P < 0.05 versus combination therapy). In addition, the median
survival of mice treated with Ad-B7/IL12/GMCSF alone, DCs
alone, the combination therapy, or high-dose combination therapy
was 18, 18, 28, and over 90 days, respectively. All treatment groups
showed significantly prolonged survival as compared to control
mice (P < 0.01, Figure 2b). Importantly, four out of six mice treated
with the high-dose combination therapy achieved complete remis-

sion and survived over 90 days. These results suggest that Ad-B7/
ILI2/GMCSF in combination with DCs can induce a potent anti-
tumor effect in the B16-F10 melanoma model.

IL-12 and GM-CSF expression and immune
cell infiltration in treated tumor tissues
To examine the mechanisms of the observed antitumor effects,
IL-12 and GM-CSF expression and immune cell infiltration in the
tumor tissues were examined. Expression of IL-12 and GM-CSF

was very minimal in tumors treated with PBS, but was present in
tumors treated with Ad-B7/IL12/GMCSF or DCs (Figure 3a,b). Tumors treated with the combination therapy showed markedly
enhanced IL-12 and GM-CSF expression relative to tumors treated
with Ad-B7/IL12/GMCSF or DCs alone. This finding was even

more dramatic in tumors treated with the high-dose combination
therapy.

Histological analyses revealed enhanced tumor necrosis in
tumor tissues from mice treated with the combination therapy
as compared with individual treatments. Significantly, nearly all
tumor cells were eliminated from mice treated with the high-
dose combination therapy. Immunohistochemical analyses using
CD4+, CD8+, CD11c-, and CD86-specific Abs were performed
to identify the immune cells that infiltrated the tumor tissues.
Significantly greater numbers of CD4+ T-cells, CD8+ T-cells, and
CD11c+ DCs were observed in tumors treated with the combina-
tion therapy than in tumors receiving individual treatments
(Figure 3c). Correlating with the data in Figure 2, tumors treated
with the high-dose combination therapy showed increased levels
of tumor-infiltrating T-cells and DCs. In addition, the expression of
CD86 as a marker of activated APCs was significantly increased
in tumors treated with the combination therapies as compared to
the individual treatments.

VEGF expression and tumor angiogenesis
is inhibited by combination therapy
IL-12 and E1A protein have been reported to inhibit tumor
angiogenesis and downregulate VEGF expression.30,31 As shown in
Figure 4a, VEGF expression was decreased in tumors from all
treatment groups as compared to the PBS control, with a more
robust reduction in the combination therapy group (P < 0.05 ver-
sus DCs alone). As expected, VEGF expression was decreased to
the lowest levels in tumors treated with the high-dose combina-
tion therapy (P < 0.05 versus the combination therapy).

Tumor angiogenesis was examined by immunohistochemical
analysis using a CD31-specific Ab. A reduced number of CD31+ vessels were observed in mice treated with any of the individual
or combination treatments as compared to the PBS controls
(Figure 4b,c). Consistent with the data above, the decrease in
CD31+ vessels was statistically greater in the combination-treated
tumors than in tumors that received DCs or Ad-B7/IL12/
GMCSF alone (P < 0.05). Likewise, the high-dose combination
therapy showed the greatest decrease ($P < 0.05$ versus the combination therapy) to nearly complete inhibition of angiogenesis.

**Combination therapy promotes DC migration to draining lymphnodes**

To explore whether DC migration to DLNs is promoted by combination therapy, DCs were labeled with a fluorescent probe, CMTPX (Supplementary Figure S2a). A significantly increased percentage of CMTPX$^+$ DCs was observed in DLNs from mice treated with the combination therapy than from mice treated with DCs alone ($P < 0.01$). This finding was enhanced in mice treated with the high-dose combination therapy ($P < 0.05$ versus the combination therapy; Figure 5a, Supplementary Figure S2b). Moreover, combination therapy significantly augmented the proportion of CD11c$^+$ DCs in DLNs, implying that combination therapy also promotes migration of endogenous DCs to DLNs ($P < 0.05$ versus Ad-ΔB7/IL12/GMCSF plus DCs; Figure 5b and Supplementary Figure S2c). Mice treated with
the combination therapy showed significantly increased total cell numbers in DLNs as compared to mice treated with DCs alone \((P < 0.01; \text{Figure 5c})\). Consistent with augmented total cell numbers in DLN from mice treated with the combination therapies, the expression of proliferating cell nuclear antigen as a marker for cellular proliferation was significantly increased compared to the individual treatments (Figure 5d). These results suggest that

