ABSTRACT

String theory abounds with light scalar fields (the dilaton and various moduli) which create a host of observational problems, and notably some serious cosmological difficulties similar to the ones associated with the Polonyi field in the earliest versions of spontaneously broken supergravity. We show that all these problems are naturally avoided if a recently introduced mechanism [16] for fixing the vacuum expectation values of the dilaton and/or moduli is at work. We study both the classical evolution and the quantum fluctuations of such scalar fields during a primordial inflationary era and find that the results are naturally compatible with observational facts. In this model, dilatons or moduli within a very wide range of masses (which includes the SUSY-breaking favored \( \sim 1 \text{ TeV} \) value and extends up to the Planck scale) qualify to define a novel type of essentially stable ultra-weakly interacting massive particles able to provide enough mass density to close the universe.
I. INTRODUCTION

Superstring unification [1] and inflationary scenario [2] have been, arguably, the most influential ideas in particle physics and cosmology over the last decade. Attempts at combining these ideas and constructing superstring-based inflationary models have introduced some interesting new ideas [3], but have, however, encountered serious difficulties [4-7]. A specific source of difficulties is the existence of massless scalar fields (the moduli) having only gravitational strength couplings to ordinary matter. Among the moduli fields, the dilaton Φ, which invariably accompanies the graviton in all superstring models, plays a special role. In the presence of a (tree-level coupled) dilaton, the cosmological evolution is drastically different from that in Einstein’s gravity. In particular, instead of driving an exponential inflationary expansion, a constant vacuum energy drives the dilaton towards large negative values (corresponding to weak couplings), while the universe expands only as a small power of time. Even apart from inflation, a massless dilaton, or moduli, field (for simplicity, as these fields share many characteristics, we shall refer to any of them as “the dilaton” and denote it as Φ) can cause a host of other cosmological problems. During the most recent, matter-dominated epoch of the universe, such field is necessarily time-dependent. The masses of elementary particles and their couplings all depend on Φ, and the cosmological time-variation of the dilaton runs into a violent conflict with observations, not to mention unacceptably large violations of the equivalence principle.

These problems are usually addressed by assuming that the dilaton develops a potential, so that one recovers the standard Einstein’s gravity after Φ settles at the minimum of the potential. The potential could originate from non-perturbative effects, such as gaugino condensation. The existence of a potential for Φ entails, however, new difficulties. On the one hand, it has been argued [7] that the minimum of the nonperturbative potential is too shallow to confine the dilaton without fine-tuning the initial conditions (see however [8]). On the other hand, any potential $V(Φ)$ for a weakly coupled field resurrects the Polonyi problem [9-12]: either the energy stored in the coherent oscillations of the vacuum expectation value
(VEV) of Φ does not dissipate before now and exceeds the critical density needed to close the universe, or the field decays before now, and thereby generically produces an excessive amount of entropy. In the case of the nonperturbative potentials suggested by current SUSY breaking models in string theory, the slow decay rate of the moduli fields leaves the universe in a radiation-dominated era at a temperature which is generically (i.e. under naturalness assumptions for the couplings) much too low to be consistent with primordial nucleosynthesis [13-15].

In the present paper, we show that all the above difficulties associated with the dilaton (and moduli) fields are naturally avoided if the new mechanism introduced in Ref. [16] for fixing Φ is at work [17]. The main idea of [16] was to exploit the fact that string loop effects, associated with worldsheets of arbitrary genus in intermediate string states, naturally generate some non-monotonic dependence upon Φ of the various couplings of Φ to the other fields. Under the assumption that the different coupling functions $B_a(\Phi)$ have extrema at some common value of $\Phi = \Phi_0$, it has been shown that interactions with massive particles in an expanding universe drive the dilaton towards the value $\Phi_0$ at which it decouples from matter. All deviations from general relativity in this model have been estimated to be extremely small at the present cosmological epoch thereby naturally reconciling a massless dilaton with existing observational data. The assumption of coincident maxima can be satisfied in a technically natural way if there exists a discrete symmetry, e.g., $\Phi \rightarrow -\Phi$. Such a symmetry would guarantee that all couplings have extrema at $\Phi_0 = 0$ (the only additional necessary assumption being that these extrema lead to minima rather than maxima of the masses as functions of $\Phi$). We note that precisely the discrete symmetry $\Phi \rightarrow -\Phi$ (or $e^\Phi \rightarrow 1/e^\Phi$) is known to hold for some of the moduli fields (T-duality), and has been conjectured to hold for the dilaton proper (S-duality: $g_s \rightarrow 1/g_s$, where $g_s = e^\Phi$ is the string coupling).

Here we extend the analysis of Ref. [16] to inflationary models. It will be shown that inflation is extremely efficient in driving a homogeneous field $\Phi$ to $\Phi_0$ (Section II). At the same time, inflation is known to generate significant quantum fluctuations in gravitational
and other fields with a very wide range of wavelengths. Fluctuations of the dilaton on co-
moving scales smaller than the present horizon are potentially dangerous because they are
not damped by the mechanism of Ref. [16]. One might worry that quantum fluctuations
could reintroduce the Polonyi-moduli problem in a different form. However, in Sec.III we
shall calculate the fluctuation spectrum and show that the predicted dilaton fluctuations are
well below the observational constraints. We next consider, in Sec.IV, the possibility that, in
addition to non-trivial matter-coupling functions with extrema at \( \Phi = \Phi_0 \), the dilaton also has
a potential with a minimum at \( \Phi_0 \). (This may be enforced by the same discrete symmetry). In
this case the dilatons are massive, and can potentially run into conflict with observations, e.g.
by overclosing the universe or by generating an excessive flux of \( \gamma \)-rays due to dilaton decays.
We shall see, however, that in our model the constraints on the dilaton mass derived in [11-13],
[18] can be substantially relaxed, due to the very weak couplings of the dilaton. We find that
dilatons with a very large range of masses (which includes the suggested SUSY-breaking value
\( \sim \) TeV and extends up to the Planck scale) can qualify to define a new type of (essentially)
stable WIMP able to provide enough mass density to close the universe.

