Detection of a small shift in a broad distribution

Bernd A. Berg

Department of Physics, Florida State University, Tallahassee, FL 32306-4350, USA

Abstract

Statistical methods for the extraction of a small shift in broad data distributions are examined by means of Monte Carlo simulations. This work was originally motivated by the CERN neutrino beam to Gran Sasso (CNGS) experiment for which the OPERA detector collaboration reported in a broad distribution a time shift by \( \pm 7.1 \) ns despite the fact that the fluctuation of the average time is with \( \pm 23.8 \) ns much larger. Although the physical result has been withdrawn, statistical methods that make such an identification in a broad distribution possible remain of interest.

Key words: Monte Carlo Methods in Statistics, Monte Carlo, Statistics, Neutrino Departure Time Distribution

1. Introduction

In highly publicized CERN announcements [1] it was claimed that neutrinos from the CNGS arrived at Gran Sasso

\[
\delta t = \left[ -57.8 \pm 7.8 \text{ (stat.)} +8.3_{-5.9} \text{ (sys.)} \right] \text{ ns} \quad (1)
\]

too early, violating the \( \delta t = 0 \) limit set by the speed of light. Meanwhile, it appears that initially overlooked systematic errors have wiped out the result, but the identification of the statistical part remains of interest as it exemplifies the extraction of a small shift from a broad distribution. The purpose of this article to shed light on subtleties of an analysis, which leads to the statistical part of the estimate (1).

The CNGS sample of 15,223 neutrinos was produced in extractions that last about 10,500 ns each.

Two different types of extractions were used leading to probability densities (PD)

\[
p_k(t), \quad k = 1, 2 \quad (2)
\]

for neutrinos departure times, which are reproduced here in Fig. 1 within a precision allowed by reading them off from Fig. 11 of [1]. The PD used in our paper have been discretized in intervals of 1 ns and can be downloaded from the author’s website [2].

One can now perform a statistical bootstrap [3] analysis by Monte Carlo (MC) generation of departure times with the PD of Fig. 1. This is already remarked in [1], where the application remains limited to testing of their maximum likelihood procedure on a sample of 100 MC data sets. As the MC generation of departure times can be repeated almost arbitrarily often with distinct random numbers, one can analyze and verify statistical meth-
ods that one wants to apply to discover a shift in the data.

For the uniform PD over 10 500 ns, it has been noted [4] that with \( n = 16 111 \) events the variance of the departure time average \( \bar{t} \) is approximately \( \Delta \bar{t} = 24 \) ns, i.e., much larger than the statistical error bar in Eq. (1). It will be discussed in this paper that the time shift \( \delta t \) (1) defined in [1] behaves indeed quite differently than a statistical fluctuation of the time average

\[
\delta t = \frac{n_1 \delta t_1 + n_2 \delta t_2}{n_1 + n_2}, \quad \delta t_i = \bar{t}_i - \hat{t}_i, \quad i = 1, 2
\]

Here \( \bar{t}_i \) are the measured departure time averages, \( \hat{t}_i \) are the mean departure times obtained from the corresponding PD, and \( n_i \) are the numbers of events in each extraction. The distinction between \( \delta t \) (1) and \( \delta \bar{t} \) (3) is made by an overline on \( t \) or not. Obviously,

\[
\langle \delta t \rangle = \langle \delta \bar{t} \rangle
\]

holds for the expectation values, but their error bars behave differently.

To set the groundwork, it is shown in section 2 for the uniform distribution that a shift \( \delta t = -57.8 \) ns can be identified with certainty (probability to miss it \( < 10^{-36} \)) when there are \( 15 223 \) events and the departure time range is 10 500 ns. In section 3 the MC generation of departure times is described. Section 4 gives examples of descriptive histograms from MC data. Suggested by the uniform distribution, the front tails of the distributions are of particular interest. For their study the cumulative distribution function (CDF) is far better suited than histograms, because it allows easily to focus on outliers. This is investigated in section 5. To estimate the shift value \( \delta t \), the maximum likelihood method is used in [1]. In section 6 features of this method are calculated by applying it to a large number of MC generated departure time samples.

