We study the phase diagram of the one-dimensional bosonic Hubbard model with contact ($U$) and near neighbor ($V$) interactions focusing on the gapped Haldane insulating (HI) phase which is characterized by an exotic nonlocal order parameter. The parameter regime ($U$, $V$ and $\mu$) where this phase exists and how it competes with other phases such as the supersolid (SS) phase, is incompletely understood. We use the Stochastic Green Function quantum Monte Carlo algorithm as well as the density matrix renormalization group to map out the phase diagram. Our main conclusions are that the HI exists only at $\rho = 1$, the SS phase exists for a very wide range of parameters (including commensurate fillings) and displays power law decay in the one body Green function. In addition, we show that at fixed integer density, the system exhibits phase separation in the ($U$, $V$) plane.

I. INTRODUCTION

The bosonic Hubbard model (BHM) has continued to attract interest since its introduction by Fisher et al.\textsuperscript{1}. This interest stems from the versatility of the model and its use in understanding many physical phenomena such as adsorption of bosonic atoms on surfaces\textsuperscript{2}, effect of disorder on superfluids and the appearance of the compressible Bose glass phase\textsuperscript{1}, quantum phase transitions between strongly correlated exotic phases etc. In addition, in the hardcore limit, the BHM can be mapped onto Heisenberg spin models and thus offers the opportunity to study these important systems under various conditions. Study of the BHM intensified with the experimental realization of Bose-Einstein condensates and the ability to load them in optical lattices\textsuperscript{3}. Under experimentally realizable conditions, these systems are described by the BHM and its extensions\textsuperscript{4} with highly tunable parameters and in one, two and three dimensions.

An increasing focus of the physics of strongly correlated quantum systems over the last several years has been the existence of unconventional phases and phase transitions. In addition to well studied Mott insulating behavior caused by an on-site repulsion, or charge order driven by a near-neighbor repulsion, usurping superfluidity, more exotic scenarios are realized in which different types of order are simultaneously present, or entirely new patterns arise. An additional motivation for studying the extended one-dimensional BHM is that it provides a concrete Hamiltonian in which this physics can be examined with powerful numerical methods.

In its simplest form which has only on-site contact interactions, the ground state of the BHM exhibits two phases\textsuperscript{4}. At integer filling and strong repulsion, boson displacement is sterically suppressed and the system is in an incompressible Mott insulating (MI) phase which is replaced by a superfluid (SF) phase at weak coupling. At incommensurate fillings, the system is always SF. Extending this model with the addition of longer range interactions or anisotropic hopping terms leads to new exotic phases. For example, extensive quantum Monte Carlo (QMC) simulations have shown that a strong enough near neighbor repulsion can lead to insulating incompressible density wave order (CDW) at integer and half odd integer fillings. Doping these phases can lead to phase separation or to supersolid (SS) phases\textsuperscript{5,12}.

The possibility of mapping the BHM onto a Heisenberg model invites the question of whether the same phases of the latter are present for the former. For example, odd integer Heisenberg spin systems in one-dimensional lattices can exhibit the exotic Haldane phase which is a gapped phase characterized by a non-local (string) order parameter\textsuperscript{18,19}. It was shown for the extended one-dimensional BHM with near and next near neighbor interactions that, at an average filling of one particle per site, the system can be mapped approximately onto the spin-1 Heisenberg model and admits a Haldane insulating (HI) phase sandwiched between MI and CDW phases\textsuperscript{20,21}. The phase diagram at unit filling for the system with only contact ($U$) and near neighbor ($V$) interactions was studied more extensively with conflicting results for the phase diagram. In Refs.\textsuperscript{22,23} the phase diagram was shown to exhibit MI, SF and CDW phases but the HI was not found due to the very limited sizes possible to simulate at the time. Subsequently, the ($\mu$, $t$) phase diagram of the extended BHM, for a...
fixed $V/U$ ratio, was obtained using Density Matrix Renormalization Group (DMRG\textsuperscript{24}), but showed only evidence for MI, SF and CDW. Recent work\textsuperscript{25}, also based on the DMRG, has shown the presence of the HI phase between the MI and CDW phases but found no evidence of SS at unit filling. Even more recent work\textsuperscript{26} on the same model has confirmed the HI phase. Curiously, however, there seems to be no consensus on the nature of the phase in the $(U, V)$ plane at unit filling for small $U$ and large $V$. References\textsuperscript{22,23,26} show it to be SF while Ref.\textsuperscript{25} shows it to be CDW and reference\textsuperscript{24} claims it to be supersolid. We will show in this paper that it is none of the above.

