\textbf{ABSTRACT}: In this research, the (1−x)(BNKT-BST)-xBFT\textsubscript{a} ceramics were fabricated via a solid-state mixed oxide method and sintered at the temperature of 1125 °C for 2 h dwell time in order to obtain dense ceramics. The XRD and Raman data revealed the coexisting rhombohedral and tetragonal phases for all samples. The density increased with increasing the additive content, which resulted in the improvements of mechanical and dielectric properties. The maximum dielectric ($\varepsilon_r$ = 1799) and mechanical properties ($H_V$ = 6.30 GPa, $H_K$ = 5.30 GPa, $E$ = 97 GPa and $K_{IC}$ = 1.95 MPa.m$^{1/2}$) were observed. The leakage current density ($J$) increased with increasing amount of the additive at high electric fields of 30 kV/cm while the resistivity ($\rho$) was also found to decrease with the additive. The magnetocapacitance (-MC\%\textsubscript{e}) value also increased with increasing of the additive. The obtained results suggested that the additive not only enhanced the mechanical but also improved electrical properties of the studied samples.

\textbf{KEYWORDS}: lead-free ceramic, bismuth sodium potassium titanate, magnetocapacitance, leakage current density

\textbf{INTRODUCTION}

Although lead-based materials such as lead zirconate titanate (PZT) show good electrical properties, these materials are toxic, volatile, and harmful to human health and the environment (PZT contains 60 wt\% of PbO) \cite{1,2}. Therefore, lead-free materials have been developed, and intensively studied due to the environmental concern \cite{1–3}. Among the materials, bismuth sodium potassium titanate or $\text{Bi}_{0.5}\text{(Na}_{1−x}\text{K}_{x})_{0.5}\text{TiO}_3$ (BNT) ceramic is an interesting lead-free piezoelectric material due to the fact that it presents good electrical properties such as good ferroelectric and piezoelectric properties \cite{2}. Much attention has thus been focused on BNT-based materials, i.e., BNT-BT, BNT-BZ, and BNT-KNN \cite{2}. Many modified BNT materials have been studied due to some problems from the pure BNT such as the large coercive field ($E_c \sim 73$ kV/cm) and high electrical conductivity which is not suitable for practical applications \cite{4}. Furthermore, the modified BNT materials present many interesting properties. Many authors have reported that bismuth sodium potassium titanate or $\text{Bi}_{0.5}\text{(Na}_{1−x}\text{K}_{x})_{0.5}\text{TiO}_3$ (BNKT) ceramics, a modified BNT, possess many desire properties as compared to the pure BNT ceramic \cite{4–7}. Jaita et al \cite{6} reported that BNKT modified by barium strontium titanate ($\text{Ba}_{0.70}\text{Sr}_{0.30}\text{TiO}_3$) or BNKT-BST showed many good electrical properties.

www.scienceasia.org
such as high electric field-induced strain response. Many modified BNKT-BST ceramics have also been developed, and these materials showed many high electrical properties. For example, BNKT-BST doped with La ceramics showed an improvement of electric field-induced strain response [8], BNKT-BST doped with FeO3 nanoparticles promoted a diffuse phase transition and reduced resistivity with high electric field-induced strain [6], and BNKT-BST doped with Nb presented high normalized strain coefficient (d33) [7]. Therefore, further modified BNKT-BST materials are expected to be good for future development of electronic materials.

Barium iron tantalate, Ba(Fe0.5Ta0.5)O3 or BFTa is a high dielectric material which presents the dielectric constant varying from 103−105 for a wide temperature range with frequency dependence and no ferroelectric property [9, 10]. At room temperature (RT), BFTa ceramic has a space group Pm3m (211) [10] and the lattice parameter of 4.056 Å [11]. Materials containing BFTa present many advantage properties as compared with those of a pure BFTa such as BFTa-Ba(Zn1/3Ta2/3)O3, which showed higher dielectric constants with lower loss tangents [12], BFTa-BiFeO3, which presented an improvement in magnetic properties [9] and K0.5Na0.5NbO3-BFTa which presented an improvement in the ferroelectric properties [13]. Phase transition temperature of BaTiO3-BFTa system can be tuned by BFTa additive [14]. It is expected that properties of other materials which contain BFTa may show many interesting properties.

