ABSTRACT

Anomalous phenomena are unexplained occurrences, such as paranormal experiences, that challenge the ontological bases of current scientific knowledge and are considered scientifically impossible. Problematically, some scientific research yields significant statistical results in favor of the existence of telepathy, precognition, mind-matter interaction, and mediumship. The current study presents and statistically justifies the Multivariable Multiaxial Suggestibility Inventory-2 (MMSI-2), a new psychological instrument to measure and detect the main psychological explanations for anomalous experiences. A nonprobabilistic sample of 3,224 subjects without a psychiatric history were recruited from the general population of Spain. Exploratory factor analysis (EFA) was used to examine the internal structure of the MMSI-2’s 174 items. Direct oblimin and promax oblique rotations were applied as criteria for axis rotation. Cronbach’s alpha coefficients and their ordinal transformation were also calculated, and gender-differentiated scales for the raw MMSI-2 scale scores were developed. The first-order factorial solution yielded a total of 16 factors that explained 92.84% of the variance. Of these, 10 corresponded to the psychological variables cited in the background literature, four classified the anomalous phenomena according to their sensory mode, and two represented prototype control scales for this class of psychometric inventory. The higher-order EFA grouped the MMSI-2 scales into four macrofactors that together explained 97.737% of the variance. Satisfactory reliability rates were obtained (alphas > 0.8). The full version of the MMSI-2 with 174 items is a valid and reliable psychometric instrument for evaluating anomalous phenomena and the theoretically concomitant psychological variables. Similarly, the scaling of scores can be used in psychological assessment as a screening tool to identify clinically suspected psychological variables.

1. Introduction

Some experiences reported by patients in clinical interviews contradict the ontological bases of current scientific knowledge and are considered “unexplained” by psychology and psychiatry (e.g., Bobrow, 2003). “Paranormal” experiences are such cases, which are formally referred to as anomalous phenomena (e.g., French and Stone, 2014). The current study introduces a new psychometric instrument to detect and assess possible psychological explanations for experiences of anomalous phenomena, called the Multivariable Multiaxial Suggestibility Inventory-2 (MMSI-2).

1.1. Theoretical background

Scientific research of anomalous phenomena is complex. The main problem is that the challenge raised regarding anomalous phenomena is also based on previously published scientific evidence (e.g., Bem, 2011; Bem et al., 2016; Mossbridge et al., 2012). This means that it is not just an ideological and epistemological debate (e.g., Carter, 2012). The most serious problem can be observed in the fact that some scientific research yields significant results in favor of the existence of these alleged anomalous phenomena (e.g., Beischel et al., 2015; Kelly and Arangangel, 2011; Schwartz and Russek, 2001) and contradicts conventional scientific knowledge related to the psychology of perception, sensation and cognition (e.g., Álvarez, 2007; Bunge, 2013; Reber and Alcock, 2019). This is an example of ‘psi’ phenomena, which include precognition,
telepathy, mediumship and anomalous mind–matter interaction (see Jinks, 2019). These behaviors are also classified as beliefs in the paranormal because they are considered impossible phenomena according to the scientific canon (e.g., Irwin, 2009). Although there are reasons to deny the scientific validity of these investigations that support the existence of ‘psi’ phenomena (e.g., O’Keeffe and Wiseman, 2005; Reber and Alcock, 2019; Wagemakers et al., 2011), the fact that studies with significant results exist also requires that such research be replicated through the use of the scientific method (e.g., Popper, 2008; Storm and Ertel, 2001; Storm et al., 2013).

En the field of psychological assessment, anomalous behaviors in which the patient believes they can read other people’s minds (e.g., telepathy) or feel the presence of dead beings (e.g., mediumship) are behaviors whose clinical value could be both pathological and non-pathological (see Irwin, 2009). Psychological models justifying ‘psi’ phenomena and other anomalous phenomena can be summarized as follows: (1) the continuum model of psychoses, which justifies ‘psi’ phenomena as hallucinatory and delirious symptoms (e.g., Johns and van Os, 2001; Stefanis et al., 2002; van Os et al., 2009); (2) the semiotic model of perception (see By et al., 1980), which explains these phenomena as perceptual errors (e.g., cognitive biases or perceptual deformations) (e.g., Barberia et al., 2018; El-Mallah and Walker, 2010); and (3) the phenomenological model, which defines these behaviors as cognitive and verbal representations based on the subject’s systems of meanings (e.g., Font, 2016; French and Stone, 2014; Irwin, 1993, 2000, 2003, 2009).

Unlike the other models, the phenomenological model does not assume that the etiology of these behaviors is necessarily related to the pathological or symptomatic, nor does it accept that they are caused by errors or mistakes made by the individual (see Irwin et al., 2013; Irwin and Watt, 2007). As some research suggests, systems of meaning and cognitive structures define the way of perceiving, thinking about, and interpreting stimuli in the environment (e.g., Fishbein and Ajzen, 1975).

Therefore, the phenomenological model assumes that the etiology of these abnormalities can be observed in the patient’s psychological profile, which can justify why a person thinks and acts in a certain way (e.g., Groth-Marnat, 2009; Jaspers, 1993).

The most relevant research takes into account, as predictive factors, certain subclinical personality traits, usually based on paranoid, narcissistic, histrionic and schizotypic attributes, that are positively correlated with anomalous experiences (e.g., Lépide-Rodrigo et al., 1996; Roe and Morgan, 2002; Simmonds-Moore et al., 2019). There are also numerous papers that identify variables influencing anomalous phenomena with very high effects—in statistical terms of effect size (see Cohen, 1988)—related to substance use or substance abuse (e.g., Luke, 2012; Sideli et al., 2019; Wilkins et al., 2012). Other variables with significant results are alternating states of exhaustion/anxiety (e.g., Roe and Bell, 2016; Simmonds-Moore, 2009; Williams et al., 2007) and thrill-seeking (e.g., Gow et al., 2004; Smith et al., 2009). Another extensively studied variable is that of traumatic experiences in childhood, which are prevalent among subjects who report anomalous phenomena (e.g., Lawrence et al., 1995; Lynn and Rhue, 1988; Parra, 2019).