Independently of the special example, the approaches discussed in sections 2 to 6 are of interest, because they address the general problem of extracting a precise estimate of a shift from a broad distribution. Summary and conclusions follow in section 7.

2. Uniform Distribution

Using the uniform PD over a time window of 10 500 ns, the standard deviation of the average

\[
\bar{t} = \frac{1}{n} \sum_{j=1}^{n} t^j
\]

is for \( n = 15 223 \) events much larger than the statistical error bar quoted in Eq. (1), namely approximately

\[
\Delta \bar{t} = 25 \text{ ns}.
\]
How can this be? That the average (5) fluctuates with the variance (6) is unavoidable. However, the effect we are after is a systematic shift of each departure time by an amount $\delta t = -57.8$ ns. Again for the uniform uniform distribution, drawn in Fig. 2, it is easily illustrated that this can very well be identified. Events indicated on the left of the figure are impossible unless there is a shift. Now, with a shift of $-57.8$ ns the probability to find a particular event to the left of the uniform PD is given by

$$p = \frac{57.8}{10500} = 0.005505\ldots$$

and the probability to find none is

$$(1 - p)^{15672} = 10^{-36.5}.$$ (8)

The distance of the smallest time from the left edge of the uniform PD is a lower bound on $\delta t$ and a direct estimate for the time shift (1) is

$$\delta t = n_{\text{left}} 10500 \text{ ns} / 15223,$$ (9)

where $n_{\text{left}}$ is the number of events observed on the left outside of the uniform PD. Confidence limits can be established from the binomial distribution.

For the tiny range of 57.8 ns indicated by the somewhat thicker line on the right side of the uniform PD in Fig. 2, the situation is the other way round. It has to be empty when there is a shift by $\delta t = -57.8$ ns. The probability that this happens by chance when there is in fact no shift is also given by (9). When $\delta t$ is not known the distance of the largest measured time from the right edge of the uniform PD is an upper bound on $\delta t$.

We do not pursue the uniform PD any further, because we are interested in the more complicated case of the less sharp PD of Fig. 1.

3. MC generation of departure times

As mentioned in the introduction, the PD of Fig. 1 have been discretized in 1 ns intervals and are available on the Web [2]. The resolution of 1 ns allows for easy MC generation of departure times and is sufficient for the intended accuracy of the estimate of a shift. In the following our thus defined models are labeled by $k = 1, 2$. The probabilities as function of time $t$ are defined by

$$p_k(t) = p_k(i^t) \text{ for } i^t \leq t < i^t + 1,$$ (10)

where $i^t$ are integer times in ns units. As it is convenient for the MC generation of departure times, the normalization for the discretized PD is (distinct from Fig. 1) chosen so that

$$p_k^{\text{max}} = \max_i [p_k(i)] = 1.$$ (11)

holds. Proper normalizations $\sum_i p_k(i) \Delta t_k = 1$ could still be achieved by choosing instead of ns some unconventional unit for $\Delta t_k$. For the generation of correctly distributed random times this is irrelevant. Model 1 probabilities $p_1(t)$ are enlarged in Fig. 3 for a short time range.
After discretization the smallest \( i_1^{\text{min}} \) and largest \( i_1^{\text{max}} \) times with non-zero \( p_k(i^t) \) values are

\[
i_1^{\text{min}} = 359 \quad \text{and} \quad i_1^{\text{max}} = 15,368,
\]

\[
i_2^{\text{min}} = 12 \quad \text{and} \quad i_2^{\text{max}} = 19,877.
\]

These ranges include a number of zero probabilities in particular for the large \( i^t \) values. MC generated departure times \( t^j_k \) \((j = 1, \ldots, n)\) with \( n \) the number of data are obtained from uniformly distributed random numbers \( t \) in a range enclosing \((i_{\text{min}}^k, i_{\text{max}}^k + 1)\), here chosen to be \((1,22000)\): for model \( k \) a proposed random time \( t \) is accepted with probability \( p_k(i^t) \) for \( i^t \leq t < i^t + 1 \). If \( t \) is rejected, the procedure is repeated until a value gets accepted, which then becomes a data point \( t^j_k \). Acceptance rates were close to 40% and the random number generator of Ref. [5] has been used. To avoid direct hits of \( i_{\text{min}}^k \) and associated rounding problems, the proposed random times are shifted by \(+2^{-25}\), which is half the discretization [6] of these random numbers.