**Figure 4** Decreased vascular endothelial growth factor (VEGF) expression and angiogenesis in tumors treated with combination therapy. Tumors were treated with phosphate-buffered saline (PBS), dendritic cells (DCs), Ad-ΔB7/IL12/GMCSF, Ad-ΔB7/IL12/GMCSF plus DCs, or Ad-ΔB7/IL12/GMCSF (H; high-dose of Ad) plus DCs, and harvested from mice at 3 days after final treatment. (a) The level of VEGF expression in tumor tissues was quantified by conventional enzyme-linked immunosorbent assay. *\(P < 0.05\). (b) CD31+ microvessel immunohistochemistry in the tumor tissues treated with PBS, DC, Ad-ΔB7/IL12/GMCSF, Ad-ΔB7/IL12/GMCSF plus DCs, or Ad-ΔB7/IL12/GMCSF (H) plus DCs. Original magnification: x100 and x400. (c) The means of CD31+ vessel density in microscopic field for each treatment group (×200). Data points represent the mean ± SE of three mice per group, and similar results were obtained from at least two separate experiments. *\(P < 0.05\); **\(P < 0.01\). GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin.

**Figure 5** Dendritic cells (DC) migration to the draining lymph nodes (DLNs). Ex vivo generated DCs were labeled with CMTPX. Two days after final treatment, single cells were collected from DLNs and the migration was quantified by fluorescence-activated cell sorting analysis. (a) The number of CMTPX+ DCs in DLNs from mice treated with phosphate-buffered saline (PBS), DC, Ad-ΔB7/IL12/GMCSF plus DCs, or Ad-ΔB7/IL12/GMCSF (H; high-dose of Ad) plus DCs were quantified on a fluorescence-activated cell sorter, and data from 50,000 events were represented. (b) CD11c+ DCs in the DLNs from mice treated with Ad-ΔB7/IL12/GMCSF and/or DCs. (c) Total cell number of DLNs from different groups of mice. Data points represent the mean ± SE of triplicate experiments. All results in this figure represent results of at least three mice per group, and similar results were obtained from at least two separate experiments. *\(P < 0.05\); **\(P < 0.01\). GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin.
lymphatics in the tumor tissues ($P < 0.01$ versus the combination therapy).

To better understand the mechanism of CCL21$^+$ lymphatic vessel upregulation in tumors treated with the combination therapy, expression of TNF-α in the tumors was measured by enzyme-linked immunosorbent assay (ELISA). TNF-α levels were augmented in the tumors treated with Ad-ΔB7/IL12/GMCSF or DCs alone and were significantly increased in the combination therapy group ($P < 0.05$ versus individual treatments; Figure 6c). Consistently, the high-dose combination therapy group had the highest levels of TNF-α expression ($P < 0.05$ versus combination therapy). These results indicate that increased TNF-α expression in tumor tissues treated with combination therapies might be the cause of the upregulation of CCL21$^+$ lymphatics.

The CD4$^+$CD25$^+$ T-cell population decreased in DLNs of mice treated with the combination therapy

CD4$^+$CD25$^+$ T-cells are important immune suppressors whose development is partially regulated by VEGF. As described above, the expression of VEGF was markedly decreased in tumors treated with the combination therapy (Figure 4a). To evaluate changes in the CD4$^+$CD25$^+$ T-cell population within the DLNs, lymphocytes were collected from DLNs of mice treated with PBS, DCs, Ad-ΔB7/IL12/GMCSF, or the combination therapy. The CD4$^+$CD25$^+$ T-cell population from the DLNs was significantly decreased in mice treated with Ad-ΔB7/IL12/GMCSF as compared to mice treated with PBS or DCs ($P < 0.01$; Figure 7 and Supplementary Figure S3). The decrease in the CD4$^+$CD25$^+$ T-cell population was still greater in mice treated with the combination therapy ($P < 0.05$ versus Ad-ΔB7/IL12/GMCSF alone).