For some applications, i.e., at high stress or high electric field, the mechanical properties are needed. However, most works for the modified BNKT-BST ceramics are concentrated in only their electrical properties. Furthermore, the mechanical properties of the modified BNKT-BST ceramics have not been widely investigated. In this work, the mechanical properties of BNKT-BST ceramics modified by BFTa were thus investigated. Electrical properties of these ceramics were also studied. It was found that BFTa additive could improve both mechanical and electrical properties of the studied ceramics.

MATERIALS AND METHODS

The conventional mixed oxide technique was applied to synthesize the mixed powder of (1−x)(Bi0.5Na0.5)0.2Ta0.2O3−0.03(Ba0.7Sr0.3)TiO3-xBa(Fe0.5Ta0.5)O3, referred to as (1−x)(BNKT-BST)-xBFTa. Reagent-grade powders of Bi2O3, Na2CO3, TiO2, K2CO3, BaCO3, SrCO3, Fe2O3, and Ta2O5 were used as the starting raw materials. All carbonate powders were first dried at 120°C for 24 h in order to remove any moisture. The raw materials of BNKT-BST and BFTa were separately stoichiometrically weighed and mixed by ball milling in 99.9% ethanol for 24 h and the slurry was dried using an oven. Dried BNKT-BST and BFTa powders were separately calcined in a closed Al2O3 crucible at 900°C/2 h and 1200°C/4 h, respectively. Both calcined powders were then weighed and mixed in order to produce an appropriate stoichiometry for the compositions (1−x)(BNKT-BST)-xBFTa with x = 0, 0.01, 0.02, and 0.03 mol fraction. The mix proportion (by mol%) of each condition of the (1−x)(BNKT-BST)-xBFTa ceramics and number of sample were showed in Table 1. After drying and sieving, the powders were granulated by adding a few drops of 4 wt% polyvinyl alcohol (PVA) as a binder and then pressed into disks with 10 mm in diameter and about 1.3 mm in thickness. Finally, the pellets were placed in a sealed alumina crucible and covered with a powder of the same composition before being sintered at 1125°C for 2 h dwell time with a heating/cooling rate of 5°C/min.

An X-ray diffractometer (XRD-Phillip, X-pert) was used to identify phase of sintered ceramics. Bulk density of all ceramics was determined using the Archimedes’ method. Raman spectra were obtained by Raman spectroscopy for all ceramics. For the measurement of mechanical properties, the samples were polished to a mirror finish. The well-polished ceramics were then subjected to microhardness tester for both Knoop (HK) and Vickers hardness (HV) determination. The indentation load used was 1000 N which was applied for 15 s holding time. Young modulus (E) was determined following the method described by Marshall et al [15]. Fracture toughness (Kic) was also calculated from the cracks’ length propagated from 4 corners of the indentation impression following the method described by Anstis et al [16]. For the electrical measurements, the samples were polished to produce very smooth and parallel surfaces, and silver

Fig. 1 X-ray diffraction patterns (XRD) of the \((1-x)\)(BNKT-BST)-xBFTa ceramics: (a) \(d = 1.2–5.0\) Å, (b) \(d = 1.90–2.01\) Å, and (c) \(d = 2.22–2.29\) Å.

paste was coated on both sides of the samples and fired at 700 °C for 30 min. Dielectric properties were carried out using 4284A LCR-meter. Leakage current density versus applied electric field \((J-E)\) curve was carried out at electric field of 30 kV/m.

The resistivity \((\rho)\) and the magnetocapacitance (-MC\%) were also calculated.