4. Histograms

In this section we pursue descriptive statistics and show histograms from samples of \( n = 7612 \) MC generated departure times per model. The exact departure time mean values for our discretized PD of Fig. 1 are (the hat indicates exact):

\[
\hat{t}_1 = \langle t \rangle_1 = 5942.2 \text{ ns}, \quad \hat{t}_2 = \langle t \rangle_2 = 6658.7 \text{ ns},
\]

where model 1 and 2 are again labeled by the corresponding subscripts. We also know from these PD the exact standard deviations for time averages \( \bar{t}_1 \) and \( \bar{t}_2 \), each over \( n = 7612 \) events:

\[
\hat{\Delta \bar{t}}_1 = 33.4 \text{ ns}, \quad \hat{\Delta \bar{t}}_2 = 33.8 \text{ ns}.
\]

Their combined standard deviation is

\[
\hat{\Delta \bar{t}} = 23.8 \text{ ns},
\]

which agrees almost with the estimate (6) from the uniform PD.

Together with the PD, Fig. 4 shows (red online) histograms of 150 ns bin width for departure times from a typical [7] MC generated sample of 7612 events per model and again the same histograms (green online) shifted by \(-57.8 \text{ ns}\). This illustrates how small the effect is, which ought to be unambiguously identified.

Rounded to nearest integers the mean values for the time averages of the data of Fig. 4 are

\[
\bar{t}_1 = (5936 \pm 34) \text{ ns}, \quad \text{(model 1)}, \quad \bar{t}_2 = (6703 \pm 34) \text{ ns}, \quad \text{(model 2)}.
\]

Both are within their error bars consistent with the mean values (12) of the PD. The actual statistical fluctuations of these two MC data sets are (using \( \bar{t}_1 = 5935.5 \) and \( \bar{t}_2 = 6703.2 \))
Fig. 5. Histograms of departure times with a combined average fluctuation of $\delta t = -59.6 \text{ ns}$.

Fig. 6. Model 1: Zoom of the leading (left plots) and trailing (right plots) MC generated departure time histograms (red online) together with the PD. Also plotted are the same histograms shifted by $\delta t = -57.8 \text{ ns}$ (green online).

$$\delta \tau_1 = \tau_1 - \dot{\tau}_1 = -6.7 \text{ ns}, \quad (17)$$
$$\delta \tau_2 = \tau_2 - \dot{\tau}_2 = 44.5 \text{ ns}, \quad (18)$$

with an average of $18.9 \text{ ns}$.

To compare the shift of $\delta t = -57.8 \text{ ns}$ with a statistical fluctuation of at least the same size, the MC generation was repeated one million times and in this process 7608 samples (0.76%) with statistical fluctuations $\delta \tau \leq -57.8 \text{ ns}$ were encountered. The PD of the first of these MC samples are shown in Fig. 5. They feature the time averages

$$\tau_1 = (5907 \pm 34) \text{ ns}, \quad \text{(model 1)}, \quad (19)$$
$$\tau_2 = (6575 \pm 34) \text{ ns}, \quad \text{(model 2)}, \quad (20)$$

with the actual statistical fluctuations (using $\tau_1 = 5906.7$ and $\tau_2 = 6575.0$)

$$\delta \tau_1 = \tau_1 - \dot{\tau}_1 = -35.5 \text{ ns}, \quad (21)$$
$$\delta \tau_2 = \tau_2 - \dot{\tau}_2 = -83.7 \text{ ns}, \quad (22)$$

resulting in an average of $-59.6 \text{ ns}$. Figures 6 and 7 zoom into the leading and trailing parts of the departure times of Fig. 4.