Some studies focus on simulation and fraud behaviors (see Álvarez, 2007; Leonard and Williams, 2019; Steiger and Hergovich, 2013). Taking as a reference the semiotics of perception, these works examine the psychological biases that would justify the invention of false memories or elements that would trigger lying as the principal mediator (e.g., French, 2003; Wilson and French, 2006). One of the biases that has been considered is the Barnum effect (e.g., O’Keeffe and Wiseman, 2005). According to Shermer (2011), this effect is observed in overly general statements that seek to validate the anomalous phenomenon, causing the subject to easily identify with the elements presented and accept them as true. Based on the contributions of Boyce and Geller (2002), this effect can be considered verbal conduct that incites deception and should be measured as a control variable. Measurement of this factor in psychometric instruments is not common; however, its inclusion seems necessary to prevent not only the bias derived from the Barnum effect but also deception and simulation behaviors (see Tombaugh, 2011). Conventional clinical evaluation tests have chosen to measure only unconscious lying as a result of image manipulation (e.g., in response to the social desirability or negative presentation of a behavior) (e.g., Ben-Porath and Tellegen, 2019; Millon, 1994; Morey, 2011). However, the control of only variables associated with image manipulation is not sufficient to evaluate lying (see Cardona, 2002; Vrij et al., 2019). On their own, are not effective indicators for the detection of deception (see Fernández-Ballesteros, 2011). In reality, the assessment of lying requires the incorporation of new measures that respond to its complexity and focus more specifically within the area of simulation and fraud (e.g., MacNeil and Soper, 2019).

Other works point to variables that are less consistent but have equally significant positive correlations (French and Stone, 2014). These variables are creativity, intuition, extraversion, and dissociative disorders (e.g., Czecková et al., 2018; Rabeyron et al., 2018; Thalbourne and Haraldsson, 1980). However, these variables present unstable statistical behavior because other research has not demonstrated significant correlations (e.g., Maraldi, 2019; Swami et al., 2011). For example, Francis et al. (2019) found no association between extraversion and anomalous phenomena. A more recent study comparing two groups—one comprising those who did not believe in the paranormal or had not had anomalous experiences and another comprising subjects who considered themselves mediums—indicated that levels of dissociation were higher for the group of nonbelievers (e.g., Vencio et al., 2018). Similarly, another publication found positive correlations between paranormal beliefs and critical thinking (e.g., Musch and Ehrenberg, 2002). In reality, both analytical and critical thinking traditionally constitute attributes that are antagonistic to belief in the paranormal (e.g., Hervovich and Arendasy, 2005). It does not seem sufficiently rigorous to explain these differences and contradictions as methodological errors or statistical artifacts (Irwin, 2009).

More behavioral approaches focus on the analysis of models related to processes of suggestion (e.g., Gibson and Heap, 1991). This approach has two aspects: on the one hand, some professionals understand suggestion as a process of alteration of consciousness that can be varied and manipulated through hypnosis techniques (e.g., Hambleton, 2008). On the other hand, another very different approach investigates suggestion as a psychological predisposition or trait that describes the emotional liability of a subject as a result of environmental influences (e.g., Hefferline et al., 1972). Along these lines, suggestibility is the degree to which a subject tends to change—presumably automatically—the typology and intensity of their emotional reactions based on the effects produced by environmental stimuli (e.g., Linton and Sheehan, 1994). This approach describes three types of suggestibility: (1) interrogative suggestibility, (2) primary suggestibility and (3) secondary suggestibility. The first of these refers to the degree of emotional liability induced in the subject exclusively by stimuli derived from social interaction (e.g., Gudjonsson, 1984, 2003). The issue lies with—and this is what determines interrogative suggestibility—how much social persuasion is needed to generate changes in the emotional reactions of the interlocutor subject. High suggestibility is observed when there are low levels of persuasion and high levels of emotional liability (e.g., Poleszyk, 2005). Primary suggestibility, in contrast, refers to ideomotor and psychobiological markers that predict the degree of emotional liability. This is in contrast to secondary suggestibility, which refers to the levels of vivid imagination needed to predict such emotional liability (e.g., Eysenck, 2017). Studies that relate levels of suggestion to anomalous phenomena take into account (e.g., Eysenck et al., 2005). According to Eysenck and Sargent (1982), Regarding altered states of consciousness, it should be noted that, with higher levels of alteration, there are more perceived anomalous experiences (e.g., Luke, 2012; Maij et al., 2017; Moreira-Almeida and Lotufo-Neto, 2017). Likewise, the greater the secondary suggestibility, the greater the propensity to develop anomalous phenomena (e.g., Eysenck, 2017; Terhune and Smith, 2006; Wiseman et al., 2003). There are also works with positive correlations that address primary suggestibility and...
interrogative suggestibility, but the consistency of their results is questionable (e.g., Brugger and Mohr, 2008; Haraldsson, 1985; Hergovich, 2003). Along these lines, it appears that secondary suggestibility and altered states of consciousness are the most frequently researched types of suggestibility and hence the best predictors of anomalous phenomena (Eysenck and Sargent, 1982).

As mentioned at the outset, the identification of variables concomitant with anomalous phenomena faces a major challenge: in some cases, the existing scientific literature is not entirely clear as to which variables correlate with anomalous phenomena and belief in the paranormal (e.g., Houran and Lange, 2004; Houran et al., 2019). Some of the trends highlighted in the preceding paragraphs have been replicated, with different results, and measurement instruments that effectively assess the correlated factors have not been confirmed in the scientific literature.

Another problem is that of which psychological variables to evaluate and how to measure the correlation between anomalous phenomena and these variables (e.g., Cameron, 2016; Lawrence, 2016). In fact, no conventional clinical questionnaires have been prepared or validated to relate previously known psychological variables to perceived anomalous phenomena (e.g., Pasricha, 2011). One of the criticisms of the instruments most commonly used in clinical diagnosis is that the items examine only pathological symptoms and do not express more attenuated indicators of the evaluated disorders (e.g., Hueso, 2011; Shiah et al., 2014). This suggests that these instruments are valid for samples of patients with an underlying psychopathology, but although they present normative scales for the general nonclinical population, the content of the items does not change categorically and remains qualitatively pathological (e.g., Butcher et al., 1995; Williams and Lally, 2017). Another very obvious difficulty is that the most widely recognized questionnaires in clinical practice conceive of anomalous experiences as exclusively psychopathological symptoms and do not allow a quantitative analysis beyond their pathological condition (e.g., Irwin, 1993, 2009). It should be noted that nonclinical questionnaires exist that do allow the examination of anomalous perceptions and belief in the paranormal at the psychometric level (e.g., Bell et al., 2006; Mason and Claridge, 2006; Stefanis et al., 2002), but they do not take into account possible concomitant psychological variables that allow clinical, psychological and forensic decisions to be made regarding the etiology of the perceived anomalous phenomena (e.g., Irwin, 2009). Practically speaking, if the evidence published does not guarantee the formulation of a conceptually sound explanatory theory, there is a need to examine and replicate at least from an exploratory standpoint (see Gallagher et al., 1994) – the methodological bases of scientific precedents (e.g., Utts, 2018).