II. THE EFFECTIVE ACTION

Up till now, most of the analysis of superstring cosmology has been based on the tree-level
effective action, corresponding to the lowest order in the string loop expansion,

\[
S_{\text{tree}} = \int d^4x \sqrt{g} e^{-2\Phi} \left\{ (\alpha')^{-1} \hat{R} + 4\hat{\nabla}^2 \Phi - 4(\hat{\nabla} \Phi)^2 \right\} + \mathcal{L}_{\text{matter}}. \tag{2.1}
\]

Here, \( \Phi \) is the dilaton, and the matter Lagrangian includes fermions, gauge and Higgs fields,
and in particular the ‘inflaton’ scalar field \( \hat{\chi} \) whose potential \( \hat{V}(\hat{\chi}) \) drives the inflation,

\[
\mathcal{L}_{\text{matter}} = -\frac{k}{4} \hat{F}^2 - \hat{\bar{\psi}} \hat{D} \hat{\psi} - \frac{1}{2} (\hat{\nabla} \hat{\chi})^2 - \hat{V}(\hat{\chi}) + .... \tag{2.2}
\]

Hats in Eqs.(2.1), (2.2) indicate that the corresponding fields are taken in the ‘string frame’,
that is, in the \( \sigma \)-model formulation of string theory.
The string coupling $g_s$, which plays the role of the expansion parameter in the string
tool expansion, is determined by the expectation value of the dilaton, $g_s = e^\Phi$. The tree-level
action (2.1) is proportional to $g_s^{-2}$, resulting in a universal, multiplicative coupling of the
dilaton to all other fields. With higher orders in the loop expansion taken into account, we
expect the common factor $e^{-2\Phi}$ to be replaced by several coupling functions $B_a(\Phi)$ multiplying
different terms in (2.1), (2.2). In particular, the effective action for the graviton-dilaton-
inflaton sector is expected to be of the form

$$S = \int d^4x \sqrt{\hat{g}} \left\{ \frac{B_g(\Phi)}{\alpha'} \hat{R} + \frac{B_\Phi(\Phi)}{\alpha'} [4\hat{\nabla}^2 \Phi - 4(\hat{\nabla} \Phi)^2] - \frac{1}{2} B_\chi(\Phi)(\hat{\nabla} \hat{\chi})^2 - \hat{V}(\hat{\chi}, \Phi) \right\}, \quad (2.3)$$

where the functions $B_a(\Phi)$ admit a series expansion

$$B_a(\Phi) = e^{-2\Phi} + c_0^{(a)} + c_1^{(a)} e^{2\Phi} + ... , \quad (2.4)$$

and a similar expansion for $\hat{V}(\hat{\chi}, \Phi)$. In the case of the moduli fields (by contrast with the
four-dimensional dilaton proper) the effective action has also the generic form (2.3), the only
difference being that the non-trivial $\Phi$-dependence is absent at tree level, and arises at one
loop and beyond.

A more convenient form of the action can be obtained by a conformal transformation
from the ‘string-frame’ metric $\hat{g}_{\mu\nu}$ to the ‘Einstein-frame’ metric

$$g_{\mu\nu} = CB_g(\Phi)\hat{g}_{\mu\nu}, \quad (2.5)$$

and by replacing the dilaton field $\Phi$ by the variable

$$\varphi = \int d\Phi \left[ \frac{3}{4} \left( \frac{B_g^{'}}{B_g} \right)^2 + 2 \frac{B_\Phi^{'}}{B_g} + 2 \frac{B_\Phi}{B_g} \right]^{1/2} . \quad (2.6)$$

This gives

$$S = \int d^4x \sqrt{g} \left[ \frac{1}{4g} R - \frac{1}{2q} (\nabla \varphi)^2 - \frac{1}{2} F(\varphi)(\nabla \chi)^2 - V(\chi, \varphi) \right], \quad (2.7)$$

where we have defined

$$\chi = C^{-1/2} \hat{\chi}, \quad (2.8a)$$
\[ F(\varphi) = B_\chi(\Phi)/B_g(\Phi), \]  

\[ V(\chi, \varphi) = C^{-2}B_g^{-2}(\Phi)\dot{V}(\dot{\chi}, \Phi). \]

The constant \( C \) in Eq. (2.5) is chosen so that the string units coincide with Einstein units at the present cosmological epoch, \( CB_g(\Phi_0) = 1 \), and the constant \( q \) in (2.7) is related to the bare gravitational constant \( \bar{G} \), \( q = 4\pi\bar{G} = C\alpha'/4 \). As shown in [16], \( \bar{G} \) is numerically nearly identical to the observed Newtonian gravitational constant so that \( q = 4\pi/m_p^2 \) with \( m_p = 1.22 \times 10^{19} \) GeV.

The minimal condition required for the mechanism of Ref. [16] to work is that all \( B_a(\Phi) \) should have an extremum at the same \( \Phi = \Phi_0 \). When formulated within the context of inflationary models and in terms of the rescaled fields \( \varphi \) and \( \chi \), this leads to requiring that the potential \( V(\chi, \varphi) \) in Eq. (2.7) has a minimum (as a function of \( \varphi \)) at \( \varphi = \varphi_0 \) for any fixed value of \( \chi \). Here, \( \varphi_0 = \varphi(\Phi_0) \). A simple toy model which satisfies this condition is the case where higher loops are supposed to respect the tree-level universality of the dilaton couplings. In this case all functions \( B_a(\Phi) \) in (2.3) are identical,

\[ B_a(\Phi) = B(\Phi), \]

and

\[ \dot{V}(\dot{\chi}, \Phi) = B(\Phi)\ddot{V}(\ddot{\chi}). \]

Then, in the Einstein-frame action (2.7), \( F(\varphi) = 1 \) and the potential has a factorized form,

\[ S = \int d^4x\sqrt{g}\left[ \frac{1}{4q}R - \frac{1}{2q}(\nabla \varphi)^2 - \frac{1}{2}(\nabla \chi)^2 - B^{-1}(\varphi)V(\chi) \right]. \]

In this model \( \varphi \) is attracted (both during inflation and the subsequent matter-dominated era(s) ) toward the maxima of \( B(\varphi) \). Although the strong universality condition (2.9) may be too restrictive, it is useful to have in mind the action (2.10) which provides a very simple model containing most of the essential physics of the more general model (2.7).
III. CLASSICAL EVOLUTION

We shall assume, as it is usually done in inflationary models, that the potential \( V(\chi, \varphi) \) in Eq.(2.7) has a minimum with \( V(\chi_0, \varphi_0) \approx 0 \) and that it has a ‘slow-roll’ region where it is a slowly varying function of \( \chi \),

\[
V_\chi'{}^2 \ll 12qV^2, \tag{3.1a}
\]
\[
(\sqrt{V})''_{\chi\chi} \ll 3q\sqrt{V}, \tag{3.1b}
\]

where we recall that \( q = 4\pi/m_p^2 \). At the same time, the coupling functions \( B_a \) and the potential \( V \) are not expected to be slowly-varying functions of \( \varphi \). For example, in the strong universality model (2.9) we expect \( B(\varphi_0) \sim 1 \) and

\[
\kappa \equiv -B''(\varphi_0)/B(\varphi_0) \sim 1 \tag{3.2}
\]
at the maximum of \( B(\varphi) \). Note that, contrary to \( \chi \) which has the usual dimension of mass, \( \varphi \) is a dimensionless variable whose expected range of variation is of order unity.

For the initial conditions of the universe, we shall assume that the fields \( \varphi \) and \( \chi \) are displaced from the minimum of \( V(\chi, \varphi) \) at \( \{\chi_0, \varphi_0\} \) but are in its basin of attraction, at least in some parts of the universe [19]. Then it is easy to see, qualitatively, how the cosmological evolution will proceed. The field \( \varphi \), which corresponds to the steep direction in \( V(\chi, \varphi) \), will evolve on a much faster time scale than \( \chi \). It will start oscillating about \( \varphi = \varphi_0 \), these oscillations will be damped by the expansion of the universe, and the universe will quickly settle into a quasi-exponential inflation driven by the potential energy of the field \( \chi \), \( \tilde{V}(\chi) = V(\chi, \varphi_0) \). The damping of \( \varphi \)-oscillations during inflation is very efficient, and we expect that by the end of inflation the dilaton will be very close to \( \varphi_0 \).