RESULTS AND DISCUSSION

Green pellets of all compositions were sintered at the optimum temperature of 1125 °C for 2 h. High bulk densities of 5.80–5.86 g/cm\(^3\) were achieved (Table 2). Based on the density values, it was clearly found that the addition of BFTa into BNKT-BST ceramic caused an increase in samples’ density value. This is probably because BFT ceramic has the higher density value (7.32–7.40 g/cm\(^3\)) \([9, 12]\) when compared to that of BNKT-BST (5.80 g/cm\(^3\)) \([6]\). Thus, the increasing of density value was observed in the studied system.

X-ray diffraction data for all ceramics are shown in Fig. 1(a). It can be seen that all compositions possess a single perovskite phase without secondary phases or impurity peaks within the limit of the XRD machine. The XRD data also revealed the coexisting rhombohedral and tetragonal phases throughout the entire compositional range \([17]\) as evidenced by a slight splitting of \((111)_{R}/(1\bar{1}1)_{R}\) rhombohedral peak at \(d = 2.22–2.28\) Å and \((002)_{T}/(200)_{T}\) tetragonal peak \(d = 1.92–2.00\) Å. For detailed analysis, the XRD patterns for selected narrow angular ranges of \(d = 1.90–2.01\) Å and \(d = 2.22–2.29\) Å are presented in Fig. 1(b) and (c), respectively. With an increasing BFTa content, the XRD peaks gradually shift to higher d-spacing. This can be caused by the differences in the ionic radii between Na\(^+\), Bi\(^{3+}\), K\(^+\), Sr\(^{2+}\), and Ba\(^{2+}\) at the A-site and Ti\(^{4+}\), Fe\(^{3+}\), and Ta\(^{5+}\) at the B-site which is a result of structural distortion.

To study the effect of BFTa addition on the phase formation in more details, Raman scattering technique was employed. Raman spectra of the (BNKT-BST)-xBFTa ceramics at RT are displayed in Fig. 2. The obtained data showed that there were 4 main regions in the spectrum, and this information agrees with many previous reports \([18–20]\). The 4 main regions in the Raman data are as follows: (1) the observed vibrational mode at \(\sim 135\) cm\(^{-1}\) is linked with the vibrations of A-site cations in the perovskite structure, influenced by A-site doping; (2) the 260 cm\(^{-1}\) mode is related to Ti–O vibrations. Furthermore, this mode becomes broader and starts splitting into two bands with increasing the additive content, and this may be due to the co-occupancy of different cations (Ti/Ta, Fe) with different sizes at the B-site that results in the distortion of the unit cell \([18]\); (3) the 450–700 cm\(^{-1}\) region hosts modes that correspond to the vibration of the TiO\(_6\) octahedra. In this region, there is an overlapping band which was slightly separated into two distinct bands for the samples containing higher amount of additive, which demonstrated particular phonon behavior in the structural evolution and a phase mixture; and (4) the high-frequency region above
700 cm\(^{-1}\) feature modes can correspond to A\(_1\) (longitudinal optical) and E (longitudinal optical) overlapping band \([19, 20]\), respectively. The Raman scattering and the XRD data indicated that the additive significantly influences the host BNKT-BST perovskite.

Fig. 3 displays SEM micrographs of as-sintered surface and fracture surface of the ceramics (inset: products after sintering process). The average grain size values are also summarized in Table 2. From the as-sintered surface images (left), microstructure and granular morphology are considerably well-developed in all samples. The unmodified sample had an average grain size of 0.59 \(\mu\)m. After adding the additive, the average grain size slightly decreased to 0.55–0.58 \(\mu\)m. The reduction in grain size may be mainly attributed to grain growth inhibition as a result from solute drag effect \([21–23]\). Thus, the incorporation of BFTa can restrain grain growth in the BNKT-BST ceramics. Normally, the growth mechanism can occur by the grain boundary motion due to a reduction of the total grain boundary surface energy. Furthermore, the thermal energy can lead to an increase in the diffusion rate and consequently intensify the formation of necks between grains. Thus, the reason for the decrease of grain size can be explained based on the difference of ionic radii between host ion (Ti\(^{4+}\)) and doped ions (Fe\(^{3+}\) and Ta\(^{5+}\)). Since the ionic radius of Fe\(^{3+}\) (0.78 Å) and Ta\(^{5+}\) (0.74 Å) are larger than that of Ti\(^{4+}\) (0.605 Å), higher Fe and Ta concentration doping can result in less mobility of the ions and cause inhibited grain growth \([22]\). For fractured surface mode (right), the unmodified sample exhibited mainly intergranular fracture mode which indicated its relatively weak grain boundaries. The additive caused fracture behavior to switch from intergranular to transgranular mode, suggesting an increase in grain bountion dary strength \([23]\).