1.2. Research objectives

The interests of this research can be summarized by two questions. First, what behavioral variables relate to, explain, and allow us to understand anomalous phenomena? Second, are these variables operative enough to validate a new psychometric test?

Accordingly, the study’s objective is to propose and develop an empirical-statistical tool to identify, evaluate, and measure causes that could explain experiences of anomalous phenomena. The study thus created, developed, and examined the validity and reliability of the Multivariable Multiaxial Suggestibility Inventory-2 (MMSI-2), an innovative psychometric instrument that examines anomalous phenomena based on various causal factors cited in the scientific literature.

2. Materials & methods

2.1. Human ethics

Participants gave their written consent to use their anonymous data for statistical purposes. All of them were over 18 years old and voluntarily collaborated without receiving any financial compensation. The procedures were carried out in compliance with the institutional regulations of the university and the Spanish Government Data Protection Law 15/1999. The Committee of Ethical Guarantees of Ramon Llull University reviewed, favorably evaluated and approved this research. Similarly, all procedures adhere to the Helsinki Declaration of 1975, revised in 2013.

2.2. Participants

This study used a nonprobabilistic convenience sample and was conducted between 2013 and 2019 (N = 3,224). The sample comprised both men (49.5%) and women (50.5%), all adults (>18; mean = 34.64; SD = 14.791) without a reported psychiatric history (i.e., no previous psychiatric diagnosis and, therefore, no officially recognized mental disorder).

Following the sampling representativity criteria proposed by Muñiz (2003), the subjects came from three different Spanish communities. The groups were: (1) The Community of Madrid (N = 1,102; with mean ages 34.32; SD = 14.416), (2) The Autonomous Community of Catalonia (N = 1,338; with mean ages 35.46; SD = 15.549), and (3) The Community of Castilla-la Mancha (N = 784; with mean ages = 33.70; SD = 13.902). Two additional sociodemographic variables were recorded to further characterize the sample. Socioeducational level was evaluated based on the standards proposed in Spain’s National Institute of Statistics and was classified into five levels: (1) no schooling (0.2%), (2) elementary education (2%), (3) compulsory secondary education or basic vocational training (14.5%), (4) baccalaureate or higher vocational training (40.4%), and (5) university or higher education (40.8%).

Each participant was consulted to determine their self-reported belief in the existence of paranormal phenomena based on three ordinal categories: 0 = ‘I do not believe at all’ (29.1% Total, 32.8% Madrid, 44.2% Catalonia, 23% Castilla-La Mancha); 1 = ‘I question it’ (36.1% Total, 34.9% Madrid, 38.2% Catalonia, 26.9% Castilla-La Mancha) and 2 = ‘I believe completely’ (34.8% Total, 34.6% Madrid, 42.7% Catalonia, 22.7% Castilla-La Mancha). All subjects voluntarily agreed to participate in the study and signed informed consent on paper or digitally.

2.3. Procedure

Figure 1 summarizes all phases involved in the psychometric and methodological development of the MMSI-2.

The first phase took place in 2012. A research project was initiated that sought to quantitatively examine perceived anomalous phenomena by relating them to possible psychological history variables. During the first year of research, the necessary bibliographic sources were consulted, and a theoretical framework was designed to inform the drafting of the items.

The second phase occurred in 2013. An initial bank of items (N = 223) was created based on the scientific literature cited above and the behavioral indicators associated with each variable found in the literature. References to possible clinical behaviors were taken from the DSM-IV-TR (American Psychiatric Association, 2002) and the DSM-V (American Psychiatric Association, 2013). The items were written exclusively by the author of the manuscript. The items consisted of affirmative and negative phrases that addressed anomalous phenomena (e.g., ‘I have been able to sense the thoughts of other people’) and psychological attributes correlated with anomalous behaviors, including personality traits, clinical trends, anxiety states, and cognitive biases (e.g., ‘I allow my emotions to affect my thoughts’). After a review of form and content by the research team at the time, the 223 items were sent to 22 professional psychologists with different specializations (including a specialization in methodology and research). The qualitative evaluation method used was that proposed by Hambleton (1980). The procedure involved assessing the degree of fit between the content of each item and the intended object of study. The judges were asked to specify the rational quality of the fit for each item using a graduated scale from 0 to 5 (where 0 = ‘the contents of the item do not conform to the variable they intend to
Although these constructs were based on the scientific consistency of their results when tested among nonclinical samples, were omitted as elements of the MMSI-2 because of the low statistical trauma, creativity, intuition, extraversion, and dissociative disorders suggestibility, (11) predisposition toward fraud, (12) thrill-seeking and effect, (7) social desirability, (8) substance use, (9) anxiety states, (10) (3) schizotypy, (4) paranoia, (5) narcissism, (6) cognitive biases/Barnum were drafted and screened, a decision was made regarding how the re-

223 items, 49 were eliminated, leaving a total of 174. Once the items were initially speci-

validity process, a single construct did not exist for all items. Each item multiple psychological constructs. This means that during the content measure

Figure 1. Flowchart summarizing the phases in development and creation of the MMSI-2. The contents available in the manuscript are highlighted in blue, while orange contents are methodological and logistical decisions.

measure’ and 5 = ‘the contents of the item are fully in line with the construct’). Note that the MMSI is a multiaxial test because it evaluates multiple psychological constructs. This means that during the content validity process, a single construct did not exist for all items. Each item was compared to the construct to which it referred. The constructs that were initially specified were (1) perceptual alterations, (2) histrionism, (3) schizotypy, (4) paranoia, (5) narcissism, (6) cognitive biases/Barnum effect, (7) social desirability, (8) substance use, (9) anxiety states, (10) suggestibility, (11) predisposition toward fraud, (12) thrill-seeking and (13) the participant's level of collaboration with the study. Childhood trauma, creativity, intuition, extraversion, and dissociative disorders were omitted as elements of the MMSI-2 because of the low statistical consistency of their results when tested among nonclinical samples. Although these constructs were based on the scientific literature cited in the previous section, no previous theoretical model was defined given the inconsistencies of some of the published evidence.