The shift by $-57.8$ (from red to green in the online version of Figs. 6 and 7) exceeds now the binsize of 50 ns, while the noise of the histogram entries increases. By visual inspection it is hardly possible to distinguish a shift of all times from a statistical fluctuation. The analysis of the uniform
distribution in section 2 suggest to display the tails of the distribution event by event. Using the empirical CDF this is done in the next section.

5. Cumulative distribution functions (CDF)

For continuous distributions a problem of histograms is that a binsize needs to be chosen. In our case we need a good resolution on the time axis, i.e., a small binsize. However, this increases the noise of the bin average. As the empirical CDF has no such free parameter, it appears more suitable for the analysis at hand. In particular it is well suited for a display of the tails of a distribution, and based on the binomial distribution we will develop their quantitative analysis relying on uniformly distributed random variables, similarly to the well known goodness of fit [6].

The exact CDF of our PD models labeled by $k$ are

$$F_k(t) = \int_{-\infty}^{t} dt' p_k(t') , \quad k = 1, 2 ,$$

(23)

where $p_k(t)$ is given by (10). The empirical CDF $E_k(t)$ of models $k = 1, 2$ are calculated from the data (see, e.g., [6]), which are here MC generated random times. Let the data be $t_k^1, \ldots , t_k^n$ and $t_k^{n+1}, \ldots , t_k^n$ sorted, so that $t_k^i < t_k^{i+1}$ holds for $i = 0, \ldots , n+1$, where the definitions $t_k^0 = -\infty$ and $t_k^{n+1} = +\infty$ have been added. The empirical CDF are then defined by

$$E_k(t) = \frac{i}{n} \quad \text{for} \quad t_k^i \leq t < t_k^{i+1} ,$$

(24)

Shifted by $\delta t$ the empirical CDF are

$$S_k(t) = E_k(t - \delta t) .$$

(25)

For the data sets of random times used in the previous section $F_k(t)$, $E_k(t)$ and $S_k(t)$ with $\delta t = -57.8$ ns are displayed in Fig. 8. The scale on the right ordinates gives the usual probability definition for which a CDF is in the range $[0,1]$, while...
the scale on the left ordinates is chosen to count the number of included data points. Fig. 8 should be compared with Fig. 9, which features a statistical fluctuation of the average time by −59.6 ns. While the −57.8 ns shift is clearly visible for all four cases in Fig. 8, there is no similar signal in three of the four cases depicted in Fig. 9. In the figures on the right side $F_k(t) = 1$ is only slowly approached, because in our approximation of the PD there are still small contributions from the region starting between 15 000 ns and 20 000 ns (about 30 events for model 2 for which the effect is larger than for model 1). These events do not spoil the over-all picture, so that the accuracy of a PD in this region does not really matter.

Visually, shift and statistical fluctuation behave already differently, though not always. The task is now to develop quantitative criteria, which are in this section based on the binomial distribution. Defining

$$F_k^i = F_k(t_k^i) \quad \text{and} \quad G_k^i = 1 - F_k^i$$

the probability for a single data point $t$ to be in the range $0 \leq F_k(t) \leq F_k^i$ is $F_k^i$ and its probability to be in the range $F_k^i < F_k(t) \leq 1$ is $G_k^i$. The probability that $i$ out of $n$ data points are in the $0 \leq F_k(t) \leq F_k^i$ range is

$$p_k^i = \frac{n!}{(n-i)!i!} (F_k^i)^i (G_k^i)^{n-i}.$$  \hspace{1cm} (27)

If there is a shift by $\delta t < 0$ we expect that too many data points populate the $0 \leq F_k(t) \leq F_k^i$ range, so
that

\[ Q_k^i = \sum_{j=i}^n p_k^j \]  

becomes small. It is easy to see that the \( Q_k^i \) are uniformly distributed random variables, when the hypothesis is correct that the data points are created with the distribution \( F_k(t) \). So the usual interpretation [6] of a likelihood that the discrepancy between the hypothesis and the data is due to chance applies to the \( Q_k^i \).