Fig. 4 (a) Plots of density, \(H_T\) and \(H_K\), (b) \(E\) and \(K_{IC}\) as a function of the BFTa content of the ceramics.

www.scienceasia.org
elastic modulus ($E$), and fracture toughness ($K_{IC}$) were determined. The $H_V$ and $H_K$ of these ceramics were determined with a Leco Hardness Tester. Indentation was performed with a Vickers and Knoop indenter under loads of 1.96 N. The load was maintained for 15 s holding time. The $H_V$ and $H_K$ values were calculated using following equations [24,25]:

$$H_V = \frac{(1.8544)P}{d^2} \quad (1)$$
$$H_K = \frac{(14.299)P}{d^2} \quad (2)$$

where $P = \text{load (N)}$ and $d = \text{half-length of long diagonal (µm)}$. The $E$ and $K_{IC}$ values were also calculated using the following equations: [24,26]

$$E = \frac{\alpha H_K}{(b/a) - (b'/a')} \quad (3)$$
$$K_{IC} = 0.016 \left( \frac{E}{H_V} \right)^{1/2} \left( \frac{P}{c^3/2} \right) \quad (4)$$

where $\alpha = \text{Marshall constant (~0.45)}$, $b/a = \text{length of the } H_K \text{ tip mark with short diagonal/length of the } H_K \text{ tip mark with long diagonal (0.14)}$, $b'/a' = \text{length of the } H_K \text{ indentation with short diagonal/length of the } H_K \text{ indentation with long diagonal}$, and $c = \text{crack length (m)}$. All mechanical corresponding values are also displayed in Table 2. Based on Fig. 4 and Table 2, it can be seen that the $H_V$ and $H_K$ values of the unmodified sample were 5.30 GPa and 4.10 GPa, respectively. The $H_V$ and $H_K$ values initially increased with increasing the additive content, and then reached the maximum value of 6.30 GPa and 5.10 GPa, respectively, for the $x = 0.03$ ceramic. An improvement of mechanical properties in the ceramics with high additive concentration is likely due to the effect of the reduced average grain size and densification improvement [27]. From $E$ and $K_{IC}$ studied in Fig. 4(b), it was found that $E$ and $K_{IC}$ increased with the increasing of the additive content. The maximum $E = 97$ GPa and $K_{IC} = 1.95 \text{ MPa.m}^{1/2}$ were also obtained for the $x = 0.03$ ceramic. Based on the multi-domain grain model, ceramics with smaller grain size could possess single domain state and residual stress generated during sintering could not be released; this may lead to the improvement of the apparent $K_{IC}$ [21]. Moreover, the additive caused fracture behavior to switch from intergranular to transgranular mode, suggesting an increase in grain boundary strength. This may be another reason for $K_{IC}$ improvement. Hence, it seems that the maximum mechanical properties obtained in this study could be correlated to the combination of smaller grain size, densification improvement and optimum strength of grains and grain boundaries [23].

At room temperature, dielectric constant ($\varepsilon_r$) and dielectric loss tan $\delta$ as a function of frequency for all ceramics are shown in Fig. 5. The $\varepsilon_r$ decreased with increasing the measurement frequencies whereas tan $\delta$ values increased. The $\varepsilon_r$ and tan $\delta$ measured at a frequency of 1 kHz are also listed in Table 3. It can be seen that the dielectric constant was improved by the additive. The $\varepsilon_r$ (at 1 kHz and RT) increased from 1616 for the unmodified ceramic to 1799 for the $x = 0.03$ ceramic while the dielectric loss was slightly increased with the additive. In this work, the better densification of the modified ceramics may be a factor for the improvement of dielectric properties [28]. However, the slight increase in dielectric loss for the samples contained higher amount of the additive may be related to a formation of Fe$^{3+}$ and Fe$^{2+}$ in the samples [29]. This may produce an enhancement of electrical conduction due to electron hoping mechanism between Fe$^{3+}$ and Fe$^{2+}$.