Items that yielded an average score equal to or greater than three points on the scale were included in the final version, while items with a lower average score were omitted from the final version of the test. Of the 223 items, 49 were eliminated, leaving a total of 174. Once the items were drafted and screened, a decision was made regarding how the responses should be coded to facilitate the valid and reliable quantification of scores. Following the recommendations of Kline (1999), a Likert-type scale with a range of response options from 1 to 5 was selected. This system allowed subjects to indicate their level of agreement according to each statement, with 1 = strongly disagree, 2 = disagree, 3 = agree, 4 = very much agree and 5 = strongly agree. Of the 174 items, 139 were positive statements, and 35 were negative statements. For the items consisting of negative statements, responses were reverse coded: 1 = strongly agree, 2 = very much agree, 3 = somewhat agree, 4 = disagree, and 5 = strongly disagree. As Price and Mueller (1986) suggest, when a psychometric test is excessively long, it is appropriate to alternate between the two types of items to avoid biases related to acquiescence, neutrality and systematic denial. Thus, the distribution of the 174 items that comprised the experimental version of the test was not entirely random. Rather, two criteria were applied: (1) affirmative and negative items were alternated; and (2) items expressing the level of collaboration with the evaluation were placed at the end of the questionnaire. The items intended to measure the participant's level of collaboration expressed impossible or absurd content that, under normative or nonpathological conditions, would force the subject to be completely at odds with what the sentence says. An example is item 153 in this version: ‘Red Riding Hood is a real person.’ If the participant has collaborated with the assessment and does not present any psychiatric pathology, they should not agree with item 153. Conversely, responses should fluctuate between values of 1 and 2 or be equal to 1. This criterion was included based on the statistical contributions of Guilford (1954), who originally noted the presence of a progressive decrease in levels of attention as a length of tests increases. This alteration is due to fatigue resulting from the length of the questiona-

The third phase of the research took place in January and March of 2014. During this period, the test application materials and informed consent forms were prepared, and the sociodemographic variables to be recorded to ensure the heterogeneity and representativeness of the sample were chosen. Based on the contents of the items and the suggestions of the team of experts, it was concluded that the MMSI, despite having a relationship with clinical evaluation, would not serve a diagnostic/psychopathological purpose (other, more suitable instruments already exist for this) and hence, the decision was made to apply it only to subjects without a reported psychiatric history. Collaboration agreements were signed with the psychological centers and companies involved in the collection of the sample (see acknowledgments). The evaluation materials were designed in both pencil-and-paper and digital formats. The format used was left to the discretion of the collaborating groups that were to use the materials.

The fourth phase of research took place between 2014 and 2016. During this phase, data collection began, and an initial matrix was prepared and refined based on the participants’ responses. Cases were disregarded if the responses contained missing values or were unclear or had excessive strikethroughs or corrections. A first pilot analysis was conducted in November 2016 to determine the heterogeneity of the sample responses. Coefficients of variation were mainly used to examine the responses and the sociodemographic variables recorded. The results showed no sample biases.

Finally, the fifth phase of research was carried out in 2017 and 2019. In this period, the sampling, drafting and debugging of the final data matrices was completed, and the analysis of the collected data began.

2.4. Instruments

The instrument used was the 174-item version of the MMSI that remained after the 223 original items were refined; this version was labeled the MMSI-2. The MMSI-2 examines 16 first-order factors:
Inconsistencies (K), Lies (L), Fraud (F), Simulation (Si), Neurasthenia (Nt), Substance Use (Cs), Suggestibility (Su), Thrill-Seeking (Be), Histrionism (Hi), Schizotypy (Ez), Paranoia (Pa), Narcissism (Na), Anomalous Visual/Auditory Phenomena (Pva), Anomalous Tactile Phenomena (Pt), Anomalous Olfactory Phenomena (Po) and Anomalous Cenesthetic Phenomena (Pc). The responses are coded using a scale of 1–5, on which the participant must indicate his or her level of agreement with what is stated in each item. It should be kept in mind that some items are scored in reverse; these reverse-scored items are those marked with an asterisk in the factorial solution presented in Tables 1, 2, 3, 4, 5, 6, and 7. The MMPI-2 also contains four higher-order factors: Clinical Personality Tendencies (CPT), Anomalous Perceived Phenomena (APP), Inconherent Manipulations (IMA), and Altered States of Consciousness (ASC). The calculation of the macrofactors is obtained from the sum of the direct scores of the corresponding first-order factors for each higher-order factor. The higher the scores for each attribute, the greater the frequency and intensity of those characteristics in the participant.

2.5. Data analysis

The statistical design of this research was multivariable and was based on the development of both a first-order and higher-order exploratory factor analysis (henceforth EFA).

The first-order EFA was applied to the matrix of correlations among the 174 test items. The extraction of the factors was performed using the unweighted least squares procedure, which is considered the most robust method because it does not require prior estimation of the commonalities of the items (see Harman and Jones, 1966). To optimize the factorial solution, direct oblimin oblique rotation was used (with δ = 0). This decision was based on the theoretical background that shows intercorrelations between the different factors that were extracted (see French and Stone, 2014). According to Pedhazur and Schmelkin (2001), in the social sciences, and especially psychometrics, oblique rotations are recommended because they assume interdependence among latent factors. Moreover, absolute independence among the extracted factors themselves is not an insurmountable assumption (e.g., Abad et al., 2015). Given the logic of oblique rotations, in this type of solution, unlike with orthogonal rotations, it is not advisable to provide the explained variance of each factor itself in the factorial solution, rather than the classic Guttman-Kaiser criterion was used to determine the number of the primary factors. This does not mean that the second-order factors are completely independent of each other, and therefore, it would not make sense a priori to apply a purely orthogonal rotation. In this EFA, the Guttman-Kaiser criterion was used to determine the number of second-order factors to retain. Taking into account the logic of O’Connor (2000), the parallel analysis method was rejected because the eigenvalue of the first factor excluded by the classical method (which was factor 5) was substantially removed from 1 ($\lambda_5 = 0.161$). This indicates that the factors extracted from factor number 4 were irrelevant due to their low variability (see also Mulaik, 2018). Therefore, in this context, it would not make sense to apply parallel analysis to determine whether it was necessary to include another factor. For the analysis of the saturations and the theoretical categorization of the secondary factors, the same procedures were used as in the first-order EFA. For the latter EFA, SPSS 25 was used.