The above results give rise to some questions. Does the HI exist for other integer fillings of the system or is it a special property of the unit filling case? The SS phase found in one dimension\textsuperscript{12} was obtained by doping a CDW phase: Does this phase also exist for commensurate fillings in one dimension for parameter choices similar to those in two\textsuperscript{28} and three dimensions\textsuperscript{29}? If the SS phase exists for commensurate fillings, where is it situated in the phase diagram relative to the CDW, MI and HI phases?

Theoretical studies of this system using bosonization have also led to mixed results: The HI was obtained and characterized\textsuperscript{31}, but consensus is absent on whether the SS phase exists in this model. Even though older studies did not specifically mention it\textsuperscript{30} or even argued that it did not exist\textsuperscript{32}, more recent studies seem to demonstrate the presence of the SS phase\textsuperscript{31,32}, even without nearest neighbor interaction\textsuperscript{31}, for both commensurate and incommensurate fillings. However, the precise nature of order and the decays of the relevant correlation functions are still far from settled. For instance, some studies predict that the single particle Green function decays exponentially in the SS phase while the density-density correlation function decays as a power\textsuperscript{32}, others predict that both of these correlation functions decay as powers\textsuperscript{31}. Finally, the universality class of the transition to the SS phase remains largely unexplored.

In this paper we extend our work in Ref.\textsuperscript{35} using the stochastic Green function (SGF) QMC algorithm\textsuperscript{36} and the density matrix renormalization group (DMRG) to study the phase diagram of the one dimensional extended BHM as a function of the contact (near neighbor) interaction $U$ ($V$) and the filling. For the DMRG calculations we use the code available in the ALPS library\textsuperscript{37}. We mention that the fermionic version of this model was also studied by means of bosonization and DMRG\textsuperscript{28} and a HI phase established.

The paper is organized as follows. In section II we present the model and discuss the various phases of interest and the order parameters which characterize them. In section III we present our QMC and DMRG results for the phase diagrams in the $(U, V)$ plane at fixed fillings, $\rho = 1$ and $\rho = 3$. We present in section IV our results for the phase diagram in the $(\mu/U, t/U)$ plane at fixed ratio $V/U = 3/4$. A summary of results and conclusions is in section V.

## II. THE MODEL

The one dimensional extended BHM we shall study is described by the Hamiltonian,

$$
H = -t \sum_i (a_i^\dagger a_{i+1} + a_{i+1}^\dagger a_i) + \frac{U}{2} \sum_i n_i (n_i - 1) + V \sum_i n_i n_{i+1}.
$$

(1)

The sum over $i$ extends over the $L$ sites of the lattice, periodic boundary conditions were used in the QMC and open conditions with the DMRG. The hopping parameter, $t$, is put equal to unity and sets the energy scale, $a_i$ ($a_i^\dagger$) destroys (creates) a boson on site $i$, $n_i = a_i^\dagger a_i$ is the number operator on site $i$, $U$ and $V$ are the onsite and near neighbor interaction parameters.

Several quantities are needed to characterize the phase diagram. It was shown recently\textsuperscript{38} that the well-known expression of the superfluid density as a function of the fluctuations of the winding number\textsuperscript{39} is valid only for Hamiltonians that satisfy

$$
[R, H] = \frac{i\hbar}{m} P,
$$

(2)

where $R$ and $P$ are the position and momentum operators and $m$ is the mass of a boson. Here $t = \hbar^2/(2m\ell^2)$ where $\ell$ is the lattice constant. It is straightforward to verify that Eq. (1) satisfies this condition and, therefore, the superfluid density is given by\textsuperscript{40}

$$
\rho_s = \frac{\langle W^2 \rangle}{2td\beta L^{d-2}},
$$

(3)

where $W$ is the winding number of the boson world lines, $d$ is the dimensionality and $\beta$ the inverse temperature. The CDW order parameter is the structure factor, $S(k)$, at $k = \pi$ where

$$
S(k) = \frac{1}{L} \sum_{r=0}^{L-1} e^{ikr} \langle n_0 n_r \rangle.
$$

(4)
and the momentum distribution, \( n_k \), is given by

\[
n_k = \frac{1}{L} \sum_{r=0}^{L-1} e^{ikr} \langle a_0^\dagger a_r \rangle. \tag{5}
\]