In this work, the effect of an applied magnetic field on dielectric constant at room temperature ($\varepsilon_r$) was also studied. A change in the $\varepsilon_r$ value under the applied magnetic field ($H$) was observed. The magnetocapacitance (-MC%) was calculated via the

[Table 3: Electrical and magnetic properties of the (1-x)(BNKT-BST)-xBFTa ceramics.]

| $x$     | $\varepsilon_r$ | tan $\delta$ | $J$ (A/cm$^2$) | $\rho$ (10$^{11}$Ωm) | -MC (%) |

following equation: [9, 30, 31]

\[ -MC(\%) = \frac{\varepsilon(H) - \varepsilon(0)}{\varepsilon(0)} \times 100 \]  

(5)

where \(\varepsilon(H)\) is the dielectric constant under an applied magnetic field of 1 Tesla and 1 kHz (at RT) and \(\varepsilon(0)\) is the dielectric constant without an applied magnetic field. Based on Fig. 6 and Table 3, the \(-MC\)% value sharply increased from 0.09\% for the unmodified sample to 2.10\% for the \(x = 0.01\) ceramic, but subsequently slightly increased with further increasing the additive content. The maximum value of \(-MC\)% is 2.19\% for the \(x = 0.03\) ceramic at the maximum magnetic field 1 Tesla and a frequency of 1 kHz, suggesting that the additive produced the MC effect [9]. This may be due to the change in resistance at bulk grain and grain boundary of the samples after the additive was added. These resistances can be changed under the applied magnetic field [9, 32], as a result in a change of \(\varepsilon_r\) value [33].

Leakage current density \((J)\) versus applied electric field \((E)\) of the ceramics was carried out as seen in Fig. 7 and the values are listed in Table 3. The unmodified ceramic showed \(J\) value of approximately \(5.74 \times 10^{-6} \) A/cm². An increase in the leakage current was observed for the higher additive content ceramics. The \(J\) value increased with increasing amount of the additive at high electric fields (30 kV/cm), and exhibited the maximum value of \(9.80 \times 10^{-6} \) A/cm² for the \(x = 0.03\) ceramic. The presence of leaky behaviour for the modified ceramic is probably because the additive produced higher leakage currents which can be linked with the electron hoping mechanism. The higher additive content ceramics exhibited the higher conductivity and were easy to breakdown when applied voltages. As expected, the resistivity (at 30 kV/cm) was also found to decrease with the amount of the additive as seen in the inset of Fig. 7. This is in accordance with the result of dielectric loss value.

CONCLUSION

In this work, the \((1-x)(BNKT-BST)-xBFTa\) ceramics have been successfully synthesized by a solid-state mixed oxide method. The coexistence of rhombohedral and tetragonal phases is present throughout the entire compositional range. The reduction of grain size was observed when the additive was added. The addition of BFTa was also found to improve the densification, mechanical and dielectric properties of the BNKT-BST ceramics. The \(x = 0.03\) ceramic showed the maximum room temperature dielectric properties \((\varepsilon_r = 1799, \tan \delta = 0.064)\) and mechanical properties \((H_V = 6.30 \text{ GPa}, H_K = 5.30 \text{ GPa}, E = 97 \text{ GPa}, \text{ and } K_{IC} = 1.95 \text{ MPa.m}^{1/2})\) compared to those of the end-members. The leakage current density \((J)\) and magnetocapacitance \((-MC\%)\) values increased while the resistivity \((\rho)\) was found to decrease with the amount of the additive. From the results, the BFTa additive can improve both mechanical and electrical properties of the studied ceramics. Overall, these results indicate that these ceramics are one of the promising candidates for further development for electrical applications.