Regarding the reliability of the test, for the 16 first-order factors, the ordinal transformation of Cronbach’s alpha coefficient was chosen based on the contributions of McDonald (1999):

$$\alpha = \frac{1}{n} \left[ \frac{n(\bar{X}^2 - \bar{Z}^2)}{n(\bar{Z}^2) + (\mu^2)} \right]$$

where

- $\bar{Z}$ is the arithmetic mean of the factorial loads,
- $\bar{X}^2$ is the square arithmetic mean of the factorial loads, and
- $\mu^2$ is the arithmetic mean of the single variance.

Cronbach’s alpha coefficient was used to calculate the reliability of the macrofactors since the scores of the 16 factors are quantitative. For these calculations, Microsoft Excel spreadsheets and the program SPSS 25 were used.

Finally, gender-differentiated general scales were created based on the standard derived scores (PT or simply T) and the sample percentiles (abbreviated as Pcs).

3. Results

3.1. First-order exploratory factor analysis

Prior to the application of the EFA, there was a need to check whether the items were sufficiently correlated with each other. For this purpose, the Kaiser-Meyer-Olkin (KMO) sample adequacy test was used. Bartlett’s test of sphericity was not applied based on the transformation of the chi square from the determinant of the polychoric correlation matrix because this statistic is highly sensitive to sample size (e.g., Ruiz, 2000). The KMO index yielded a favorable result regarding the use of the EFA technique (KMO = 0.941). The results of the factorial solution by means of direct oblimin rotation are presented in Tables 1, 2, 3, 4, 5, 6, and 7. The sedimentation graph is also presented, with the simulated average eigenvalues for 100 random samples (representing the parallel analysis method) (See Figure 2). As shown, crossing the two curves retained 16 primary factors. To illustrate and more easily indicate the crossing point, the graph is presented only for the first 30 factors (which were the most significant for this statistical decision).

The solution extracted a total of 16 factors that together explained 92.84% of the variance. Factor 1 consisted of 11 items that expressed visual and auditory perceptual alterations. This factor was classified as Anomalous Visual/Auditory Phenomena (Pva) and obtained an eigenvalue of 46.472. Factor 2 included 6 items that reflected tendencies related to...
| Items   | Extracted factors |   |   |   |
|---------|-------------------|---|---|---|
| Pva 39  | 0.653             |   |   |   |
| Pva 47  | 0.651             |   |   |   |

the Barnum effect. It obtained an eigenvalue of 28.778 and was classified as Simulation (Si). Factor 3 included 23 items that coincide with behaviors typical of social desirability. It yielded an eigenvalue equal to 22.043 and was classified as Lies (L). Factor 4 described behaviors associated with states of anxiety and acute fatigue. It included 15 items that demonstrated an eigenvalue equal to 14.819 and was classified as Neurasthenia (Nt). Factor 5 was classified as Histrionism (Hi) as it included 13 items whose behaviors may be associated with attenuated symptoms typical of histrionic personality disorder. It had an eigenvalue of 10.622.

Factor 6 contained 12 items and demonstrated an eigenvalue of 7.857. These items had two types of content in common. On the one hand, some items described beliefs that are present in individuals without prior psychopathological diagnosis (e.g., item K-154: ‘I believe I deserve to be respected’). On the other hand, there were items that contained absurd and impossible content (e.g., Item K-153: ‘Red Riding Hood is a real

| Pc 105  | 0.664    |
| Eigenvalue | 1.845 | 1.413 |

Note: Factor loadings under 0.4 were eliminated (N = 3,224). Na= Narcissism; Pc= Anomalous Cenesthetic Phenomena.
person’) and were closely related to the participant’s degree of collaboration and the identification of potential inconsistencies in each subject’s responses. For this reason, Factor 6 was classified as Inconsistencies (K). Factor 7 had an eigenvalue of 6.415 and included 20 items. It described behaviors that indicate tendencies involving low morals, manipulation, and deviousness (e.g., Item F-9: ‘If my best friend committed fraud, I would not report it’). Thus, it was classified as Fraud (F). Factor 8 included seven items related to substance use and abuse. It had an eigenvalue of 5.586 and was categorized as Substance Use (Cs). Factor 9 showed an eigenvalue of 4.681 and comprised seven behaviors associated with emotional lability and permeability resulting from environmental influences. Thus, this variable was classified as Suggestibility (Su). Factor 10 included 10 items related to distrust, skepticism, and certain attenuated symptoms of paranoid personality disorder. It had an eigenvalue of 3.639 and was classified as Paranoia (Pa). Factor 11 included 7 items describing perceptual distortions of a tactile nature. It obtained an eigenvalue of 2.973 and was classified as Anomalous Tactile Phenomena (Pt). Factor 12 had an eigenvalue of 2.294 and included 7 items related to perceptual distortions of an olfactory nature. For this reason, it was classified as Anomalous Olfactory Phenomena (Po). Factor 13 comprised 12 items expressing attenuated symptoms characteristic of narcissistic personality disorder. It had an eigenvalue of 1.845 and was categorized as Narcissism (Na). Factor 14 comprised 9 items that allude to hallucinatory experiences related to depersonalization and derealization. It had an eigenvalue of 1.413 and was classified as Anomalous Cenesthetic Phenomena (Pc). Factor 15 was classified as Thrill-Seeking (Be) and included just four items with an eigenvalue of 1.156. The final first-order factor included 11 items associated with social withdrawal, magical thinking and isolation. These traits are characteristic of schizotypal personality disorder and were also expressed in a subtle or attenuated manner; hence, this factor was classified as Schizotypy (Ez). Its eigenvalue was 0.961.