To present an example we give in Fig. 10 an enlargement of the left tail from Fig. 8 by picking out the 32 smallest times per model. Upon inspection of the numbers one finds for model 1 \( t_1^* = 359.985 \) ns and \( F_1^i = F_1(t_1^*) = 5.7 \times 10^{-9} \). This implies \( Q_1^1 = Q_1^2 = 4.3 \times 10^{-5} \) for model 1. For model 2 \( t_2^* = 29.968 \) ns, which gives \( F_2^i = F_2(t_2^*) = 3.5 \times 10^{-6} \) and for \( n = 7612 \) one finds \( Q_2^2 = 0.026 \). Combined, these two events alone give a probability \( Q = Q_1^1 Q_2^1 = 1.15 \times 10^{-6} \) for the likelihood that the discrepancy is due to chance.

To understand the typical behavior encountered for our two distribution functions, we generated 10,000 MC samples. In Fig. 11 average values for \( Q_k^i \) are shown. The almost straight lines at 0.5 are the averages obtained when one generates random times with the underlying PD. The two other lines correspond to the average \( Q_k^i \) obtained when each sample undergoes a shift of \(-57.8 \) ns.

At a first glance the average \( Q_k^i \) values for the smallest times look far less promising than what we may have hoped for from the inspection of our trial sample. For model 1 the average is at 0.017 and for model 2 even at 0.25. At a second look we shall see that this comes mainly from the outliers of the non-Gaussian distribution of the \( Q_k^1 \), while for a majority of cases our trial sample remains typical. Besides \( Q_k^1 \) for the smallest times, an attractive choice for \( Q_k^1 \) is at or close to the minimum of the average, which we choose to be \( i = 80 \) for model 1 and \( i = 160 \) for model 2. Due to the increased number of data there are fewer outliers than for \( Q_k^1 \). Note that for different \( i \) values the \( Q_k^i \) are not statistically independent, because the calculation of \( Q_k^i \) includes all data already used for \( Q_k^j \) with \( j < i \).

We define \( P_k^i(p) \) to be the probability for \( Q_k^i \leq p \). Fig. 12 plots \( P_k^i(p) \) and we find \( Q_1^1 = 0 \) for more than 80% of the samples and \( Q_2^1 = 0 \) for almost 23% of the samples. To combine the results from both models we notice that

\[ Q_3^{ij} = Q_1^i Q_2^j \left[ 1 - \ln(Q_1^i Q_2^j) \right] \]  

is again a uniformly distributed random variable with the interpretation that the discrepancy between data and hypothesis is due to chance (\( Q_3^{ij} \rightarrow Q_1^i Q_2^j \) for \( Q_1^i \) or \( Q_2^j \) to zero). We use the notation \( Q_3^1 = Q_3^{10} \) and find \( Q_3^1 = 0 \) for more than 85% of the samples, where (29) is of course performed before sorting.

We define now \( Q_1^{\min} = Q_1^{50}, Q_2^{\min} = Q_2^{100} \) and \( Q_3^{\min} \) the combination (29) of the two. \( P_k^{\min}(p) \) are

![Fig. 11. Average \( Q_k^i \) as functions of \( i \) from 10,000 samples.](image1)

![Fig. 12. Probabilities \( P_k^i \) for \( Q_k^i \leq p \), \( \delta t = -57.8 \) ns, from 10,000 samples.](image2)
the corresponding probabilities for $Q_k^{\min} \leq p$. In Fig. 13 the $P_k^{\min}(p)$ are plotted versus $p$ using a log scale on the abscissa. The $Q_k^{\min}$ probabilities tend to be small, but never zero. For the combined data we find $Q_3^{\min} < 10^{-7}$ for about 14% and $Q_3^{\min} < 10^{-3}$ for more than 82% of the samples. Now $Q_3^{\min}$ works quite independently from $Q_1^{\min}$, reducing the situations, where their combined estimate $Q_k^{\min} = Q_3^{\min} Q_3^{\min} \left[ 1 - \ln(Q_3^{\min} Q_1^{\min}) \right]$ gives $Q_k^{\min} > 10^{-3}$ to approximately 2.6%. Compare Fig. 13. Although the application of Eq. (29) is not entirely correct in this situation, the related bias is small as it comes from the contribution of single data points $r_k^{\tau}$ to each of the $Q_k^{\min}$.