Antitumor effect induced by Ad-ΔB7/IL12/GMCSF in combination with immature DCs

Immature DCs differentiated from progenitor cells can actively uptake and process exogenous antigen. Following maturation, DCs downregulate their antigen acquisition and processing abilities and display increased immunogenicity. Immature DCs differ from mature DCs pulsed with tumor antigen in vitro in that immature DCs can take up in situ tumor antigens. B16-F10 melanoma models were used to evaluate the therapeutic effects of combination therapy using immature DCs in comparison to mature DCs. Similar antitumor effects were observed in combination therapies using mature or immature DCs (Figure 8a). This finding indicates that the combinatorial strategy using the cytokine-expressing oncolytic Ad can promote maturation of immature DCs within the tumor tissue. Therefore, Ad-ΔB7/IL12/GMCSF-mediated expression of IL-12 and GM-CSF prior to DC injection might reverse the immunosuppressive microenvironment within the tumor, resulting in a microenvironment favorable to the maturation and function of immature DCs.

We further assessed the effect of the treatment schedule of oncolytic Ad and DCs on gross antitumor efficacy. The antitumor efficacy and survival rates were significantly improved in tumors treated with Ad-ΔB7/IL12/GMCSF prior to DC vaccination (Figure 8b,c; filled triangles) or in tumors treated with Ad-ΔB7/
IL12/GM-CSF and DCs on alternating days (open diamonds) as compared to tumors treated with Ad-ΔB7/IL12/GMCSF following DC vaccination (filled squares) \( P < 0.05 \). Clearly, tumor treatment with Ad-ΔB7/IL12/GMCSF prior to DC vaccination induced the most potent antitumor efficacy.

**DISCUSSION**

Tumor-induced immune suppression mediated by a variety of molecules, such as VEGF, IL-10, and transforming growth factor-β, is a major problem faced by cancer immunotherapy. These molecules produced by several tumor compartments not only impair the recruitment and maturation of DCs and T-cells in the tumor tissue, but also induce abnormal systemic DC differentiation and activation. This immune modulation is a major obstacle in DC-based cancer vaccination.\(^{33,34}\) Therefore, many recent studies have focused on optimizing DC vaccination protocols to overcome tumor-induced immune suppression.

IL-12 is a potent immune-stimulatory cytokine that can reverse tumor microenvironment immunosuppression.\(^{16}\) DCs activated in the presence of IL-12, IL-18, and anti-CD40 antibody have been shown to potently improve antitumor immunity.\(^{35}\) In addition, DCs transduced with the IL-12 gene and melanoma-
VEGF expression in a murine breast cancer model, and inhibiting trials of DC vaccination. To increase the efficiency of DC vaccination, DC migration to DLNs must be enhanced. In this study, mice treated with the combination therapy showed significantly increased number of mature DCs in tumor-bearing mice. IL-12 and GM-CSF were selected for use in combination therapies to activate and enhance host immune responses.

This study demonstrates that the combination of DC vaccination and oncolytic Ad coexpressing both IL-12 and GM-CSF greatly enhanced the antitumor effects and survival rates in a murine melanoma model, as compared with individual treatments (Figure 2a,b). Moreover, IL-12 levels were also markedly increased in tumor tissues that received the combination therapy (Figure 3a). IL-12 not only enhances Th1 immunity and cytotoxic T-lymphocytes cytotoxicity, but at high concentrations, IL-12 can also activate natural killer cells. Activated natural killer cells promote DC maturation, which induces a positive feedback loop in that the mature DCs secrete additional IL-12. In addition, GM-CSF secreted from Ad-Δβ7/IL12/GMCSF-infected tumor cells can also recruit and induce maturation of DCs within tumor tissues (Figure 3c). Taken together, these findings suggest that IL-12 and GM-CSF are potent stimuli that can activate and boost the host immune system, and can also synergistically promote DC vaccination efficacy.

VEGF not only plays a critical role in the development of tumor angiogenesis, but also inhibits the differentiation and maturation of DCs. In vivo administration of neutralizing VEGF-specific antibody can improve the function of DCs and increase the number of mature DCs in tumor-bearing mice. IL-12 downregulated VEGF expression in a murine breast cancer model, and inhibited tumor angiogenesis. Here, VEGF expression was inversely related to IL-12 expression. Specifically, VEGF expression was significantly reduced in tumors treated with the combination therapy as compared with control tumors or tumors that received individual treatments (Figure 4a). Likewise, enhanced antiangiogenesis was observed in tumors that received the combination treatments (Figure 4b,c). These data suggest that IL-12-mediated antiangiogenesis played a role in the combination therapy-induced antitumor effect. Importantly, reduction of VEGF expression due to the combination therapy might contribute to the reduction of the tumor microenvironment immnosuppression, therefore enhancing DC vaccination efficacy.