The charge gap is given by,

\[
\Delta_c(n) = \mu(n) - \mu(n-1) = E_0(n+1) + E_0(n-1) - 2E_0(n)
\]

where \( \mu(n) = E_0(n+1) - E_0(n) \) and \( E_0(n) \) is the ground state energy of the system with \( n \) particles and is obtained both with QMC and DMRG. The neutral gap, \( \Delta_n \), is obtained using DMRG by targeting the lowest excitation with the same number of bosons. In both CDW and HI phases, the chemical potentials at both ends are set to (opposite) large enough values, in DMRG, such that the ground state degeneracy and the low energy edge excitations are lifted. With the SGF we did simulations in both the canonical and grand canonical ensembles.

For spin systems, the nonlocal Haldane string order parameter is given by,

\[
O_s(|i - j| \to \infty) = \langle S^z_i \exp(i\theta \sum_{k=i}^j S^z_k)S^z_j \rangle \tag{7}
\]

where \( \theta = \pi \) for the spin-1 system. This order parameter detects the Haldane phase where the \( S_z = 1 \) and \( S_z = -1 \) alternate along the lattice and are separated by varying numbers of \( S_z = 0 \) sites. In other words, the system exhibits, in this phase, long range anti-ferromagnetic order but with no characteristic momentum. In the BHM at \( \rho = 1 \), when \( U \) and \( V \) are large (with \( 2V < U \)), most sites are singly occupied. Quantum fluctuations allow some sites to be unoccupied or doubly occupied, but higher occupations are suppressed. One can therefore make the analogy with spin systems and define \( S_z(i) \equiv \delta n_i = n_i - \rho \) (\( \rho = 1 \)) and define two nonlocal order parameters for the BHM, the string and the parity parameters:

\[
O_s(|i - j| \to \infty) = \langle \delta n_i e^{i\theta \sum_{k=i}^j \delta n_k} \delta n_j \rangle, \tag{8}
\]

\[
O_p(|i - j| \to \infty) = \langle e^{i\theta \sum_{k=i}^j \delta n_k} \rangle. \tag{9}
\]

In practice we take the order parameters to be \( O_{s/p}(L_{\text{max}}) \) where, in QMC with PBC, \( L_{\text{max}} = L/2 \) and in DMRG, with OBC, \( L_{\text{max}} \) is the longest distance possible before edge effects start being felt. For higher integer filling, \( \rho = 2, 3 \ldots, \theta \neq \pi \) and has to be determined as discussed in Ref. [41].

The various thermodynamically stable phases that may appear in the system are characterized by the above quantities and are summarized in Table II. To explore the possibility of phase separation (PS), it is not enough to look at order parameters since if the system is in a phase separated state (a mixture of two or more thermodynamic phases), there will be contributions from the order parameters of all the phases present. To preclude or confirm the presence of phase separation, we study the behavior of the density \( \rho \) as a function of the chemical potential, \( \mu \), and also the density profile in the system.
on $\rho = 1$ and $\rho = 3$) and we fix one of the interaction parameters, $U$ or $V$, while the other is varied. The physical quantities discussed above ($\rho_s$, $S(k = \pi)$, $\mathcal{O}_p$, $\mathcal{O}_\pi$) are calculated and the various phases deduced from Table I. For example, in the top panel of Fig. 1 we show $\mathcal{O}_p$ and $S(\pi)$ as functions of $V$ for the system at $\rho = 1$ and fixed $U = 4$ and several lattice sizes. Extrapolating these quantities to $L \to \infty$ yields the two critical values $V_1^c = 2.3$, where $\mathcal{O}_p$ vanishes, and $V_2^c = 3.25$ where $S(\pi)$ becomes nonzero. For all $V$ at $U = 4$, $\rho_s = 0$ (not shown in Fig. 1) and, therefore, there is no SF phase at $U = 4$. The string order parameter, $\mathcal{O}_s$, vanishes for $V < V_1^c$ (not shown in the figure) and takes on a finite value for $V > V_1^c$. According to Table I this means that for $V < V_1^c$ the system is in the MI phase; for $V_1^c < V < V_2^c$ the system is in the HI phase and for $V > V_2^c$, the system enters the CDW phase.