To describe this quantitatively, let us consider the field equations for \( \chi \) and \( \varphi \)

\[
\nabla(F(\varphi)\nabla\chi) - \frac{\partial}{\partial\chi} V(\chi, \varphi) = 0, \tag{3.3}
\]
\[
\nabla^2 \varphi - \frac{1}{2}q\frac{\partial F(\varphi)}{\partial\varphi}(\nabla\chi)^2 - q\frac{\partial}{\partial\varphi} V(\chi, \varphi) = 0. \tag{3.4}
\]
During the slow-roll phase of inflation, the universe can be locally described by a flat Robertson-Walker metric,

\[ ds^2 = -dt^2 + a^2(t)dx^2, \]  

with the expansion rate \( H = \dot{a}/a \) given by

\[ H^2 = \frac{1}{3} \left[ 2qV(\chi, \varphi) + \varphi^2 + qF(\varphi)\dot{\chi}^2 \right] \approx \frac{2}{3} qV(\chi, \varphi_0). \]  

The spacetime is approximately de Sitter, with the curvature

\[ R \approx 12H^2 \approx 8qV(\chi, \varphi_0). \]  

To study the approach of \( \varphi \) to \( \varphi_0 \), we expand \( V(\chi, \varphi) \) in powers of \( (\varphi - \varphi_0) \). For notational consistency with \cite{16}, it is convenient to denote by \( \beta_i \) the (positive) dimensionless parameter measuring the curvature (with respect to \( \varphi \)) of the inflationary mass scale around the minimum \( \varphi_0 \):

\[ \Lambda_i(\chi, \varphi) \equiv V^{1/4}(\chi, \varphi) \approx \Lambda_i(\chi, \varphi_0)[1 + \frac{1}{2} \beta_i(\varphi - \varphi_0)^2]. \]  

Here, the index \( i \) stands for ‘inflation’. In the simple model (2.9), in which the potential is factorized, \( V(\chi, \varphi) = B^{-1}(\varphi)V(\chi) \), one has \( \beta_i = \kappa/4 \), where \( \kappa \) was introduced in equation (3.2) above. In the general case, the value of \( \beta_i \) depends on the physics determining the mass scale \( \Lambda_i \). As discussed in Ref. \cite{16} (see Eq. (4.6b) there), if the hierarchy \( \Lambda_i \ll m_p \) (which seems necessary in inflationary models) is due to nonperturbative effects, one expects to have \( \beta_i \sim \ln(\Lambda_{\text{string}}/\Lambda_i) \gg 1 \).

Substituting this in Eq. (3.4) and using (3.6), (3.7), we obtain

\[ (\nabla^2 - \xi_i R)\delta\varphi = 0, \]  

where \( \delta\varphi = \varphi - \varphi_0 \) and

\[ \xi_i = \frac{1}{2} \beta_i. \]  

\( \text{--7--} \)
We note that Eq.(3.9) has exactly the form of that for a massless, non-minimally coupled field. The curvature $R$ is a slowly-varying function of time during inflation, and the effect of the curvature term in (3.9) is similar to that of a positive mass squared term $m^2 \sim H^2$ for the fluctuations of $\varphi$. Inflation is followed by a $\chi$-dominated expansion when the inflaton field $\chi$ oscillates about the minimum of its potential (say $V \approx \frac{1}{2}m_\chi^2(\varphi)\chi^2$). During this $\chi$-dominated period, $\delta \varphi$ will approximately satisfy, after taking an average over the $\chi$ oscillations, an equation of the same form as (3.9) but with a different value of $\xi_\chi \equiv \frac{1}{2}\beta_\chi$ (here $\beta_\chi \equiv [\partial^2\ln m_\chi(\varphi)/\partial\varphi^2]_{\varphi=\varphi_0}$ measures the $\varphi$-curvature of the mass of the $\chi$ field; see the Appendix for a more exact equation satisfied by $\delta \varphi$).

Neglecting the spatial gradients of $\varphi$ (which are rapidly suppressed by the cosmological expansion) we can finally rewrite (3.9) in the form

$$\delta \ddot{\varphi} + 3H\dot{\varphi} + 12\xi_\chi H^2\delta \varphi = 0. \quad (3.11)$$

During the slow roll period, the field $\varphi(t)$ changes at a much faster rate than $H(t)$, and we can solve (3.11) using a WKB-type \textit{ansatz},

$$\delta \varphi = e^{W(t)}, \quad (3.12)$$

and assuming $|\dot{W}| \ll \dot{W}^2$. Substitution of (3.12) into (3.11) gives a quadratic equation for $\dot{W}$ with the solution

$$\dot{W}(t) = \left(-\frac{3}{2} \pm \sqrt{\frac{9}{4} - 12\xi} \right) H(t). \quad (3.13)$$

Alternatively we can follow the method of Ref. [20] and write the equation describing the evolution of $\varphi$ in terms of the parameter $p$ measuring the number of $e$-foldings:

$$p = \ln \frac{a(t)}{a(t_i)} = \int_{t_i}^{t} H dt, \quad (3.14)$$

where $t_i$ denotes the time at the onset of inflation. The latter equation can be written in all eras of interest, inflation, $\chi$-dominated (in the approximation where one averages over
the $\chi$ oscillations), radiation-dominated, and matter dominated. When neglecting $(\varphi'_p)^2$ with respect to 1, this equation reads

$$\frac{2}{3}\varphi''_p + (1 - \lambda) \varphi'_p = -(1 - 3\lambda)\beta(\varphi - \varphi_0)$$  \hspace{1cm} (3.15)

where $\lambda$ is the ratio between pressure and energy density (i.e. $-1$, $0$ or $1/3$ in vacuum-, $\chi$- or matter-dominated eras, respectively), and where $\beta$ is the parameter measuring the curvature of the $\varphi$-dependent mass scale driving the evolution of $\varphi$ in the corresponding era (e.g. $\beta_i$ in the inflationary era and $\beta_\chi$ in the $\chi$-oscillation dominated era).

