The coset construction for non-equilibrium systems

Abstract

We propose a systematic coset construction of non-equilibrium effective field theories (EFTs) governing the long-distance and late-time dynamics of relativistic, finite-temperature condensed matter systems. Our non-equilibrium coset construction makes significant advances beyond more standard coset constructions in that it allows us to formulate non-equilibrium effective actions along the lines of those constructed by Crossley, Glorioso, and Liu [1-3] that account for quantum and thermal fluctuations as well as dissipation. Because these systems exist at finite temperature, the EFTs live on the closed time path of the Schwinger-Keldysh contour. Since the coset construction and the non-equilibrium effective actions may be unfamiliar to many readers, we include brief introductions to these topics in an effort to make this paper self-contained. To demonstrate the legitimacy of this coset construction, we successfully reproduce the known EFTs for fluids and superfluids at finite temperature. Then, to demonstrate its utility, we construct novel EFTs for solids, supersolids, and four phases of liquid crystals, all at finite temperature. We thereby combine the non-equilibrium effective action and the coset construction to create a powerful tool that can be used to study many-body systems out of equilibrium.

1 Introduction

When trying to understand a many-body system, the goal is often not to keep track of all of the degrees of freedom; there are simply too many. Instead, the aim is to focus only on quantities that persist over long distances and extended time scales. To do this, one course-grains over the microscopic, or ultraviolet (UV) degrees of freedom to obtain an effective theory of the macroscopic, or infrared (IR) observables. Often, one of the most important guiding principles in constructing such effective theories are their symmetries and their corresponding Noether currents. For example the standard formulation of hydrodynamics comes from the equations for conservation of energy, momentum, and particle number [4]. Even though such an approach is heavily based in symmetry considerations it is not very systematic as other non-symmetry constraints must be imposed. In particular, it relies on the somewhat ill-defined notion of ‘near equilibrium’ to construct constitutive relations among the conserved quantities and local thermodynamic parameters. Once this is done, the second law of thermodynamics must be imposed by hand, putting constraints on various coefficients. While this method has led to very powerful and general statements about hydrodynamic systems, there remain some difficulties. In particular, it is not at all clear what are the rules of the game for constructing hydrodynamic theories. For example, one might wonder if there are additional constraints beyond the second law of thermodynamics that one must impose. Additionally, a way to extend hydrodynamic theories to methodically account for thermal fluctuations or quantum effects is not at all clear. An approach that utilizes symmetries as the only input could resolve some of these issues.

In order to make the approach to hydrodynamics—and many-body physics as a whole—more systematic, over the last decade or so there has been a great effort to reformulate hydrodynamics from the point of view of an effective action [1-3,5-26]. The reasons for doing so are as follows. Effective actions provide powerful tools for describing systems in high energy and particle physics because they can be constructed from symmetry principles alone. Once the symmetries and field content are specified, one constructs the effective action by writing down a linear combination of all terms that are consistent with the symmetries. Thus, there is no guesswork when formulating effective actions. Applying these methods to condensed matter systems has provided powerful tools of analysis.

From the effective field theory (EFT) perspective, many-body systems can often be understood as systems that spontaneously break spacetime symmetries. In fact, it is often possible to classify the state of matter of a many-body system by its spontaneous symmetry breaking (SSB) pattern alone [10]. Then, the long-distance and late-time dynamics are described entirely by Goldstone bosons. For our purposes, this is very good news: there is a powerful and systematic way to construct EFTs of Goldstones known as the coset construction [30-31]. This construction takes the symmetry-breaking pattern—which is specified by the state of matter of the system—as the only input. The coset construction has been used to formulate numerous EFTs describing various states of matter [12].

Historically, the EFT approach to many-body physics has been unable to account for statistical fluctuations and dissipation. The reason is that ordinary actions describe noiseless, conservative systems and are therefore incapable of accounting for stochastic and dissipative dynamics. However, this changed with recent work [1-3,16-21] in which a new kind of non-equilibrium action was formulated using the in-in formalism on the Schwinger-Keldysh (SK) contour. Using symmetry principles alone these new non-equilibrium EFTs can account for both statistical fluctuations as well as dissipation. Because these EFTs are constructed on the SK contour, the field content is doubled. In addition to the global symmetry group, there exist emergent gauge symmetries at finite temperature, the origins of which remain poorly understood [1].
Nevertheless, despite significant advances, in the current literature there exist very few systems for which the non-equilibrium EFTs are known. The reason is that no overarching understanding of the field content, emergent gauge symmetries, or symmetry-breaking pattern has yet been provided for non-equilibrium systems. In this paper, we address these problems by combining two powerful tools: the non-equilibrium EFT approach to many-body systems and the coset construction.¹ We term the result the non-equilibrium coset construction.