These transitions can also be seen in the behavior of $\Delta_c$ and $\Delta_n$, the charge and neutral gaps, shown in the lower panel of Fig. 1 as functions of $V$ at $\rho = 1$ and $U = 4$. These are the extrapolated gap values, i.e., $L \to \infty$, from the DMRG results obtained for sizes ranging from $L = 64$ to $L = 256$. We see that at the MI-HI transition, $V = 2.3$, both gaps vanish and at the HI-CDW transition, $V = 3.25$, $\Delta_n$ vanishes while $\Delta_c$ does not. This behavior is expected and the DMRG values agree with those obtained via QMC (top panel Fig. 1).

The behavior of the string order parameter is shown in Fig. 2 as a function of $U$ for fixed $V = 1.5$ and for several

![FIG. 2: (color online) The string order parameter, $\mathcal{O}_s$, versus $U$ for $V = 1.5$ and several sizes. Also shown are the extrapolated values giving the two critical values $U_1^c = 1.6$ and $U_2^c = 2.8$. For $U_1^c < U < U_2^c$ (the interval between the vertical dashed lines) the system is in the HI. For $U < U_1^c$, the system is in the SF phase and for $U > U_2^c$, it is in the MI phase.](image)

![FIG. 3: (color online) The superfluid density, $\rho_s$, and CDW order parameter $S(\pi)$ as functions of $U$ at fixed $V = 4.5$ and $\rho = 1$. For $U > 1$: $\rho_s = 0$ and $S(\pi) \neq 0$ indicate a CDW phase. For $U \lesssim 1$: $\rho_s \neq 0$ and $S(\pi) \neq 0$ suggest the possibility of a supersolid phase.](image)

![FIG. 4: (color online) The density, $\rho$, as a function of the chemical potential, $\mu$, for several values of the near neighbor interaction, $V$, at fixed contact interaction, $U = 1/2$. For all values of $V$ there is a discontinuous jump in $\rho(\mu)$ indicating a first order phase transition. For $V \geq 3$, the $\rho = 1$ value (indicated by the dashed line) is inside the jump. This means that there is no thermodynamically stable phase with $\rho = 1$ for these values of $V$. This figure was obtained with QMC simulations in the grand canonical ensemble.](image)

### III. PHASE DIAGRAMS AT FIXED FILLINGS

We start with the phase diagram in the $(U, V)$ plane at fixed unit density. To map out the phase diagrams, we fix the filling at a commensurate value (here we focus
sizes. Also shown are the extrapolated values using \( O(L) = O(L \to \infty) + \text{const.} / L \) and demonstrating that for \( 1.6 < U < 2.8 \), \( O \), although small, is nonvanishing. Therefore, the system is in the HI in this interval. For \( U < 1.6 \) the system is SF since \( \rho_s \neq 0 \). For \( U > 2.8 \), upon examining the other quantities such as \( O_p \) (nonzero) and \( \rho_s \) (vanishes) we conclude that the system is in the MI phase.

![Graph](image1)

**FIG. 5:** (color online) When, in a canonical simulation, the number of particles is fixed at a value which corresponds to a thermodynamically unstable phase, the system undergoes phase separation. In this figure, we show QMC results for \( L = 64 \), \( U = 1/2 \) and \( V = 4.5 \). The phase with \( N = 47 \) particles, dashed horizontal line in (a), is seen to be uniform and corresponds to the SF phase. Adding a few particles, however, destabilizes the system as when there are \( N = 57 \) particles. As more particles are added, the size of the region displaying CDW increases as is seen in (b) for \( N = 64 \) and (c) for \( N = 70 \). In (d), with \( N = 81 \) the system appears to be entirely CDW. However, this CDW region is in fact a supersolid. One way to see that is to notice that the density oscillates between 0 and 2.5. Also, the system in (d) exhibits both long range density order (CDW) and non-vanishing superfluid density. Note: In the QMC simulation, the CDW profile indicative of a CDW phase. However, the site becomes uniform displaying an oscillating local density that for \( \rho_s \) (nonzero) and \( \rho_s \) (vanishes) we conclude that the system is in the MI phase.