The equation (3.15) is that of a damped harmonic oscillator. The critical value of $\beta$ separating the overdamped-type solution from the damped-oscillation-type one is $\beta_c = 3/8$ (in both the vacuum-dominated and the matter-dominated cases). During inflation, the approach of $\varphi$ toward $\varphi_0$ is oscillatory if $\beta_i > \beta_c$, i.e. $\nu^2 < 0$, where we define

$$\nu^2 \equiv 6(\beta_c - \beta_i) = \frac{9}{4} - 12\xi_i.$$  \hspace{1cm} (3.16)

From what we said above, we expect to be in this regime ($\nu = i|\nu|$). Then

$$\delta\varphi = Ae^{-3p/2} \cos(|\nu|p + \delta),$$  \hspace{1cm} (3.17)

where $A$ and $\delta$ are constants. The number of $e$-foldings during inflation is $p_i \gtrsim 65$, so that if initially $|\delta\varphi| \sim 1$, i.e. $A \sim 1$, then, by the end of inflation,

$$|\delta\varphi| \lesssim e^{-3p_i/2} \lesssim 10^{-42}.$$  \hspace{1cm} (3.18)

During $\chi$-domination the average pressure of the oscillating $\chi$-field is nearly zero, the expansion law is $a(t) \propto t^{2/3}$, and the approach of $\varphi$ toward $\varphi_0$ is described by Eq. (3.15) with $\lambda = 0$ and $\beta = \beta_\chi$. This yields, when $\beta_\chi > \beta_c$, an additional factor of attraction of $\delta\varphi$ toward zero of order $e^{-3p_\chi/4}$, where $p_\chi$ is the number of $e$-foldings during $\chi$-domination. [Note that in the simple model (2.10) one has $\beta_\chi = \frac{1}{2}\kappa = 2\beta_i$.] The energy of $\chi$-oscillations eventually thermalizes, and the universe enters the radiation era with $a(t) \propto t^{1/2}$. Since $\lambda = 1/3$ or
$R = 0$ then, we see either from (3.15) or from (3.9) that $\delta \varphi$ essentially stops evolving during the radiation era independently of the value of $\beta$. During the subsequent matter-dominated era, $\delta \varphi$ will be further attracted toward $\varphi_0$ by an additional factor $e^{-3p_m/4}$, where $p_m \sim 9$ is the number of e-foldings separating us from the end of the radiation era. Finally, the present value of $\delta \varphi$ is expected to be

$$|\delta \varphi| \lesssim 10^{-49}.$$ \hfill (3.19)

Note that the estimate (3.19) is independent of the precise values of $\beta_i$ and $\beta_\chi$ as long as they are both $> 3/8$. A nonzero value of $\delta \varphi$ causes a number of potentially observable deviations from general relativity [16]. However, all observable non-Einsteinian effects are proportional to the square of $\delta \varphi$. The present observational bounds (from equivalence principle tests) are, within the context of the model (2.9),

$$\kappa |\delta \varphi|_{\text{obs}} \lesssim 5 \times 10^{-6}.$$ \hfill (3.20)

Even if we were to assume that $\beta_i$, or equivalently $\xi_i$, is anomalously smaller than unity, it would only be in the extreme case where $\xi_i \lesssim 10^{-2}$ that the attraction factor due to inflation $\sim e^{-4\xi_i p_i}$ would not be much smaller than unity. We see that inflation is extremely efficient in driving a homogeneous, classical field $\varphi$ to $\varphi_0$. In the case, considered below, where the field $\varphi$ has a potential (sharing the discrete symmetry of the coupling functions $B_a(\varphi)$), we conclude that we have here a natural, non fine-tuned, solution to the Polonyi-moduli problem as the VEV of $\varphi$ is left, at the end of inflation, very precisely at the place where it stores no potential energy. However, as the change in the equation of state at the end of inflation can result in copious creation of dilatons we must consider whether this can regenerate a non trivial quasi-classical VEV for $\varphi$. This will be discussed in the next section.

IV. QUANTUM CREATION OF DILATONS

Particle creation during and shortly after inflation can be studied using the standard methods of quantum field theory in curved spacetime [21]. For a massless scalar field with
coupling to the curvature, as in Eq.(3.9), this has been done by Ford [22] in the limit where
the coupling to the curvature is nearly conformal, $|\xi_i - 1/6| \ll 1$. He assumed also that the
$\chi$-dominated period is very short, so that inflation is followed by thermalization in about one
Hubble time. He found that the energy density of created particles at the end of inflation
($t = t_*$) is

$$\rho_{\varphi}(t_*) \sim 10^{-2}(6\xi_i - 1)^2 H_*^4,$$

(4.1)

where $H_*$ is the expansion rate at $t = t_*$. We have calculated the energy density and the spectrum of dilatons without assuming
$(\xi_i - 1/6)$ to be small and without assuming that the $\chi$-dominated period is necessarily short.
We found that the matching to a $\chi$-dominated expansion brings several qualitatively new
features but does not change drastically the overall quantitative results of a matching to a
radiation-dominated era. To keep things simple we discuss in the text only the latter case.
The details of our calculation are given in the Appendix (which contains also a brief discussion
of the matching to a $\chi$-dominated expansion), and here we shall only state the results.

The spectrum is expressed in terms of the co-moving wave number $k$, which is equal to the
physical momentum of the wave at $t = t_*$ (we set $a(t_*) = 1$). At later times the momentum
is $p(t) = k/a(t)$, and the wavelength is $\lambda(t) = (2\pi/k)a(t)$. We find that the energy spectrum
of dilatons is peaked at $k \sim H_*$ and is exponentially suppressed for $k \gg H_*$. In the limit of
long wavelengths, $k \ll H_*$,

$$d\rho_{\varphi}(t) = \frac{\Gamma^2(\nu)}{32\pi^3 a^4(t)} \left(\nu - \frac{1}{2}\right)^2 \left(\frac{2H_*}{k}\right)^{2\nu+1} k^3 dk$$

(4.2)

for $\nu$ real (i.e. $\xi_i < 3/16$ in Eq. (3.16)) and

$$d\rho_{\varphi}(t) = \frac{H_*}{8\pi^2|\nu|a^4(t)} \left(|\nu|^2 + \frac{1}{4}\right) k^2 dk$$

(4.3)

for $\nu = i|\nu|$, where in the latter case we assumed for simplicity that $\exp(-\pi|\nu|) \ll 1$. [Note
that $\xi_i = 1/6$ corresponds to $\nu = 1/2$ for which Eq. (4.2) indeed predicts no particle production.]
When inflation is followed by $\chi$-domination, the dilaton spectrum contains a second peak at $k \sim m_\chi$ which contributes roughly the same number density as the peak at $k \sim H_*$ and an energy density differing by a factor $\sim m_\chi/H_*$. By integrating the spectra (4.2) or (4.3) up to $k_{\text{max}} \sim H_*$ we find (roughly independently of $\nu$ as long as $|\nu - 1/2| \gtrsim 1$) that the total dilaton energy density is of order

$$\rho_\varphi(t) \sim 10^{-2} H_*^4 a^{-4}(t).$$

(4.4)

In other words, we find that when $6\xi_i - 1$ becomes $\gtrsim 1$, the factor $(6\xi_i - 1)^2$ present in the nearly conformal case (4.1) saturates to something of order unity.