Following maturation, DCs upregulate costimulatory molecules and acquire the ability to migrate to regional lymph nodes. Migration of DCs to regional lymph nodes is an essential step in the induction of immune responses and, therefore, is an important aspect of DC vaccination. However, only a small proportion of injected DCs migrated to DLNs in cancer patients during clinical trials of DC vaccination. To increase the efficiency of DC vaccination, DC migration to DLNs must be enhanced. In this study, mice treated with the combination therapy showed significantly increased numbers of endogenous as well as exogenously injected DCs that migrated to the DLNs (Figure 5a,b). This migration likely played a significant role in enhancing DC vaccination efficacy in tumor-bearing mice. This finding is in line with our previous study that indicated that DC migration can be promoted when DCs are combined with oncolytic Ad coexpressing IL-12 and 4-1BB ligand.

Migration of mature DCs to draining lymph nodes is driven by the interaction of high levels of CCR7 on mature DCs with its ligand, CCL21 in the lymphatics. Mice treated with Ad-Δβ7/IL12/GMCSF alone or in combination with DCs showed a markedly increased number of CCL21-positive lymphatic vessels surrounding tumor tissues as compared with mice treated with PBS or DCs alone (Figure 6a,b). This suggests that the increased DC migration in the combination therapy group was due to upregulation of CCL21+ lymphatic vessels in the tumor tissue. Martin-Fontecha et al. reported that TNF-α-induced tissue inflammation greatly increases DC migration to DLNs due to upregulation of CCL21 expression on lymphatic vessels in situ. Therefore, TNF-α may be an inflammatory stimuli associated with the regulation of CCL21 expression on endothelial cells of the lymphatics. Interestingly, combination therapy significantly increased the level of TNF-α in tumors (Figure 6c). TNF-α was likely secreted by tumor-infiltrating T-cells, monocytes, and macrophages recruited to the CCL21+ lymphatic vessels in the tumor tissues by IL-12 and GM-CSF expressed by Ad-Δβ7/IL12/GMCSF. However, it remains unclear whether IL-12 or GM-CSF directly regulates CCL21 expression on endothelial cells of the lymphatics.

Emerging evidence suggests that CD4+CD25+ T cell-mediated immune suppression is a crucial tumor immune evasion mechanism and is often a barrier for successful tumor immunotherapy. A previous study demonstrated that local IL-12 expression by tumor tissues can reverse the tumor immune suppression by inducing apoptosis of CD4+CD25+Foxp3+ T-cells. In our study, the CD4+CD25+ T-cell population was reduced in the DLNs of tumor-bearing mice treated with Ad-Δβ7/IL12/GMCSF alone or in combination with DCs as compared with the PBS and DCs-alone treatment groups. It is likely that the high level of IL-12 expressed in the tumor tissue contributed to CD4+CD25+ T-cell elimination (Figure 7). In addition, VEGF is associated with the development of CD4+CD25+ T-cells in tumor-bearing mice and cancer patients. Therefore, the decreased VEGF expression in the tumors from mice that received the combination therapy likely contributed to the CD4+CD25+ T-cell population reduction in the DLNs.

Interestingly, combination therapy using immature DCs had similar antitumor effects as the combination therapy using mature DCs (Figure 8a). IL-12 and GM-CSF secreted from Ad-Δβ7/IL12/GMCSF likely directly activated the immature DCs or induced an immune response that produced a number of immune-stimulating factors to circumvent the immunosuppressive microenvironment. Moreover, injected immature DCs can efficiently uptake tumor antigens in situ that were generated by oncolytic Ad-mediated oncolysis of cancer cells.

The order of virus and DC injection also affected the antitumor effects of the combination therapies (Figure 8b,c). These results indicate that injection of the cytokine-expressing oncolytic Ad prior to DC vaccination can reduce immune suppression and induce favorable immune response conditions within the tumor.
tissue, resulting in improved efficacy of DC vaccination. In addition, combination therapy also elicited notable antitumor effects in large tumors (Figure 8d,e), suggesting that combination therapy can overcome the limitation of DC vaccinations to reduce tumor burden in established solid tumors.49

This study demonstrates synergistic antitumor effects between Ad-ΔB7/IL12/GMCSF and DCs in a murine melanoma model. The mechanism is associated with the elimination of immune suppression in the tumor and promotion of DC maturation and migration to DLNs. These findings provide the basis for a feasible oncolytic Ad-based cytokine gene therapy in combination with DC vaccination for cancer treatment in the clinic.