**FIG. 6:** (color online) The phase diagram in the \( (U, V) \) plane for \( \rho = 1 \). The open squares are the results of Ref. 25, all other symbols are results of our QMC simulations. Our results confirm those of Ref. 25 where the error bars are small and improve them where the error bars are large. In addition, we have determined the SF-HI boundary and also the boundary of the phase separation region. The dashed line is given by \( U = 4V/3 \) and will be discussed in the text.

By studying \( \rho(\mu) \) in this way for various values of \( U \) and \( V \) we map out the region in the \( (U, V) \) plane where phase separation takes place. The question then is: What are the phases into which the system separates? To answer this, we examine the density profiles (in the canonical ensemble) in the system at various fillings. In Fig. 6 we show the density profiles for five fillings, \( N = 47, 57, 64, 70, 80 \) on a lattice with \( L = 64 \). For \( N = 47 \) (dashed line in Fig. 6(a)) the density is uniform and the system is SF. As more particles are added, for example for \( N = 57 \) in Fig. 6(a), the system becomes inhomogeneous developing two regions, one with uniform density (and still SF) and one with alternating site densities giving the appearance of a developing CDW phase. As more particles are added, the region with alternating site densities expands at the expense of the uniform one, Fig. 6(c)(d). When enough particles are added, the system becomes uniform displaying an oscillating local density profile indicative of a CDW phase. However, the site density alternates between 0 and 2.5 indicating that it is, in fact, a supersolid (SS) phase because in a true CDW
phase, the local density will alternate between 0 and an integer value. This is confirmed by measurement of $\rho_s$. Therefore, the observed phase separation is between the SF and SS phases. Note that in the QMC simulation, the CDW region does not always appear in the same place. Since these simulations are done with periodic boundary conditions, we have centered these regions to facilitate comparison. In addition, results obtained with the DMRG exhibit similar density profiles and give rise, therefore, to the same boundaries for the phase separation in the $(U, V)$ plane. From a mean-field point of view, the usual Gutzwiller ansatz only predicts a second order SF-SS phase transition and, therefore, no phase separation for $\rho = 1$. Finally, since the occupation number in the density profiles shown in Fig. 4 ranges from 0 to almost 2.5, a mapping of the bosonic Hubbard model to a spin chain model would require values of the total spin $S$ larger than 1, which explains that this phase separation is not present in the $S = 1$ chain. Actually, for a fixed value of $V$, one can clearly see that $S$ increases with decreasing values of $U$: for $U = 0$, the CDW can have an arbitrary number of bosons on every other site. It is therefore tantalizing to map this situation to the classical anisotropic Heisenberg model with a single ion anisotropy, which does have a first order phase transition as a function of the magnetic field ($\mu$ for bosons), the spin-flop transition. However, this transition is between the Neel order and the spin-flop phase, which, in the bosonic language, corresponds to a transition between the CDW and the SF phases, not between the SS and the SF ones. A proper mean-field understanding of the present transition is thus still lacking.

The resulting phase diagram at fixed $\rho = 1$ is shown in Fig. 6. The open squares are the results of Ref. [25], all other symbols are results of our QMC simulations. Our results confirm some of the results of Ref. [25] in particular where their error bars are small, and improve them where their error bars are large. In addition, we have determined the SF-HI boundary and also show the newly found phase separation region. The dashed line is given by $U = 4V/3$ and will be discussed below.

Applying the same techniques at fixed filling $\rho = 3$ gives the phase diagram Fig. 7. As for the case of $\rho = 1$, Fig. 6, the $\rho = 3$ phase diagram, Fig. 7 exhibits MI, SF, CDW phases and phase separation. However, it does not exhibit the HI phase. Instead, sandwiched deep between the CDW and MI phases, is a Luttinger liquid (LL) phase with $\langle a_\dagger a \rangle \sim r^{-1/2K}$ and parameter $K < 2$ and is, therefore, not SF. In addition, the $\rho = 3$ phase diagram exhibits a supersolid phase not present at $\rho = 1$. The absence of the HI at $\rho = 3$ is likely due to the fact that here, unlike for $\rho = 1$, the bosonic system cannot be simply mapped on to a Heisenberg spin chain system.