The descriptive statistics for this first EFA are shown in Table 8, which also includes the descriptive statistics for the higher order factors and the alpha reliability coefficients, which will be discussed in the following paragraphs.

### 3.2. Second-order exploratory factor analysis

Once the 16 primary factors were defined, a second-order EFA was applied to empirically justify the macrofactors. A favorable KMO was obtained for the use of a higher-order EFA (KMO = 0.837). This analysis...

and was classified as *Incoherent Manipulations* (IMA). The final factor had an eigenvalue of 1.188, included the Cs and Nt scales, and was classified as *Altered States of Consciousness* (ASC).

### 3.3. Reliability and scaling of direct scores

The reliability rates of the primary factors and macrofactors are shown in Table 8. According to the classification by George and Mallery (2003), all of them were satisfactory and excellent (>0.8). These results suggested that no item or scale should be deleted from the test to optimize its internal consistency.

Following the recommendations of Muñiz (2003), scaling of the MMSI-2 was carried out based on two normative groups differentiated by gender. The percentiles (Pc) and standard derived scores (or simply T scores) were used. Tables 12, 13, 14, 15, and 16 present the standardized scales with corresponding direct scores for both PT and Pc.

### 4. Discussion

The initial objective of this research was to examine the psychometric properties of the MMSI-2. A secondary objective was to analyze the factorial covariation among indicators that measure anomalous

(continued on next page)
four are anomalous phenomena (Pva, Pt, Po and Pc), and the K and L scales are included as prototypical variables of this type of psychometric inventory (e.g., Millon, 1994; Morey, 2011). As explained in the procedure section of this study, the remaining variables based on theory (childhood trauma, creativity, intuition, extraversion and dissociative disorders) had already been dismissed from the 174-item version. This compatibility is indicated that the items on the MMSI-2 were developed correctly and constitute valid empirical indicators for measuring the constructs included in the 16 factors/scales of the test. Similarly, regarding factorial loads, it can be observed that the reverse-scored items had negative saturations, a fact that also confirms the goodness of the measurement of each indicator/item.

As a second observation, it should be noted that the first-order EFA with factors that coincide with the constructs from the literature does not examine the relationship of the 10 psychological variables plus the K and L scales with the anomalous perceived phenomena. The results of the first-order EFA may prove the exploratory validity of the MMSI-2 measurement of each indicator/item.

If such an intercorrelation does exist between the scales, its effects should be observable in the second-order factor solution.

4.1. Analysis of results

First, it must be kept in mind that the MMSI-2 is a multiaxial instrument because it incorporates different evaluation constructs. The factorial solution offered by the first-order EFA (see Tables 1, 2, 3, 4, 5, 6, and 7) is compatible with the psychological variables previously observed in the published scientific literature. As can be observed in the conceptual framework, of the 15 psychological variables that were initially identified in the theoretical evidence (e.g., paranoia, narcissism, histrionism, schizotypy, substance abuse, exhaustion/anxiety, thrill-seeking, childhood trauma, simulation, fraud, creativity, intuition, extraversion, dissociative disorders and suggestibility), the first-order EFA allowed up to 10 to be identified. It should be recalled that of the 16 primary factors, four are anomalous phenomena (Pva, Pt, Po and Pc), and the K and L scales are included as prototypical variables of this type of psychometric inventory (e.g., Millon, 1994; Morey, 2011). As explained in the procedure section of this study, the remaining variables based on theory (childhood trauma, creativity, intuition, extraversion and dissociative disorders) had already been dismissed from the 174-item version. This compatibility is indicated that the items on the MMSI-2 were developed correctly and constitute valid empirical indicators for measuring the constructs included in the 16 factors/scales of the test. Similarly, regarding factorial loads, it can be observed that the reverse-scored items had negative saturations, a fact that also confirms the goodness of the measurement of each indicator/item.

As a second observation, it should be noted that the first-order EFA with factors that coincide with the constructs from the literature does not examine the relationship of the 10 psychological variables plus the K and L scales with the anomalous perceived phenomena. The results of the first-order EFA may prove the exploratory validity of the MMSI-2 measures and analyze the relationships between the items; however, they do not serve to examine the possible relationships among the extracted factors. If such an intercorrelation does exist between the scales, its effects should be observable in the second-order factor solution.
Table 18. Contents and behaviors assessed by each scale in the MMSI-2 (scales 9-16).

| Scales | Content assessed |
|--------|------------------|
| Pva    | Hearing voices of deceased beings |
|        | Seeing deceased beings (ghosts) |
|        | Seeing supernatural beings |
|        | Seeing strange shadows |
|        | Hearing unidentified noises |
|        | Hearing music of unknown origin |
| Pt     | Feeling unexplained chills |
|        | Feeling touch without anyone else present |
|        | Perceiving the presence of others who are not physically there |
|        | Feeling of pressure in different parts of the body |
| Po     | Change in the quality of odors |
|        | Scenting unexplained odors |
|        | Perceiving the scent of a deceased being |
|        | Perceiving smells at impossible distances |
| Pc     | Déjà vu experiences |
|        | Strange sensations in everyday places |
|        | Inability to recognize familiar places |
|        | Recognizing to unfamiliar places |
|        | Sudden changes in the size of body parts |
| Hi     | Seductive behaviors |
|        | Eccentric behaviors |
|        | Affective conflicts |
|        | Tendency to exaggerate |
|        | Fear of feeling alone |
| Ez     | Superstitious behaviors |
|        | Difficulties in socialization |
|        | Tendency to isolate |
|        | Tendency toward apathy |
|        | Magical thinking |
| Pa     | Social mistrust |
|        | Persecutory anxieties |
|        | Irrational interpretations |
|        | Difficulties in making commitments |
|        | Feelings of betrayal |
| Na     | Self-referral ideas |
|        | Difficulties in integrating criticism |
|        | Impatience |
|        | Need for differentiation |
|        | Search for ambitions |

Note: Pva = Anomalous Visual/Auditory Phenomena; Pt = Anomalous Tactile Phenomena; Po = Anomalous Olfactory Phenomena; Pc = Anomalous Cenesthetic Phenomena; Hi = Histrionism; Ez = Schizotypy; Pa = Paranoia; Na = Narcissism.