MATERIALS AND METHODS

Cell lines and cell culture. B16-F10 (murine melanoma) cells were maintained in Dulbecco’s modified Eagle’s medium (Gibco BRL, Grand Island, NY) supplemented with 10% fetal bovine serum (Gibco BRL), 100 IU/ml penicillin, and 100 μg/ml streptomycin. Mice. C57BL/6 mice were obtained from SLC (Tokyo, Japan). Mice were used at 6–7 week of age, and all animal studies were performed according to institutionally approved protocols at Yonsei University College of Medicine.

Adenoviral vectors. To generate an Ad expressing IL-12 and GM-CSF at the E1 and E3 region, respectively, we first constructed an E3 shuttle vector expressing GM-CSF. The murine GM-CSF gene was excised from pCDNA3.1/GMCSF using NheI and XhoI, and sub-cloned into the Ad E3 shuttle vector, pSP72-E3, generating a pSP72/E3/GMCSF shuttle vector. The newly constructed pSP72/E3/GMCSF was then cotransfected with an Ad total vector (pmdl324BstBI) into Escherichia coli BJ5183, yielding a pAdl324AE3/GMCSF Ad plasmid. Structure of the resultant recombinant vector was confirmed by restriction enzyme digestion and PCR analysis. To construct an Ad E3 shuttle vector expressing IL-12 and GM-CSF, we first excised pCA14/IL12-49 was sub-cloned into the XCMAlabe vector,25 generating an Ad-β-galactosidase (1 μg/ml, Sigma) were added at day 7 for DCs maturation. After incubation for 24 hours, mature DCs were harvested and used in following studies. Immature DCs were cultured at same condition for 6 days as described above. But, the cell was not exposed to the tumor lysate and lipopolysaccharide.

Fluorescence-activated cell sorting (FACS) analysis. For the phenotypic analysis, the DCs were stained with surface molecules using immunofluorescence and analyzed by FACS analysis. Cells were stained with anti-mouse CD11c, CCR7, CD40, CD80, CD86, or MHC I/II (Pharmlingen, San Diego, CA) Ab at 4°C for 45 minutes. After twice of PBS washing, the cells were incubated with fluorescein isothiocyanate-conjugated goat anti-rat IgG secondary Ab at 4°C for 15 minutes. For the assessment of CD4+CD25+ T-cell population in the DLN, single cells were obtained from DLN after mechanical dissociation. The cells were stained with anti-mouse CD4 (phycoerythrin) and anti-mouse CD25 (fluorescein isothiocyanate) Ab at 4°C for 45 minutes. All samples were analyzed on a BD Biosciences BD-LSR II Analytic Flow Cytometer, using FACS Diva software (BD Biosciences, San Jose, CA).

In vivo antitumor effect. B16-F10 cells (5 × 10⁶) were injected subcutaneously into the right abdomen of 6–7 week-old male C57BL/6 mice. When the tumor volumes reached of around 120–130 mm³, mice were sorted into groups with similar means of tumor volumes. Treatment groups included PBS-only control, Ad-ΔB7/IL12/GMCSF only (5 × 10⁹ VP/injection), DCs only (1 × 10⁷ cells/injection), or a combination of DCs and Ad-ΔB7/IL12/GMCSF. In parallel, one group of mice was given a treatment regimen of a high dose of Ad-ΔB7/IL12/GMCSF (5 × 10²⁶ VP/injection) in combination with DCs (1 × 10⁷/injection). Tumor-bearing mice were intratumorally injected with three doses of Ad on days 0–2, followed by three injections of DCs on days 3–5. Tumor growth was monitored every other day using a caliper, and tumor volume was calculated by the following formula: volume = 0.523 LW², where L is length and W is width. Animals with tumors that were >3,000 mm³ were killed for ethical reasons.