Our approach is as follows: We start from the observation that at finite temperature, there exist Goldstone-like excitations corresponding to each symmetry generator even if it is not spontaneously broken. However, the Goldstones corresponding to the unbroken generators behave very differently than those arising from SSB. In particular the Goldstones corresponding to unbroken generators have infinitely many gauge symmetries analogous to the chemical shift symmetries of [9]. These gauge symmetries lead to diffusive behavior. Since the non-equilibrium effective action is defined on the SK contour, the field content is doubled. This requires the introduction of two cosets; one for each leg of the SK contour. We use these cosets to construct building-blocks for the non-equilibrium effective actions that transform covariantly under both the global symmetries as well as the chemical shift-type gauge symmetries.

To demonstrate the validity of this new coset construction, we use it to formulate actions for already known EFTs, namely those of fluids and superfluids at finite temperature. Then, to demonstrate the utility of our approach, we construct novel EFTs for solids, supersolids, and four phases of liquid crystals, all at finite temperature. We thus vastly expand the number of known non-equilibrium EFTs. Moreover, our formalism can be used to construct EFTs for essentially any state of matter that is describable by Goldstone (or Goldstone-like) excitations. The coset construction and the non-equilibrium EFT formalism may be unfamiliar to some readers. To make this paper as self-contained as possible, sections §2 and §3 give quick reviews of these topics. Readers already familiar with these topics can skip these sections entirely.

Throughout this paper we will use the ‘mostly plus convention’ so the Minkowski metric takes the form $\eta_{\mu \nu} = \text{diag}(-, +, +, +)$.

2 The zero-temperature coset construction: a review

Consider a relativistic quantum field theory whose full symmetry group is $\mathcal{G}$, which includes both internal symmetries as well as the Poincaré group. Suppose that the ground state of the system spontaneously breaks the symmetry group $\mathcal{G}$ to the subgroup $\mathcal{H}$. Then the IR dynamics of the system are described by Goldstone modes. If only internal symmetries are spontaneously broken, then for every broken symmetry generator in the coset $\mathcal{G}/\mathcal{H}$, there is a corresponding Goldstone boson. However, if spacetime symmetries are spontaneously broken, there are often fewer Goldstones than broken symmetry generators [23-29].

Often, the only gapless modes in the system are the Goldstones. If we are only concerned with the deep IR dynamics, we can integrate out all non-Goldstone modes to obtain an effective action for the Goldstones. It turns out that there is a systematic method for writing down Goldstone effective actions known as the coset construction. This section will give a brief review of the coset construction for spontaneously broken internal and spacetime symmetries. For in-depth discussions of the coset construction for spontaneously broken internal symmetries, consult [30] and for spontaneously broken spacetime symmetries, consult [31].

The coset construction is an especially powerful technique since it provides a systematic method

¹The coset construction was recently used in [22] to build simple EFTs on the SK contour; however their approach only dealt with internal symmetries.
for generating effective actions of Goldstone bosons using the SSB pattern as the only input. Supposing the symmetry-breaking pattern is $\mathcal{G} \to \mathcal{H}$, we represent the symmetry generators by

$$
\begin{align*}
P_\mu &= \text{unbroken translations} \\
T_A &= \text{other unbroken generators} \\
\tau_\alpha &= \text{broken generators},
\end{align*}
$$

where the generators $\tau_\alpha$ and $T_A$ may be some combination of internal and spacetime generators and we have assumed that there exist some notions of spacetime translations that remain unbroken. In this way, states can still be classified according to the corresponding notions of energy and momentum [10]. Importantly, we do not require that the unbroken generators $P_\mu$ be the original Poincar translation generators (represented by $P_\mu$); instead they can be some linear combination of $P_\mu$ and internal symmetry generators [10]. It will turn out that although $P_\mu$ and $T_A$ both refer to unbroken generators, they will play very different roles in the coset construction. Therefore, it is convenient to define the subgroup $\mathcal{H}_0 \subset \mathcal{H}$ that is generated exclusively by $T_A$.

The EFT of the Goldstones must be invariant under the full symmetry group $\mathcal{G}$. While the action of the unbroken symmetry subgroup $\mathcal{H}$ is linearly realized on the fields, the action of the broken coset $\mathcal{G}/\mathcal{H}$ is nonlinearly realized. In general, therefore, generic symmetry transformations will act in a highly non-trivial manner on the Goldstones. As a result writing down the most general effective action consistent with symmetries can be rather challenging unless we use the construction that follows.