FIG. 7: (color online) Applying the same methods as for the $\rho = 1$ case, the $\rho = 3$ phase diagram is mapped out. Unlike for $\rho = 1$, there is no HI here but there is SS. The region of the Luttinger liquid phase (LL) with the Luttinger parameter $K > 2$ is indicated by SF and where $K < 2$ by LL.

FIG. 8: (color online) Shows several quantities for $\rho = 1$ as functions of $t/U$ with the fixed ratio $V/U = 0.75$. (a) The CDW order parameter for $L = 64$ and $\rho_s$ for $L = 64, 100, 150$; (b) the parity and string order parameters; (c) the neutral and charge gaps. (a) and (b) were obtained with QMC and (c) with DMRG. The region to the right of the dashed line is the HI. It terminates at $t/U = 0.55$. In the HI, $\rho_s \to 0$ very slowly as $L$ increases. Note the difference between the neutral and charge gaps. The gaps are given in units of the hopping $t$.

IV. PHASE DIAGRAM AT FIXED $V/U = 3/4$

In this section we study the phase diagram in the $(\mu/U, t/U)$ plane at fixed ratio $V/U = 3/4$. This value of $V/U$ is chosen because the CDW phase is favored over
As the transition out of the CDW phase is approached, HI for which shows the neutral and charge gaps, $\Delta_n$ and $\Delta_c$, remain nonzero showing other words, the neutral gap vanishes at the CDW-HI transition but the charge gap remains nonzero. In other words, unlike the CDW phase, $\Delta_n \rightarrow 0$ in the SF phase which is indicated by the star symbol on the dashed straight line in Fig. 6.

We start by fixing $\rho = 1$ and studying the various phases as $t/U$ is changed (with $V/U = 3/4$). This path is shown as the dashed straight line in Figs. 9 (a) and 10 (b) (a). Figure 8 shows that for $t/U > 0.23$, $\rho_s$ increases from zero but $S(\pi)$ remains nonzero. $S(\pi)$ vanishes for $t/U > 0.42$ (confirmed by DMRG in panel (c) of the same figure). In other words, unlike the $\rho = 1$ case, there is an interval where the system exhibits simultaneous long range diagonal (density) order and superfluidity. This is the hallmark of the SS phase. In the $\rho = 1$ case, the HI intervenes between the CDW and SF phases while at $\rho = 2$ the SS phase takes that role. To confirm the nature of the SS phase, we show in Fig. 10 the structure factor, $S(k)$, on the system size, $n_k/L \rightarrow 0$ with increasing $L$ while $S(k)$ remains constant indicating long range CDW order.

As mentioned previously, the behavior at $\rho = 1$ may be understood by drawing on the analogy with the $S = 1$ spin system. The question then arises as to whether the same analogy holds for the other integer fillings. To answer this question we perform the same analysis but for $\rho = 2$. The results are shown in Fig. 8. Figure 8(a) shows that for $t/U > 0.33$, $\rho_s$ increases from zero but $S(\pi)$ remains nonzero. $S(\pi)$ vanishes for $t/U > 0.42$ (confirmed by DMRG in panel (c) of the same figure). In other words, unlike the $\rho = 1$ case, there is an interval where the system exhibits simultaneous long range diagonal (density) order and superfluidity. This is the hallmark of the SS phase. In the $\rho = 1$ case, the HI intervenes between the CDW and SF phases while at $\rho = 2$ the SS phase takes that role. To confirm the nature of the SS phase, we show in Fig. 10 the structure factor, $S(k)$, and the momentum distribution, $n_k/L$, on the system size, $n_k/L \rightarrow 0$ with increasing $L$ while $S(k)$ remains constant indicating long range CDW order.

The behavior of the single particle Green function in the SS phase is clarified in Fig. 10 which shows $G(x)$ for $\rho = 2$ in the SF, SS and CDW phases. The QMC is done with periodic boundary conditions and consequently, the Green function will be symmetric with respect to $r = L/2$. To handle this, we plot in the figure, on semi-log scale, the Green function versus $x = (L/\pi)\sin(\pi r/L)$ whose limit as $L \rightarrow \infty$ is $x = r$. It is seen that in the SF and SS phases, $G(x)$ decays as a power ($K = 2.5$ and...
$K = 1.2$ respectively) although in the SS phase there are modulations due to the long range density order. In the CDW phase, $G(x)$ decays exponentially as expected.