For the peace of mind we show in Fig. 14 the $P_k^{\min}$ values when no shift is applied to the data. As claimed the $Q_k^{\min}$ turn out to be uniformly distributed random variables in the $[0, 1]$ range with a small bias visible for $Q_k^{\min}$. These are the almost straight $P_k^{\min}(p) = p$ lines. The same analysis shows for $P_k^{\min}(p)$ from 10 000 samples, which are selected so that each exhibits a statistical fluctuation $\delta \tau \leq -57.8$ as about 0.76% of the samples exhibit such a fluctuation it requires the generation of more than 13 million samples. Clearly, the effect on $Q_k^{\min}$ is minor and $P_k^{\min}(p)$ probabilities for $Q_k^{\min} \leq p$ are only slightly enhanced compared to the straight line. The same analysis shows for $Q_k^{\min}$ practically no deviation from the straight $P_k^1(p) = p$ lines as is demonstrated in Fig. 15. These statements remain true when a bias of the type discussed in [4], which enhances the initial tail of the PD, contributes to the shift in the mean value $\delta \tau$.

In summary, there is high probability that a study of the initial tails of the departure time distributions reveals whether there is a statistically relevant shift or not. A similar study could be performed for the back tail of the departure times. One could further expand the analysis of this section to provide an explicit estimate of the shift $\delta t$, similarly as with Eq. (9) for the uniform PD.
6. Maximum likelihood method

For the statistical estimate of the time shift value $\delta t$ a maximum likelihood method is the choice of Ref. [1]. Its properties are studied in this section using 10,000 MC generated samples for each of the PD.

The log likelihoods for our PD (2) are given by

$$\ln L_k(t) = \sum_{i=1}^{n} \ln \left[ p_k(t^i + t) \right], \ k = 1, 2 \quad (30)$$

where the times $t^i$ are MC generated with the PD $p_k(t)$. It is instructive to replot Fig. 1 for logarithms of the probabilities. This is done in Fig. 16 with $p_k(t)$ normalized to $\sum_{i} p_k(t^i) = 1$ where (in accordance with our discretization) $t^i$ is incremented in 1 ns steps. These plots exhibit clearly the locations of small and zero probabilities, which data will (statistically) avoid when they are created with the underlying PD $p_k(t)$. However, when shifting the $t^i$ values by $t$, regions of low probabilities may be hit as discussed in the previous sections.

For our typical sample [7], the resulting $\ln L_k(t)$ functions are displayed in Fig. 17. For model 1 we see for decreasing $t$, just before $-60$ ns, a sharp drop $\ln L_1(t) \rightarrow -\infty$. This comes because the smallest time, $t^{\pi} + t$ hits a tiny probability, which we already encountered in the previous section.

For model 2 the log-likelihood function $\ln L_2(t)$
is smooth down to $t = -65$ ns, while for positive
$t > 12$ ns the largest data point $t^\pi n + t$ hits a
region of very small probability.

Fig. 18 shows a model 2 log-likelihood function
$\ln L_k(t)$ for another of our first ten samples and this
plot is quite similar to the one for extraction 2 in
[1]. In the samples one finds a variety of deviations
from Gaussian shapes, small ones due to the bulk
structure of the PD and large ones due to a few
events in the tails.