Using the approximate conservation of the comoving entropy $\propto N T^3 a^3$ and Hubble’s law at thermalization ($H_* \sim N_*^{1/2} T_*^2 / m_p$) we can write for the present energy density in massless dilatons

$$\Omega_\varphi \equiv \frac{\rho_\varphi}{\rho_c} \sim 10^{-2} \left( \frac{H_*}{m_p} \right)^2 \left( \frac{N}{N_*} \right)^{1/3} \Omega_r.$$  

(4.5)

Here $\rho_c$ is the critical density, $N$ is the number of spin degrees of freedom in radiation and relativistic particles (at present), $N_*$ is its value at $t_*$ (i.e. at thermalization), $\Omega_r = \rho_r/\rho_c = 4 \times 10^{-5} h^{-2}$, $\rho_r$ is the radiation density, $h \sim 1/2$ is the Hubble parameter, and $m_p$ is the Planck mass. The characteristic wavelength of dilatons for the peak at $k \sim H_*$ (when $\xi_i \gtrsim 1/12$ [23]) is

$$\lambda_\chi \sim 2\pi H_*^{-1} Z_* \sim 4(m_p/H_*)^{1/2} \text{mm},$$

(4.6)

where $Z_* \sim N_*^{1/2} N^{-3/2} (H_* m_p)^{1/2}/T$, with $T = 2.74K = (0.83$ mm$)^{-1}$, is the redshift at $t = t_*$. The presence of a $\chi$-oscillatory era would add a (possibly overlapping) second peak with characteristic wavelength differing by a factor $\sim H_*/m_\chi$.

Waves of wavelength smaller than the Hubble length, $\lambda(t) < t$, can be treated classically, and their amplitude can be estimated from

$$\varphi_k(t) \sim a(t) \left[ \frac{q}{k} \frac{d \rho_\varphi(t)}{dk} \right]^{1/2},$$

(4.7)
and at the present time we find, using Eqs. (4.2), (4.3)

\[ \varphi_k \sim 0.1 q^{1/2} Z_*^{-1} k (H_* / k)^{\nu + 1/2}, \quad \nu > 0, \] (4.8)

\[ \varphi_k \sim 0.1 Z_*^{-1} (q H_* k)^{1/2}, \quad \nu = i |\nu|. \] (4.9)

For \( k \sim H_* \), corresponding to wavelengths \( \sim \lambda_c \), both of these equations give

\[ \varphi_{H_*} \sim (T/m_p)(H_*/m_p)^{1/2} \sim 10^{-32} (H_*/m_p)^{1/2} \lesssim 10^{-34}, \] (4.10)

where we have used the bound [2] \( H_* \lesssim 10^{-5} m_p \) on the rate of inflation. (Larger values of \( H_* \) result in an excessive amount of relic gravitational waves). In the case of \( \nu^2 < 1/4 \) (\( \xi_i > 1/6 \)) [including \( \nu^2 < 0 \), i.e. \( \xi_i > 3/16 \)] the dilaton amplitude \( \varphi_k \propto |k^{1/2-\nu}| \) decreases towards longer wavelengths. This means that for the wavelengths and time scales of relevance to laboratory experiments the quantum-regenerated \( \delta \varphi \) is many orders of magnitude below the observational bounds (3.20).

A different behavior is obtained for \( \nu > 1/2 \) (\( \xi_i < 1/6 \)), when \( \varphi_k \) grows towards longer wavelengths. The largest growth occurs for nearly minimal coupling, \( \xi_i \approx 0, \nu \approx 3/2, \) when \( \varphi_k \propto k^{-1+4\xi_i} \), and on the present Hubble scale \( k \sim Ha \sim H Z_* \) with \( H^{-1} \sim 10^{28} \) cm

\[ \delta \varphi_{\text{max}} \sim \Omega_r^{1/2} (H/T)^{4\xi_i} (H_* / m_p)^{1-2\xi_i} \sim 10^{-7} 10^{-106\xi_i} (10^5 H_* / m_p)^{1-2\xi_i}. \] (4.11)

Even for anomalously small curvature couplings \( \xi_i \lesssim 10^{-2} \), and the maximal allowed value of \( H_* \), the dilaton amplitude is smaller than \( \delta \varphi \sim 10^{-7} \), and therefore smaller than the observational limits (3.20) which become less stringent when \( \kappa = 8 \xi_i \) is itself small, i.e. when the interaction of dilatons with matter is suppressed due to a small value of \( \xi_i \).

It should be noted that Eqs.(4.7)-(4.9) cannot be used for wavelengths longer than the Hubble length, where real particles cannot yet be distinguished from vacuum polarization effects. In particular, we cannot conclude from (4.8) that \( \varphi_k \) can become arbitrarily large in the limit of long wavelengths. To estimate the dispersion of the dilaton field on super-horizon scales, we calculated the quantum expectation value \( \langle \varphi^2 \rangle \). The calculation is outlined in the
Appendix, and the result is that for $\nu > 1/2$ we have $\langle \varphi^2 \rangle(t) \sim \varphi_{k_H}^2$, where $k_H$ corresponds to the Hubble scale at time $t$. This indicates that super-horizon wavelengths do not significantly contribute to $\delta \varphi$.

V. MASSIVE DILATONS

Up till now we have been considering the case where the dilaton remains exactly massless at low energy. However, as we remarked above, under the assumption of a discrete $\varphi$-symmetry (or some other universality feature such as the one built in the model (2.9)) the existence of a mass term for $\varphi$ does not create the usual Polonyi problem because, after inflation, the VEV of $\varphi$ is left very precisely pinned at the minimum of its potential. We must, however, investigate what constraints on the dilaton mass $m_\varphi$ are obtained by requiring that the present mass density of the quantum-generated dilatons does not exceed the critical density $\rho_c$. To simplify the discussion, we shall consider only the case of $\nu^2 < 1/4$, when long-wavelength modes with $k \ll H_*$ are unimportant, and the particle interpretation of the field $\delta \varphi$ becomes valid shortly after $t_*$. The mass $m_\varphi$ and the dilaton number density $n_\varphi$ should then satisfy the condition

$$\Omega_\varphi \equiv \frac{n_\varphi m_\varphi}{\rho_c} \lesssim 1. \quad (5.1)$$

To estimate $n_\varphi$, we note that the ratio

$$r = n_\varphi / n_r, \quad (5.2)$$

where $n_r$ is the density of particles with masses smaller than the temperature, remains approximately constant in the course of cosmological evolution (assuming that the dilaton lifetime exceeds the age of the universe, see below). At the end of inflation, we find from integrating the number density spectrum (see Appendix)

$$n_\varphi(t_*) \sim 10^{-2} H_*^3. \quad (5.3)$$

Using the other equations

$$n_r(t_*) \sim N_* T_*^3, \quad (5.4)$$

\[\text{-14-}\]
\[ H_\ast \sim N_\ast^{1/2} T_\ast^2 / m_p, \quad (5.5) \]

where \( T_\ast \) is the thermalization temperature, we get

\[ r \sim 10^{-2} N_\ast^{-1/4} (H_\ast / m_p)^{3/2}. \quad (5.6) \]

Inserting this in (5.1) we obtain

\[ \Omega_\varphi \sim 10^{-2} N_\ast^{-1/4} (H_\ast / m_p)^{3/2} (m_\varphi / T) \Omega_r, \quad (5.7a) \]

where, as above, \( \Omega_r = \rho_r / \rho_c = 4 \times 10^{-5} h^{-2} \). Numerically this reads

\[ \Omega_\varphi \sim \left( 10^5 \frac{H_\ast}{m_p} \right)^{3/2} \frac{m_\varphi}{10 \text{GeV}}. \quad (5.7b) \]

When the equality \( \Omega_\varphi = 1 \) is satisfied, dilatons dominate the mass density of the universe.