Specifically, it would be expected that the secondary APP would distribute the primary factors without isolating the perceptual scales from other factors. The fact that the solution yielded the secondary factor and that its variables showed no significant saturation in any other macrofactor suggests that the Pva, Pt, Po and Pc scales may present behavior that is independent of the other scales. Consequently, this fact calls into question the relationship of anomalous phenomena with the other psychological variables. It should be noted that this observation does not imply that the macrofactor APP is independent of the other higher-order factors given that the rotation used in the solution was oblique and influenced the loadings of the primary factors (and not the second-order factors). However, the independence of these four scales can also be checked by analyzing the correlation matrix in Tables 9 and 10. The correlations of the variables Pva, Pt, Po and Pc presented values close to 0 when they were related to other psychological variables. If these scales were related to the other variables, they should have had correlations other than 0. These nuances do not disprove the theoretical background that defends the relationship between anomalous phenomena and the highlighted psychological variables. However, they do call these theories into question and suggest, as indicated by French and Stone (2014), that anomalous behaviors related to ‘psi’ phenomena and parapsychology do not have an obvious psychological explanation if they go beyond the psychopathological. The question that arises from this observation confronts the following thought: depending on how anomalous phenomena are evaluated, their covariant behavior may be more or less independent with respect to the other variables. It should be kept in mind that the MMSI-2 examines anomalous phenomena by relating them to ‘psi’ phenomena and parapsychological experiences. By way of speculation, one might wonder what would happen with the second-order EFAs or the correlation matrix in Tables 9 and 10 if anomalous phenomena were evaluated exclusively as psychotic hallucinatory symptoms. It would then be possible for such intercorrelations to vary, yielding different results.

Along these same lines, the CPT scale includes the Pa, Na, Hi and Ez scales as subclinical features but also adds Su and Be, which had very high factorial loads. Specifically, the term “personality” was added to the CPT scale because it is understood that suggestibility and thrill-seeking are also stable psychological traits (e.g., Irwin et al., 2013). Therefore, according to the theoretical framework, the suggestibility that the MMSI examines should be related to secondary suggestibility (and not to altered states of consciousness) as it is concomitant with other subclinical personality traits (e.g., Smith et al., 2009). This observation is also supported by the content of the items pertaining to Su, which conceptually coincide with the understanding of suggestibility as a personality tendency (e.g., Eysenck, 2017; Hefferline et al., 1972). This differs from the macrofactor ASC, which probably does not measure traits, but rather measures dynamic psychological states (e.g., Groth-Marnat, 2009; Hambleton, 2008). According to the theory, both Nt and Cs are common characteristics that are observable during alterations of consciousness (e.g., Alvarado, 1998; Jinks, 2019). However, the latter secondary factor also suggests that the anxiety evaluated by MMSI-2 is not a stable psychological trait but a situational anxious state.

The macrofactor IMA demonstrated a grouping of variables consistent with what was expected based on the theory (e.g., Alvarez, 2007; French and Stone, 2014; Wilson and French, 2006). All the scales included in the IMA are variables that can be interpreted as manipulations of the answers based on deception. Unlike what was expected, while theoretically social desirability (L) is a common tendency observable in personality measures (e.g., Eysenck, 2017; Groth-Marnat, 2009), this test involves a scale that does not demonstrate high saturation in the CPT factor. The correlation matrix (see Tables 9 and 10) supports this idea and suggests that this scale also has independent behavior. In fact, Fernández-Ballesteros (2011) pointed out that social desirability is a factor that provides a very low explained variance in personality inventories, a statement that does not seem so inconsistent with the low correlations obtained in the MMSI-2. The same behavior can be extrapolated to the K, F, and Si scales. Additionally, taking into account the difficulties present in the analysis of fraudulent behavior (e.g., MacNeil and Soper, 2019), the macrofactor IMA invites us to think about the extent to which the MMSI-2 scales could be useful in lie detection, especially in forensic assessments. The EFA applied in this sample, and specifically its eigenvalues, indicates that this is a group of scales and items that provides more statistical information than other constructs (see Tables 1, 2, 3, 4, 5, 6, and 7; e.g., $\lambda_5 = 28.778 > \lambda_{50} = 0.961$). The reason why these scales have so much weight in the MMSI-2 (according to their eigenvalues and factorial charges) is unknown. However, this statistical evidence could be used and tested in other areas of evaluation where these variables have been evaluated with little reliability (e.g., Cardona, 2002; Vrij et al., 2019).
Third, it should be recalled that the MMSI-2 was created as a tool with which to compare psychological hypotheses that seek to explain anomalous phenomena and test the ‘psi’ hypothesis. To do this, it is appropriate to interpret the scales created and analyze the scope they offer in psychological evaluation. Direct scores may be useful in future statistical research; however, if the assessment or comparison of hypotheses is applied individually (e.g., through the development of psychological profiles), then it is necessary to determine the position the patient occupies within a normative group (see Kline, 1999; Muniz, 2003). At the same time, following Martinez-Arias et al. (2006), in this context, the scales also make it possible to define the empirical thresholds that determine the extent to which an evaluated subject develops behaviors occurring at a frequency and intensity that is becoming clinically suspect. These cut-off points are normative and determined according to the transformation scale used. According to the psychometric contributions of other authors (e.g., Ben-Porath and Tellegen, 2019; Morey, 2011), in the case of the MMSI-2, the use of T scores instead of percentiles is recommended. Percentiles have been shown to facilitate statistical research but have shown less benefit for the analysis of the patient/client’s psychometric profile. PT have an average value of 50 points, and their standard deviations have a value of 10 points (e.g., Abad et al., 2015). The following cut-off points are recommended for both men and women: PT ≥ 50 and PT ≥ 60. The significance of the scores is questionable when they exceed the average value (PT = 50) and clear when a PT ≥ 60 is obtained. Due to the eigenvalues and asymmetric-positive distribution of scores in the K, F, Cs and IMA scales, the use of more restrictive cut-off points (PT ≥ 40) is recommended. This suggestion is based on the fact that the behaviors described in the items of these scales are dysfunctional and are inconsistent with psychological normality. However, this proposal should be validated in subsequent studies, and hence, caution is recommended. The value of all of these cut-off scores and these scales is observed when a subject scores high on both the scales that examine abnormal phenomena and one of the other psychological variables. The possible debate raised by the MMSI-2 involves whether significant scores for psychological variables could explain significant values on the APP scale. This debate will probably be clarified when the factors are analyzed in subsequent confirmatory studies, as recommended by Gorsuch (1983).

