A 31-year-old man was admitted to our hospital due to hydrocephalus with neurosarcoidosis. Ventriculo-peritoneal shunting was performed in the right lateral ventricle with intravenous methylprednisolone. Subsequently, after 4 months, additional ventriculo-peritoneal shunting in the left lateral ventricle was performed due to the enlarged left lateral ventricle and slits-like right lateral ventricle. After 6 months, he was re-admitted due to upward gaze palsy, and magnetic resonance image showed an isolated fourth ventricle with both the inlet and outlet of fourth ventricle obstructed by recurrent neurosarcoidosis. Owing to the difficulty of using an endoscope, we performed neuronavigator-guided ventriculo-peritoneal shunting via the left lateral transcerebellar approach for the treatment of the isolated fourth ventricle with intravenous methyl prednisolone. The patient was discharged with improved neurological status.

Treatment of Hydrocephalus Associated with Neurosarcoidosis by Multiple Shunt Placement | SH Kim, et al.

Secrecy days; this was followed by prednisolone (1 mg/kg/day) for 4 weeks. On post-operative day 5, the patient showed progressive improvement of confusion and disorientation, and at 3 weeks post-operation, he was discharged without any neurological deficit.

Four months after discharge, the patient was re-admitted due to headache, and gait disturbance. Brain CT revealed an enlarged left lateral ventricle with periventricular edema and a collapsed right ventricle, at which a ventricular catheter was inserted (Fig. 2A). Additional ventriculo-peritoneal shunting was performed through left Kocher's point (Fig. 2B).

On post-operative day 5, gait disturbance including headache improved gradually, and in post-operative week 4, he was discharged without any neurological deficit.

Six months after second shunt operation, he complained of upward gaze palsy, and gait disturbance. Brain CT showed an increased fourth ventricle with periventricular edema and both lateral ventricles were well-collapsed with ventricular catheter in situ (Fig. 3A, B). Gadolinium-enhanced MRI of the brain revealed an enlarged fourth ventricle with other enhanced lesions in the left occipital lobe, left cerebellar peduncle (Fig. 3C, D).

Therefore, we planned ventriculo-peritoneal shunting for the isolated fourth ventricle by neuronavigation with intravenous methyl prednisolone. Neuronavigator-guided fourth ventriculoperitoneal shunting was performed via the left lateral transcerebellar approach with neuronavigation (In2vision; Cybermed, Seoul, Korea). The fourth ventriculo-peritoneal shunt was not connected to the previous shunt. The CSF profile collected at the operative field revealed severe leukocytosis (121 leukocytes/mm³) and an increase in the level of protein to 2.03 g/L. After 2 weeks of steroid treatment, CSF collected at the valve dome was normalized (6 leukocytes/mm³ and 0.62 g/L protein). On post-operative day 10, upward gaze palsy and gait disturbance gradually disappeared, and the patient was discharged 4 weeks post-operatively with mild neurological deficit. Four months later, the patient's previous upward gaze palsy and gait disturbance was resolved and CT at follow-up showed a reduction in the size of the fourth ventricle compared to the previous pre-operative CT scan (Fig. 4).

**DISCUSSION**

Sarcoidosis is a very rare granulomatous disease in Korea, and its cause remains unknown. Neurosarcoidosis most often presents with cranial nerve palsies, predominantly affecting the optic and facial nerves, reflecting its predilection for the base of the brain. The diagnosis of neurosarcoidosis is confirmed by biopsy showing noncaseating granulomas in the absence of organisms or other potential causes. In patients with hydrocephalus, the treatment depends upon the clinical status. In the case of asymptomatic hydrocephalus, treatment is not required. However, ventricular drainage is usually lifesaving in symptom-
triculic (B). A catheter in the fourth ventricle (A) and decreased size of the fourth ventricle in the present case, because impairment of brain stem functions may lead to sudden death. Even though the prognosis for neurosarcoidosis itself is good, hydrocephalus associated with neurosarcoidosis has poor long-term prognosis with a mortality rate of 75%. Benzagmout et al. reported that after the treatment with ventricular shunt and corticosteroid therapy, acute hydrocephalus associated with neurosarcoidosis was resolved. In the present case, we first performed ventriculo-peritoneal shunt in the right lateral ventricle for hydrocephalus in neurosarcoidosis, and observed the slit-like right lateral ventricle 4 months after discharge. Hamada et al. reported that endoscopic treatment was effective for the treatment of obstructive ventricles in neurosarcoidosis. Further, they suggested that loculated hydrocephalus, which was often treated by placement of an additional shunt, can be better treated with neuroendoscopy since multiple shunt placement was complicated and often results in shunt malfunction. It was necessary to perform endoscopic plasty of the occluded right foramen of Monro and fenestration of the septum pellucidum for the treatment of hydrocephalus during endoscopic biopsy.

Isolated fourth ventricle requires neurosurgical intervention, because impairment of brain stem functions may lead to sudden death. Shin et al. reported that in the presence of a functioning shunt in the lateral ventricle, treatment options for the isolated fourth ventricle include the placement of an additional fourth ventricular catheter, via a variety of trajectories or endoscopic approaches to open the cerebral aqueduct. An endoscopic approach can only be performed if a membranous occlusion of the aqueduct is present on preoperative MRI. Further, the standard precoronal approach can only be used in cases with a dilated supratentorial ventricular system. In the present case, because the supratentorial ventricular system was markedly collapsed and both the inlet and the outlet of the fourth ventricle were obstructed by enhanced lesions, the endoscopic procedure was not considered as an appropriate treatment option. Therefore, to minimize the complications related to fourth ventricular shunt insertion, we performed ventriculo-peritoneal shunting via the left lateral trans cerebellar approach using a neuronavigator. The risks of this procedure included brain stem penetration by the ventricular catheter, with focal neurological deficit because of the compressed cerebellum and brain stem expansion by decompressing the isolated fourth ventricle following ventriculo-peritoneal shunting. However, in the present case, there were no complications caused by the catheter during follow-up.

CONCLUSION

We report a case of hydrocephalus associated with neurosarcoidosis treated by multiple shunt placement with clinical features and a review of literature.