This can happen for the whole range of masses \( m_\varphi \gtrsim 10 \text{GeV} \). Let us note in particular that the value \( m_\varphi \sim 1 \text{TeV} \) suggested by many current SUSY breaking models [13], [14] is allowed and corresponds to \( H_\ast \sim 10^{-7} m_p \), i.e. \( T_\ast \sim 10^{15} \text{GeV} \). We remark also that the value \( m_\varphi \sim m_p \) [24] corresponds to a “weak scale inflation” \( H_\ast \sim 100 \text{GeV} \) [17] (i.e. to an intermediate scale reheating temperature \( T_\ast \sim 3 \times 10^{10} \text{GeV} \sim (m_W m_p)^{1/2} \)). Other authors have suggested the possibility that dilatons may provide the dark matter of the universe [18], [25]. An important difference of our model is that our allowed mass range is \( m_\varphi \gtrsim 10 \text{GeV} \) (which contains notably \( m_\varphi \sim 1 \text{TeV} \)) and still corresponds to essentially stable dilatons, with a decay time much larger than the age of the universe (as is discussed next). [Usually [18], stable dilatons exist only for \( m_\varphi \lesssim 100 \text{MeV} \) because of Eq. (5.9) below.]

Let us finally examine whether additional constraints on the dilaton mass follow from an eventual flux of \( \gamma \)-rays resulting from the dilaton decay, \( \varphi \to \gamma \gamma \). This decay is described by the term

\[ \mathcal{L}_{\text{int}} \propto (\varphi - \varphi_0) F_{\mu\nu}^2 \quad (5.8) \]
in the effective Lagrangian. When expressed in terms of a canonically normalized scalar field \( \varphi_{\text{can}} = \varphi/\sqrt{q} \), Eq. (5.8) contains a coupling constant \( \propto 1/m_p \). By dimensional analysis, if the dimensionless coefficient in front of (5.8) is of order unity, the corresponding lifetime is

\[
\tau_\varphi \sim \frac{m_p^2}{m_\varphi^3}.
\] (5.9)

In our case, however, all coupling functions are expected to have extrema at \( \varphi = \varphi_0 \), and thus the dimensionless coefficient in front of (5.8) is \( \propto \delta \varphi \), i.e. is exceedingly small. Then \( \gamma \)-rays can only be produced in binary collisions \( \varphi \varphi \rightarrow \gamma \gamma \). The corresponding interaction term is

\[
L_{\text{int}} \propto (\varphi - \varphi_0)^2 F_{\mu \nu}^2,
\] (5.10)

with a dimensionless coefficient of order unity. The corresponding annihilation cross-section is extremely small [26],

\[
\sigma \sim \frac{m_\varphi^2}{vm_p^4},
\] (5.11)

where \( v \) is the average velocity of dilatons. The lifetime \( \tau_\varphi \) can be found from \( n_\varphi \sigma v \tau_\varphi \sim 1 \), which gives

\[
\tau_\varphi \sim \frac{m_p^4}{n_\varphi m_\varphi^2}.
\] (5.12)

The annihilation rate per unit spacetime volume is

\[
\frac{n_\varphi}{\tau_\varphi} \sim \frac{n_\varphi^2 m_\varphi^2}{m_p^4} \lesssim \frac{\rho_c^2}{m_p^4} \sim t_0^{-4},
\] (5.13)

where \( t_0 \) is the present age of the universe. Hence, there is no more than one annihilation in the entire visible universe during its whole lifetime!

Note that as all coupling functions have extrema at \( \varphi = \varphi_0 \), the type of dark matter our mechanism leads to has only exceedingly weak interactions with ordinary matter. Basically, its presence can be felt only through the gravitational effect of its mass. This leaves little hope of detecting it in laboratory experiments. For instance, for a macroscopically sizable mass \( m_\varphi \sim m_p \sim 2 \times 10^{-5} \text{g} \), the average present cosmological density of dilatons would be at most \( n_\varphi \sim 10^{-24} \text{cm}^{-3} \).
ACKNOWLEDGEMENTS

T.D. thanks I. Antoniadis, M. Gasperini and G. Veneziano for informative discussions. A.V. is grateful to Larry Ford and Keith Olive for discussions. He also wishes to thank the Institut des Hautes Etudes Scientifiques for hospitality during the period when most of this work was done and the National Science Foundation for partial support.

APPENDIX

In this Appendix we study the spectrum of created dilatons in simple models in which de Sitter inflation is followed either by a radiation-dominated expansion or by a $\chi$-dominated one. We consider first the transition to a radiation-dominated era. Using the conformal time coordinate $d\eta = dt/a(t)$, the corresponding metric can be written as

$$ds^2 = a^2(\eta)(-d\eta^2 + dx^2),$$  \hspace{1cm} (A.1)

$$a(\eta) = -(H_*\eta)^{-1}, \quad \eta < \eta_*, \hspace{1cm} (A.2a)$$

$$a(\eta) = H_* (\eta - \bar{\eta}), \quad \eta > \eta_*.$$  \hspace{1cm} (A.2b)

Here, $H_* = const$ is the expansion rate during inflation, $\eta_* < 0$ is the thermalization time when inflation ends, and $\bar{\eta} = \eta_* + (H_*^2 \eta_*)^{-1}$. It will be convenient to set $\eta_* = -H_*^{-1}$, so that $a(\eta_*) = 1$. The calculation in this Appendix follows the standard techniques reviewed in [14].

The field operator $\delta \hat{\varphi}(x) = \hat{\varphi}(x) - \varphi_0$ satisfies a massless, non-minimally coupled field equation (3.9),

$$\left(\nabla^2 - \xi_i R\right) \delta \hat{\varphi}(x) = 0,$$  \hspace{1cm} (A.3)

and can be expanded in terms of creation and annihilation operators,

$$\delta \hat{\varphi}(x) = q^{1/2} \frac{1}{a(\eta)} \int \frac{d^3k}{(2\pi)^{3/2}} \left[ \hat{a}_k \psi_k(\eta) e^{ikx} + h.c. \right].$$  \hspace{1cm} (A.4)

Here, hats indicate operator quantities and should not be confused with the notation of Section II where they indicate quantities in the ‘string frame’. The mode functions $\psi_k(\eta)$ satisfy the normalization condition

$$\psi_k^* \psi_k^* - \psi_k \psi_k^* = -i,$$  \hspace{1cm} (A.5)
corresponding to \([a_k, \hat{a}_k^\dagger] = \delta(k-k')\). We shall assume that the quantum state of the dilaton field during the inflationary period \(\eta < \eta^\ast\) is the de Sitter-invariant Bunch-Davis vacuum (i.e. that \(\psi_k(\eta) \sim e^{-i k \eta} / \sqrt{2k}\) when \(\eta \rightarrow -\infty\)). The corresponding mode functions are

\[
\psi_k(\eta) = A(-\eta)^{1/2} H^{(1)}_\nu(-k\eta),
\]

where

\[
A = (\pi/4)^{1/2} e^{i\pi/4} e^{i\pi \nu/2},
\]

\(H^{(1)}_\nu(z)\) are Hankel functions, and \(\nu\) is given by Eq.(3.16).