The same behavior is observed for $\rho = 3$ and, in fact, for $\rho = 5/2$. For the $\rho = 3/2$ case, it appears that the system exits the CDW phase directly into the SF phase (see below).

To map out the phase diagram in the ($\mu/U, t/U$) plane we need to characterize the phases at incommensurate fillings. In the top panel of Fig. 12, we show $\rho_s$ and $S(\pi)$ as functions of $t/U$ at a filling of $\rho = 1.25$ and $V/U = 3/4$. We see that two phases are present: SS, where CDW and SF are present simultaneously, and SF.

So, for fixed $V/U = 3/4$, we have shown the presence of four phases: CDW, HI, SS and SF. By performing scans such as those that led to Figs. 8, 9, 12 and by calculating the charge gaps for the CDW phase, we find the boundaries of these phases and map the phase diagram in the ($\mu/U, t/U$) plane. The phase diagram is shown in Fig. 13. In Fig. 13, all symbols represent results from QMC simulations for $L = 128$ (stars) and $L = 64$ (all other symbols), $\beta = 128$. The solid black lines near the lobe tips are obtained from DMRG with $L = 192$. The end points of the lobes are obtained by studying the finite size dependence of $\Delta_n$ using DMRG except for $\rho = 1$ which is obtained using QMC by extrapolating $\sigma_s$ to the thermodynamic limit (the star symbol in Fig. 6).

The inset is a zoom of the tip of the $\rho = 1$ lobe.

Several comments are in order. Except for a small region of SS squeezed between it and the $\rho = 1$ lobe, the $\rho = 1/2$ lobe is surrounded almost entirely by LL phase with $K < 2$ and, therefore, not SF, see Fig. 14. The fact that in the extended BHM a SS does not exist when the $\rho = 1/2$ CDW phase is doped with holes, but does when it is doped with particles, was already addressed in Ref. [12]. The $\rho$ = 1 lobe sticks out of the SS phase and the part sticking out is, in fact, the HI phase. No other CDW lobe behaves this way. The $\rho = 3/2$ lobe terminates right at the boundary with the SF phase: To within the resolution of our simulations, the transition from the $\rho = 3/2$ CDW lobe goes directly into the SF phase without passing through the SS phase. This peculiar behavior for $\rho = 3/2$ was also observed with additional DMRG results for different values of $V/U$ ranging from 0.65 to 1: The SS layer between the CDW and SF phases, if present, is too thin to observe for the considered system sizes. An accurate determination of the ($U, V$) phase diagram for
this filling will require a more thorough finite size scaling analysis. All other CDW lobes, $\rho \geq 2$, are surrounded entirely by the SS phase. It is interesting to compare this figure with Fig. 3 of Ref. [28] and with the mean-field predictions.

V. CONCLUSIONS

Even though the one dimensional BHM with near neighbor interaction is a rather simple model, it continues to attract attention and to yield surprises such as new phases with exotic order parameters and quantum phase transition.

In this paper we used the SGF QMC algorithm and DMRG to elaborate the details of the phase diagram of the extended BHM in one dimension and expose novel features and exotic phases. We mapped the phase diagrams in the $(\mu/U, t/U)$ plane at fixed $V/U = 3/4$ and in the $(U, V)$ plane at two fixed commensurate fillings, $\rho = 1, 3$. We find that, for this system, the HH seems to exist only at $\rho = 1$, invalidating the Heisenberg spin analogy at higher integer fillings. We study the charge and neutral gaps and the nonlocal string order parameter characterizing this phase. For higher densities, we find that the supersolid phase, SS, is very robust and exists for a very wide range of parameters including at commensurate fillings. We show that the one-body Green function decays as a power in the SS phase, not exponentially as sometimes argued. We also showed that when the filling is fixed, there exists a region in the $(U, V)$ plane where the system undergoes phase separation. This phase separated region can be mistaken for a supersolid phase if only the order parameters $\rho_s$ and $S(\pi)$ are studied. Evaluation of $\rho(\mu)$ and also the spatial density profile reveals the phase separation unambiguously.