Following [1] a step further, parabolic fits are
made to the central region of each sample. To au-
tomatize the fitting procedure the central region
of a model $k$ sample was defined to be the $t$ range
connected with $\delta t_k$ so that $\ln L_k(t) > \ln L_k^{\text{max}} - 10$
holds, where the maximum of the log-likelihood
function is

$$\ln L_k^{\text{max}} = \max_t \left[ \ln L_k(t) \right] = \ln L_k(\delta t_k).$$

Such parabolic fits are included in Fig. 17 and 18.

Let us investigate $\delta t_k$ estimates for random times
generated with the PD (10). In the limit of infinite
statistics

$$\lim_{n \to \infty} \frac{1}{n} \ln L_k(t) = \sum_i p_k(i) \ln p_k(i + t)$$

holds, where the sums ($k = 1, 2$) corresponds to
our discretization time steps of 1 ns. They include
$p_k(i) = 0$ contributions. For $t = 0$ they are zero
due to

$$\lim_{p \to 0} (p \ln p) = 0.$$  

For $t \neq 0$, e.g. already $t = \pm 1$ ns, we can create mis-
matched contributions $p_k(i) \ln p_k(i + t)$ with $p =
p(i)$ finite and $q = p(i + t) = 0$, so that

$$\lim_{q \to 0} (p \ln q) = -\infty$$

becomes possible. Hence, in the limit of infinite
statistics

$$\lim_{n \to \infty} \langle \delta t_k \rangle_n = 0 = \lim_{n \to \infty} \left\langle (\delta t_k)^2 \right\rangle_n,$$

where $\langle \ldots \rangle_n$ are expectation values for samples of
$n$ data per model. Deviations of $\delta t_k$ from zero re-
fect statistical fluctuations and bias due to a finite
statistics. In the following we investigate this for
$n = 7612$.

Direct estimates of $\delta t_k$ are obtained by simply
evaluating the log-likelihood functions (30) for a
sufficiently large region around $t = 0$, which is here
taken to be $[-65 \text{ ns}, 65 \text{ ns}]$. The positions of the
maxima of the parabolic fits give also estimates of
$\delta t_k$, which deviate to some extent from the direct
estimates. For instance, for our typical sample of
Fig. 17 we find by direct estimate ($t$ in steps of 1 ns)

$$\delta t_1 = 5 \text{ ns} \quad \text{and} \quad \delta t_2 = 6 \text{ ns},$$

while the parabolic fits give

$$\delta t_1 = (2.3 \pm 9.9) \text{ ns}, \quad \delta t_2 = (3.7 \pm 10.6) \text{ ns},$$

where, as in [1], the error bars are standard devia-
tions obtained from the parabolic fits under the
assumption that the center of the likelihood function is described by a Gaussian distribution. That the $\delta t_k$ values in (36) and (37) are both positive is an accident. E.g., for the sample of Fig. 18 one finds by direct estimate $\delta t_2 = -6$ ns and $\delta t_2 = (-4.7 \pm 11.4)$ ns from the parabolic fit.

The analysis of our 10 000 samples allows to improve on the questionable Gaussian assumption. It turns out that the direct estimates of the $\delta t_k$ values from $\ln L_k^{\text{max}} = \ln L_k(\delta t_k)$ are more robust than the estimates from parabolic fits, which can become unstable due to non-Gaussian behavior. One rare example is shown in Fig. 19. In that case a small $t$ shift, either to the left or to the right, does immediately shift one of the extrema $t_2^\pm$ or $t_2^n$ into regions of very small likelihood, so that a parabolic fit becomes impossible.

For a finite statistics the extraction of $\delta t_k$ from a given log-likelihood function $\ln L_k(t)$ is a non-linear procedure, so that we have to anticipate a bias [6], which means

$$\langle \delta t_k \rangle_n \neq 0.$$  

(38)