The mode functions for the radiation-dominated period \(\eta > \eta^\ast\) are

\[
\psi_k(\eta) = \frac{1}{(2k)^{1/2}} \left[ \alpha_k e^{-ik(\eta-\bar{\eta})} + \beta_k e^{ik(\eta-\bar{\eta})} \right],
\]

and Eq.(A.5) gives a normalization condition for \(\alpha_k\) and \(\beta_k\),

\[
|\alpha_k|^2 - |\beta_k|^2 = 1.
\]

The coefficients \(\alpha_k\) and \(\beta_k\) can be determined by matching the mode functions (A.6) and (A.8) and their derivatives at \(\eta = \eta^\ast\). The dilaton spectrum (in number density and energy density) can then be found from

\[
\frac{d n_\varphi}{d^3 \mathbf{k}} = \frac{1}{2\pi^2 a^3(t)} |\beta_k|^2 k^2 dk,
\]

\[
\frac{d \rho_\varphi}{d^3 \mathbf{k}} = \frac{1}{2\pi^2 a^4(t)} |\beta_k|^2 k^3 dk.
\]

The instantaneous thermalization model (A.2) is not adequate for modes with wavelengths shorter than the de Sitter horizon at \(\eta^\ast\), \(k \gtrsim H^\ast\). In a more realistic model, the transition from the vacuum to the radiation equation of state takes at least a Hubble time, and particle creation in such modes is exponentially suppressed, \(\beta(k \gg H^\ast) \approx 0\). In the opposite limit, \(k \ll H^\ast\), we can find \(\alpha_k\) and \(\beta_k\) using the asymptotic form of the Hankel functions for small values of the argument,

\[
H^{(1)}_\nu(z) \approx \frac{i}{\sin(\nu \pi)} \left[ e^{-i\nu \pi} \left( \frac{z}{2} \right)^\nu - \frac{1}{\Gamma(1 - \nu)} \left( \frac{z}{2} \right)^{-\nu} \right].
\]
For $\nu > 0$, the first term in (A.11) is negligible, and we find $\alpha_k \approx -\beta_k$ and

$$|\beta_k|^2 = \frac{1}{16\pi} \left( \nu - \frac{1}{2} \right)^2 \Gamma^2(\nu) \left( \frac{2H_*}{k} \right)^{2\nu+1}. \tag{A.12}$$

In deriving (A.12) we have used the identity

$$\Gamma(z)\Gamma(1-z) = \frac{\pi}{\sin(\pi z)}. \tag{A.13}$$

In the case of imaginary $\nu$, $\nu = i|\nu|$, we shall assume for simplicity that $\exp(-\pi|\nu|) \ll 1$. Then again the first term in (A.11) can be neglected, and we obtain $\alpha_k \approx -\beta_k$ with

$$|\beta_k|^2 \approx \frac{H_*}{4k|\nu|} \left( |\nu|^2 + \frac{1}{4} \right). \tag{A.14}$$

Combining (A.12) and (A.14) with (A.10) we obtain Eqs.(4.2),(4.3). Let us note in passing that the spectrum (A.14) is formally of the Rayleigh-Jeans form: $|\beta_k|^2_{RJ} = T_{RJ}/k$, that is the limit of $(e^{k/T_{RJ}} - 1)^{-1}$ when $k \ll T_{RJ}$. (Similar spectra also come out of the superinflationary scenario of Refs. [3], [18]). By contrast, we shall see below that when inflation is followed by $\chi$-domination one does not get a Rayleigh-Jeans-type spectrum.

The dispersion of the dilaton field on super-horizon scales, $k \ll \eta^{-1}$, can be estimated by calculating the expectation value

$$\langle (\delta \hat{\phi})^2 \rangle = (2\pi)^{-3}a^{-2}q \int |\psi_k(\eta)|^2 d^3k. \tag{A.15}$$

The contribution of long wavelengths ($k \ll H_*$) to this integral can be found using Eqs.(A.8),(A.12) and (A.14) with $\alpha_k \approx -\beta_k$. This gives

$$\langle (\delta \hat{\phi})^2 \rangle \approx \frac{q}{4\pi^3 H_*^2(\eta - \bar{\eta})^2} \int d^3k k^{-1} |\beta_k|^2 \sin^2[k(\eta - \bar{\eta})], \tag{A.16}$$

and for $\nu > 0$ we find

$$\langle (\delta \hat{\phi})^2 \rangle \sim q \frac{(\nu - 1/2)^2 \Gamma^2(\nu)}{16\pi^3 H_*^2(\eta - \bar{\eta})^2} (2H_*)^{2\nu+1} \int_0^{\sim H_*} dk k^{-2\nu} \sin^2[k(\eta - \bar{\eta})]. \tag{A.17}$$

It is easily seen that for $\nu < 1/2$ the integral is dominated by the upper limit ($k \sim H_*$), while for $1/2 < \nu < 3/2$ the dominant contribution is given by $k \sim \eta^{-1}$, that is, by the modes of
wavelength comparable to the Hubble length. In the latter case the upper limit of integration can be extended to infinity, and we obtain a somewhat unwieldy expression

\[ \langle (\delta \dot{\phi})^2 \rangle \sim -2\pi^{-3} \sin(\nu \pi) \Gamma(1 - 2\nu) \Gamma^2(\nu) (\nu - 1/2)^2 q H_*^2 [4a(\eta)]^{2\nu - 3}, \]  

where \( a(\eta) \) is given by (A.2b). Disregarding numerical factors, this gives

\[ \langle (\delta \dot{\phi})^2 \rangle \sim q H_*^2 [a(\eta)]^{2\nu - 3}. \]  

This is to be compared with the dilaton amplitude \( \varphi_k \) which can be found from Eqs. (4.7), (4.2),

\[ \varphi_k^2(t) \sim \frac{q k^2}{a^2(t)} \left( \frac{H_*}{k} \right)^{2\nu + 1}. \]  

It is easily seen that \( \langle (\delta \dot{\phi})^2 \rangle \sim \varphi_k^2 \) for \( k \sim \eta^{-1} \).