To specify the behaviors assessed in each factor or scale, Tables 17 and 18 summarize and classify the attributes measured in each dimension.

EFAs are a good start and constitute a very useful empirical basis for assigning validity to a psychometric instrument (see Mulaik, 2018), however, the extracted factors must be subsequently replicated with a confirmatory factor analysis (henceforth CFA). While EFAs attribute validity to measures, CFAs also confirm and validate the structural model that justifies the conceptual bases of the instrument (e.g., Ruiz, 2000). Indeed, as with Houran et al. (2019), the main problem encountered in this research was the lack of previously validated theoretical models. As mentioned in the previous sections, although instruments exist that examine anomalous perceptions among nonclinical samples (e.g., Bell et al., 2006; Mason and Claridge, 2006; Stefanis et al., 2002), consistent statistical results are not provided when anomalous phenomena are related to other psychological variables outside the psychopathological framework (see Irwin, 2009; Parker, 2006). Thus, from an empirical perspective and taking into account sample size, EFA was chosen as the most suitable mathematical design for this type of scenario (see Kline, 1999; Mulaik, 2018). In fact, this limitation emphasizes that the MMSI-2 also requires a valid theoretical foundation that verifies the relationships among the constructs it evaluates. However, it is not possible to determine a theoretical model without consistent prior evidence, and this psychometric work based on EFAs is thought to be able to provide such evidence.

Another drawback is seen in the trait vs. state aspect of some of the scales in the MMSI-2. It is unclear whether the macrofactor CPT includes variables of a trait type and the ASC dimension includes factors of a state type. To verify the state vs. trait conditions in the respective scales, a test-retest design of repeated samples must be applied to simultaneously analyze the reliability of differences between the scores (e.g., Abad et al., 2015). These reliability indices would be complementary to internal consistency and would not alter the obtained alpha coefficients, which were excellent (e.g., George and Mallory, 2003).

A very obvious limitation also lies in the interpretation of scores using PTs. Scaling in this type of test is essential, but it seems necessary to validate the cut-off points using designs that analyze the sensitivity and specificity of the MMSI-2. These designs can be based on ROC curves and logistic regression, although an external classifier would need to be determined to allow comparison between the MMSI forecasts and classifications that were assumed as criteria. It is true that the scales offer T scores, which are useful in psychometric evaluation to facilitate decision-making in response to the degree of significance of the scores. However, individual T scores do not allow us to resolve the dilemma derived from research into ‘psi’ phenomena with significant results. If a subject obtained significant scores on the APP scales and high values for the other psychological variables, it would not be possible to confirm that the anomalous phenomena were produced by high scores on these psychological variables. However, this hypothetical profile would provide sufficient grounds to suspect that psychological scales are predictors of perceived anomalous phenomena. This limitation means that new research and contrasts are needed to examine the variation in PTs on the APP scales based on the possible effects of scores obtained for the other variables.

Given these limitations and the scientific literature cited, future lines of research should address three key points: (1) the conceptual understanding of observable differences between anomalous experiences understood as attenuated psychotic hallucinations and anomalous phenomena evaluated as anomalous experiences related to ‘psi’ phenomena; (2) the statistical analysis of new psychometric properties of the MMSI-2 that identify and confirm the factorial solution presented in this report; and (3) the goodness of cut-off points that would allow evaluative decisions (though not diagnostic ones) to be made (see also Jabbari et al., 2018; Lappalainen, 2019; Van Zeebroeck, 2019).

4.2. Conclusions

This study presents three main findings. First, the study obtained 12 empirical markers (the 12 scales of the MMSI-2) for identifying, examining, and measuring possible causes of perceived anomalous phenomena. Four specific markers were also obtained for evaluating abnormal experiences. Second, the study demonstrated that it is possible to define and establish an empirical-statistical model for evaluating anomalous phenomena. This model should allow for examination of perceptual anomalies to determine whether they are the result of hallucination, biases, deliberate fraud, or behaviors without a psychological-psychiatric explanation. Third, it is also concluded that it is necessary to review this factor model and validate it through a CFA and structural equation models.

Ultimately, the MMSI-2 is accepted as a valid and reliable psychometric instrument for evaluating anomalous phenomena and the theoretically concomitant psychological variables. The 174 items and the 20 psychometric scales of the MMSI-2 can be used in future studies aimed at psychological profile analysis and statistical research to confirm the predictive relationship between different psychological variables and anomalous phenomena.

Declarations

Author contribution statement

A. Escolá-Gascón: Conceived and designed the experiments; Performed the experiments; Analyzed and interpreted the data; Contributed reagents, materials, analysis tools or data; Wrote the paper.
This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

The authors declare no conflict of interest.

No additional information is available for this paper.

The author of the MMMI-2 wishes to express his gratitude to the academic, professional and business groups or associations that participated in the collection of the sample. The collaborating groups were: Sisters of Immaculate Conception (Madrid, Spain) and MAGIC International® (Barcelona, Spain). The academic professionals who collaborated with data collection were (appearing in order of the date of collaboration): Esther Mosquera (Researcher Assistant, 2012–2014, Barcelona, Spain); Sister Bárbara Ávila (Theologian and Clinical Psychologist, 2013–2015, Madrid, Spain); Sister María Luz Martínez (Theologian and Clinical Psychologist, 2013–2015, Madrid, Spain); Isabel Miró (Clinical Psychologist, 2013–2019, Barcelona, Spain); Rosa María Gamboa (Clinical Psychologist, 2013–2019, Barcelona, Spain); Naia Cartañá (Biostatistician, 2013–2019, Barcelona, Spain); Yolanda Romero de Tejada (Clinical Psychologist, 2014–2018, Barcelona, Spain); Judith García (Researcher Assistant, 2014–2018, Barcelona, Spain); Manuel Lascasas (Researcher Assistant, 2015–2018, Barcelona, Spain); Victor Fernández (Researcher Assistant, 2015–2018, Albacete, Spain).