Expression of IL-12 and GM-CSF. IL-12 and GM-CSF expression were determined using an ELISA according to the manufacturer’s instructions. B16-F10 melanoma cells were plated onto six-well plates at 1 × 10⁶ per well and then infected with Ad-ΔB7/IL12/GMCSF at MOIs of 50, 100, and 500. At 48 hours after infection, supernatants were harvested and the level of IL-12 and GM-CSF was determined with conventional IL-12 ELISA kit (ENDOGEN) and GM-CSF ELISA kit (R&D systems, Minneapolis, MN), respectively. For the assessment of cytokine expression in tumor tissue, tumor tissues were removed from mice treated with Ad and/or DCs at 3 days after final treatment. Tissues were homogenized and liquefied in PBS containing protease inhibitor cocktail (Sigma). IL-12, GM-CSF, VEGF, and TNF-α. level were measured by conventional ELISA kits (ENDOGEN and R&D systems). Each experiment was carried out three to four times with three replicates in each group.

Histology and immunohistochemistry. Tumor tissues were harvested from mice after 3 days of final treatment, and embedded in paraffin and sectioned at a thickness of 4 μm for hematoxylin and eosin (H&E) staining. For immunohistochemical staining, tumor tissues were snap-frozen and sectioned at a thickness of 7 μm. Tumor sections were blocked with 4% PBS–bovine serum albumin (Sigma) for 1 hour and incubated overnight with appropriate dilution of anti-CD4 (purified rat anti-mouse CD4 monoclonal Ab; Pharmingen), anti-CD8 (purified rat anti-mouse CD8 monoclonal Ab; Pharmingen), anti-CD86 (purified rat anti-mouse CD86 monoclonal Ab; Pharmingen), anti-CD11c (purified hamster anti-mouse CD11c monoclonal Ab; Pharmingen), or anti-CCL21 (purified rat anti-mouse CCL21 monoclonal Ab; R&D systems) in Ab diluents (DAKO, Glostrup, Denmark). After overnight incubation, the sections were washed twice in PBS and incubated with horseradish peroxidase-conjugated goat anti-rat or mouse anti-hamster Ab (Southern Biotechnology, Birmingham, AL) for 1 hour Diaminobenzidine/
hydrogen peroxidase (DAKO) was used as the chromogen substrate. All slides were counterstained with Meyer's hematoxylin.

**Evaluation of DC migration in vivo.** DCs were labeled with CellTracker Red CMTPX (Invitrogen, Carlsbad, CA) on day 6 of DC culture and were harvested on day 8. The tumor-bearing mice were intratumorally injected with DCs (1 × 10^6/time) alone three times every day or intratumorally injected with Ad-Δ87/IL12/GMCSF (5 × 10^5 VP/time or 5 × 10^5 VP/time) three times every day prior to DC injection. At 48 hour after final treatment, the DLNs were harvested and dissociated into single cells for FACS analysis. The number of CMTPX^+ DCs and CD11c^+ DCs was quantified on a fluorescence-activated cell sorter (Becton Dickinson, Sunnyvale, CA) and data from 50,000 events were collected for further analysis.

**Statistical analysis.** The data was expressed as mean ± SE. Statistical analyses of the data were performed using the two-tailed Student’s t-test (SPSS 13.0 software; SPSS, Chicago, IL). P values of <0.05 were considered statistically significant (⁎ P < 0.05; ** P < 0.01). Analysis of variance was used for multiple group comparison on antitumor effect examination.

**SUPPLEMENTARY MATERIAL**

**Figure S1.** Characterization of bone marrow-derived DCs.

**Figure S2.** DC migration assay in vivo.

**Figure S3.** Fluorescence-activated cell sorting analysis of CD4^+CD25^+ T-cells in draining lymph nodes (DLNs) from mice treated with Ad-Δ87/IL12/GMCSF and/or DCs.

**ACKNOWLEDGMENTS**

This work was supported by grants from the Ministry of Knowledge Economy (10030051, C.-O.Y.), the Korea Science and Engineering Foundation for Medical Science, Yonsei University College of Medicine, (27-2009-00252, C.-O.Y.), and a Faculty Research Grant from Yonsei University (2009-0029220, C.-O.Y.), the Korea Food and Drug Administration (KFDA-10172-332 to C.-O.Y.), and a Faculty Research Grant from Yonsei University College of Medicine (6-2010-00052, C.-O.Y.). S.-N.Z., J.-H.H., J.-Y.Y., and K.-J.C. are graduate students sponsored by the Brain Korea 21 Project for Medical Science, Yonsei University College of Medicine, Seoul, South Korea. I.-K.C. is a graduate student sponsored by KOSEF through National Core Research Center for Nanomedical Technology. The authors declared no conflict of interest.