Let us finally briefly indicate the peculiarities of the more general case where the inflationary evolution (A.2a) is followed by a \( \chi \)-dominated expansion with an averaged scale factor (we assume \( \Gamma_\chi \ll H(\eta) \ll m_\chi \) away from \( \eta = \eta_* \) and average over the oscillations at frequency \( m_\chi \))

\[ \langle a(\eta) \rangle = \left[ 1 + \frac{1}{2} H_*(\eta - \eta_*) \right]^2 \quad (\eta > \eta_*). \]  

During this period, \( \delta \varphi \) couples to the \( \chi \)-matter through the \( \varphi \)-dependence of the potential energy \( V(\chi, \varphi) \approx \frac{1}{2} m_\chi^2 (\varphi) \chi^2 \approx \frac{1}{2} m_\chi^2 (\varphi_0) \chi^2 \left[ 1 + \frac{1}{2} \beta_\chi \delta \varphi \right]^2 \) which yields

\[ \nabla^2 \varphi - q V_{\varphi\varphi}(\chi, \varphi_0) \delta \varphi = \nabla^2 \varphi - 2 \beta_\chi q V(\chi, \varphi_0) \delta \varphi = 0. \]  

Then the Fourier modes \( \psi_k(\eta) \) of Eq. (A.4) satisfy the conformal-time evolution equation

\[ \partial^2_n \psi_k(\eta) + (k^2 - U(\eta)) \psi_k(\eta) = 0, \]  

\[ U(\eta) \equiv \frac{a''}{a} - qa^2 V_{\varphi\varphi}(\chi, \varphi_0) = \frac{a''}{a} - 2 q \beta_\chi a^2 V(\chi, \varphi_0). \]  

The first forms of equations (A.22) and (A.24) are valid in both the inflationary period (where \( V_{\varphi\varphi}(\chi, \varphi_0) = 4 \beta_i V(\chi, \varphi_0) \)) and the \( \chi \)-dominated one. During inflation the effective potential reads \( U(\eta) = 2(1 - 3 \beta_i) \eta^{-2} \), while during \( \chi \)-domination

\[ U(\eta) = \frac{2}{(\eta - 3 \eta_*)^2} \left[ 1 - 3 \beta_\chi + 3(1 - \beta_\chi) \cos[2m_\chi(t - t_*))] \right] \quad (\eta > \eta_*). \]
The effective potential (A.25) contains two distinct spectral features: a monotonic piece \( \propto (\eta - 3\eta_*)^{-2} \) varying on the (averaged) Hubble time scale, and an oscillatory piece involving \( \cos[2m_\chi(t-t_*)] \). Correspondingly, the spectrum of quantum fluctuations generated by solving the Schrödinger-like equation (A.23) will have two peaks: one at \( k \sim H_* \) and one at \( k \sim m_\chi \). [Depending upon the inflationary scenario considered, these peaks might be separated or might overlap.] One can compute the Bogolyubov coefficient \( \beta_k \) of the first peak by matching at \( \eta = \eta_* \) the exact solutions of Eq. (A.23) when dropping the cosine term in Eq. (A.25). As above, these are Hankel functions with \( \nu = \nu_i \equiv i\sqrt{6(\beta_i - 3/8)} \) in the inflationary period and \( \nu = \nu_\chi \equiv i\sqrt{6(\beta_\chi - 3/8)} \) during the \( \chi \)-dominated one. (We assume here for definiteness that both are imaginary). This yields for the “Hubble-time scale” peak in the long wavelength limit \( k \ll H_* \)

\[
|\beta_k|_{\text{H}}^2 = \frac{1}{2} \frac{|\nu_\chi|}{|\nu_i|} \left[ \left( \frac{1}{2} - \frac{|\nu_i|}{|\nu_\chi|} \right)^2 + \left( \frac{3}{4|\nu_\chi|} \right)^2 \right]. \tag{A.26}
\]

Note that this \( |\beta_k|_{\text{H}}^2 \) is independent of \( k \), and therefore different from the Rayleigh-Jeans-type spectrum (A.14). Integrating (A.26) up to some effective cut-off \( k_{\text{max}} = \kappa H_* \) leads to

\[
\begin{align*}
\rho^H_{\phi} &\sim \frac{1}{64\pi^2} \kappa^4 \frac{H_*^4}{a^4}, 
\tag{A.27b} \\
n^H_{\phi} &\sim \frac{1}{48\pi^2} \kappa^3 \frac{H_*^3}{a^3}, 
\tag{A.27a}
\end{align*}
\]

The value of \( \kappa \) depends upon the details of the transition between inflation and \( \chi \)-domination.

We expect that \( \kappa \lesssim 1 \). Assuming \( \kappa \sim 1 \), we get the total energy density (4.4) roughly independently of whether inflation is followed by a radiation-dominated era or a \( \chi \)-oscillatory one.

Finally, the “oscillatory” peak \( k \sim m_\chi \) can be estimated by applying Born perturbation theory to Eq. (A.23): namely, \( \beta_k^{\text{osc}} \approx (2ik)^{-1} \int U^{\text{osc}}(\eta)e^{-2ik\eta}d\eta \). This yields (\( \theta \) denoting the Heaviside step function)

\[
|\beta_k|_{\text{osc}}^2 = \frac{9}{8} \pi (\beta_\chi - 1)^2 \frac{H_*^2 m_\chi^{3/2}}{k^{9/2}} \theta(k - m_\chi), \tag{A.28}
\]
and, for instance,

\[ n^\text{osc}_\phi = \frac{3}{64\pi} (\beta_\chi - 1)^2 \frac{H^3_*}{a^3}. \]  

(A.29)

[These estimates are accurate when \((\beta_\chi - 1)H^2_* \ll m^2_\chi\) and should give the right order of magnitude when \(\beta_\chi - 1 \sim 1\).] In order of magnitude the number density (A.29) is comparable to (A.27a). The corresponding energy density would differ from (A.27b) by a factor \(\sim m_\chi / H_*\).

19 Quantum cosmology suggests that inflating universes can spontaneouly nucleate out of nothing and provides a possible way of determining the initial conditions in nucleating universes. [For a recent review and references see, e.g., A.Vilenkin, Phys.Rev.50, 2581 (1994)]. For the model (2.7), the nucleation is described by a de Sitter instanton with the fields \( \varphi \) and \( \chi \) at one of the extrema of the potential \( V(\varphi, \chi) \). The instanton action, \( |S| = \frac{3m_p^4}{8V(\varphi, \chi)} \), is minimized by maximizing \( V(\varphi, \chi) \). For the simple model (2.10) this means maximizing \( V(\chi) \) and minimizing \( B(\varphi) \). Hence, according to quantum cosmology, the universe is most likely to start at the highest maximum of \( V(\chi) \) and at the lowest minimum of \( B(\varphi) \). These are just the right initial conditions for inflation.

23 In the opposite case of nearly minimal coupling, \( \xi_i \ll 1/12 \), the dilaton energy spectrum is nearly flat over a wide range of wavelengths (as in the case of gravitons).

24 Our calculation of \( n_\varphi \) in Sec.IV is valid only for \( m_\varphi^2 \ll 12\xi_i H^2_\ast \). However, in the opposite limit the fractional change in \( (m_\varphi^2 + \xi_i R) \) at the end of inflation is small, and the production of \( \varphi \)-particles should be suppressed. Hence, we expect that the bound on \( m_\varphi \) in this regime should be even weaker.
Instead of using dilatons as WIMPS, other authors have mentioned that the Polonyi-type energy of oscillation of the VEV of $\phi$ around the minimum of its potential could close the universe. See e.g. Ref. [13] and a recent preprint of P.J. Steinhardt and C.M. Will (Washington University Report, WUGRAV-94-10).

Eq.(5.11) can be understood on dimensional grounds if we note that each factor of $(\phi - \phi_0)$ in the interaction Lagrangian gives a factor of $m_p^{-1}$ in the scattering amplitude, and thus we should have $\sigma \propto m_p^{-4}$. The factor of $v^{-1}$ is a kinematic factor appearing in all low-energy cross-sections.