The exact maximum position, from which the deviation by a shift $t$ has to be calculated, is at $\langle \delta t_k \rangle_n$. This bias falls off with $1/n$, so that it tends to get swallowed by the $1/\sqrt{n}$ behavior of the statistical noise. For the direct $\delta t_k$ estimates we find in our models

$$\langle \delta t_1 \rangle_{7612} = (-0.62 \pm 0.10) \text{ ns},$$  

(39)

$$\langle \delta t_2 \rangle_{7612} = (+0.22 \pm 0.11) \text{ ns},$$  

(40)

which is in each case smaller than our discretization. The standard deviations were

$$\Delta \delta t_1 = 9.8 \text{ ns} \quad \text{and} \quad \Delta \delta t_2 = 10.2 \text{ ns}.$$  

(41)

Combining both models gives the number of the abstract

$$\Delta \delta t = 7.1 \text{ ns}.$$  

(42)

To obtain estimates of these numbers from parabolic fits one has to eliminate 19 samples for which the fits are erratic. Afterwards, averaging the standard deviations of the fits gives

$$\Delta \delta t_1 = (9.7 \pm 0.9) \text{ ns}$$  

(43)

$$\Delta \delta t_2 = (10.1 \pm 1.1) \text{ ns},$$  

(44)

where the error of the error is with respect to estimates on a single sample. Hence, for both models combined

$$\Delta \delta t = (7.0 \pm 0.7) \text{ ns}.$$  

(45)

The $\Delta \delta t = 7.5 \text{ ns}$ value from the Gaussian fit to our typical sample is well consistent. Bias estimates stay much smaller than the standard deviation, but differ from (39) as the fitting itself imposes a new non-linearity. We abstain from giving these numbers, because they reflect also details of the fitting procedure like our definition of the central region.

As the distributions of the $\delta t_k$ are non-Gaussian, one may wonder whether Gaussian confidence limits provide a correct interpretation of the error bar (42). Indeed, the empirical peaked CDF [6] found for the $\delta t$ estimates via the direct method is broader than the Gaussian peaked CDF with standard deviation 7.1 ns. See Fig. 20, which relies for the empirical peaked CDF on $10^6$ random times samples. The largest fluctuation in the negative direction is at $-35.5$ ns which has thus a probability of approximately $10^{-6}$. This is safely away from $-57.8$ ns.

Finally in this section, we address correlations between the statistical fluctuations of $\delta t_k$ and those of $\delta t_k$. Using $i = 1, \ldots, N = 10 000$ samples, we denote $\delta t_k^i$ for sample $i$ by $\delta t_k^i$ and $\delta t_k$ by $\delta t_k^{\text{max}}$ by $\delta t_k^i$. They have expectation values

$$\langle \delta t_k^i \rangle_{7612} = \langle \delta t_k - \text{bias} \rangle_{7612} = 0.$$  

(46)
Fig. 21. Scatter plot of $(\delta t_i, \delta t_i - \text{bias})$, $i = 1, \ldots, n$, $N = 10000$ (model 1).

The bias correction is so small that it can as well be ignored. Defining the correlation coefficients by

$$C(\delta t_k, \delta t_k) = \frac{\sum_{i=1}^{n} \delta t_i^2 (\delta t_i - \text{bias})}{\sum_{i=1}^{n} |\delta t_i (\delta t_i - \text{bias})|}, \quad (47)$$

their calculation from our $N = 10000$ samples gives

$$\langle C(\delta t_1, \delta t_1) \rangle_{7612} = -0.47, \quad (48)$$
$$\langle C(\delta t_2, \delta t_2) \rangle_{7612} = -0.43. \quad (49)$$

This, at the first glance, non-intuitive anticorrelation is for model 1 displayed in Fig. 21. It may be explained as follows. When $\delta t$ fluctuates to negative values, there is an overpopulation of small $t$ values in the sample. Therefore a shift in the same direction has a higher probability to produce large negative contributions to the log-likelihood function (30) than a shift in the opposite direction.

When the boundaries of the distribution are sufficiently sharp, uniform probabilities from binomials of the CDF provide excellent indicators. Subsequently it has been demonstrated that the maximum likelihood method gives a quantitative estimate of the shift $\delta t$ and its statistical error, while bootstrap simulations allow one to avoid Gaussian assumptions. Obviously, the analysis of this paper can be re-done for other desired sample sizes.