We are interested in ensuring that the effective action remain invariant under all symmetry transformations. The symmetries that act linearly are easy to deal with, but those that act nonlinearly present more of a challenge. By definition, spontaneously broken generators act non-linearly on the fields while unbroken generators act linearly. However, unbroken translations act non-linearly on the coordinates, meaning that the coset of symmetry generators that have some sort of non-linear action is $\mathcal{G}/\mathcal{H}_0$. It is convenient to parameterize this coset by

$$
\gamma(x, \pi) = e^{ix_\mu P_\mu} e^{i\pi^\alpha(x) \tau_\alpha}. 
$$

Then, up to normalization, $\pi^\alpha(x)$ correspond to the Goldstones.

By the definition of the coset $\mathcal{G}/\mathcal{H}_0$, it is possible to express any element of $\mathcal{G}$ as the product of an element of the coset and an element of $\mathcal{H}_0$. As a result, for any element $g \in \mathcal{G}$, we may write

$$
g \cdot \gamma(x, \pi) = \gamma(x', \pi') \cdot h_0(x, \pi, g),
$$

where $h_0$ is some element of $\mathcal{H}_0$ and $x'$ and $\pi'$ are transformed coordinates and fields. It is important to note that for given $\pi$ and $g$, the terms on the l.h.s. of (3) can be explicitly computed if we know the commutation relations among the generators. We can therefore read off the transformations of the coordinates and Goldstones under an arbitrary symmetry transformation from (3). In particular, under the transformation by $g$, we have $x \to x'$ and $\pi \to \pi'$.

Using the parameterization (3), we can construct the Maurer-Cartan one-form $g^{-1}dg$. This one-form has the property that it can always be expressed as a linear combination of the symmetry generators [30-31], so we have

$$
g^{-1} \partial_\mu g = iE_\mu^\nu (\bar{P}_\nu + \nabla_\nu \pi^\alpha \tau_\alpha + B^A_\nu T_A) .
$$

\[2\]This is a somewhat hand-wavy justification for including $e^{ix_\mu P_\mu}$ in the coset. But in any case it turns out that (2) has the correct symmetry properties for our purposes.
Using the symmetry algebra alone, it is possible to compute the coefficients of each generator in the above expression. It can be checked that $\nabla_\mu \pi^\alpha$ transforms covariantly under the full symmetry group $\mathcal{G}$; we therefore will refer to it as the covariant derivative of $\pi$. Additionally, $B^A_\mu$ transforms like a connection (i.e. gauge field) and we can therefore use it to compute higher-order covariant derivatives by
\[
\nabla^\mathcal{H}_\mu = (E^{-1})^\nu_\mu \partial_\nu + i B^A_\mu T_A.
\]
And finally, $E^\nu_\mu$ serves as a vierbein; in particular, the invariant integration measure is $d^4x \det E$. It should be noted that the indices $\mu, \nu$ need not be contracted in the usual way if the Lorentz group is broken.

After computing $g^{-1} \partial_\mu g$, it is then easy to identify the covariant building-blocks. At leading order in the derivative expansion we have $\nabla_\mu \pi^\alpha$; and higher-order-derivative terms are given by $\nabla^\mathcal{H}_\mu (\nabla_\nu \pi^\alpha)$, $\nabla^H_\mu \nabla^H_\nu (\nabla_\rho \pi^\alpha)$, etc. Then, the symmetry-invariant terms of the effective action are simply constructed by taking manifestly $\mathcal{H}_0$-invariant combinations of these covariant terms. If boosts are broken but rotations are not, then examples of such invariant terms are $(\nabla_0 \pi^\alpha)^2$ and $(\nabla_i \pi^\alpha)^2$, where repeated indices are summed over.

### 2.1 Inverse Higgs

We mentioned earlier that when only internal symmetries are broken, the number of Goldstones exactly matches the number of broken generators. However, when spacetime symmetries are broken, this need not be the case. In this section, we will see how this works from the perspective of the coset construction.

Pragmatically, the rules of the game are as follows: Suppose that the commutator between an unbroken translation generator $\bar{P}$ and a broken generator $\tau'$ contains another unbroken generator $\tau$, that is $[\bar{P}, \tau'] \supset \tau$. Suppose further that that $\tau$ and $\tau'$ do not belong to the same irreducible multiplet under $\mathcal{H}_0$. Then it turns out that it is consistent with symmetry transformations to set the covariant derivative of the $\tau$-Goldstone in the direction of $\bar{P}$ to zero. This gives a constraint that relates the $\tau'$-Goldstone to derivatives of the $\tau$-Goldstone, allowing the removal of the $\tau'$-Goldstone. The setting of this covariant derivative to zero is known as an inverse Higgs constraint.

The physical reasons for imposing these inverse Higgs constraints have been investigated in [11,29,32]. Essentially, there are two possibilities. Firstly, sometimes when spacetime symmetries are spontaneously broken, the resulting Goldstones do not correspond to independent fluctuations. As a result, there can be multiple Goldstone field configurations that all correspond to the same physical state. From this viewpoint, the inverse Higgs constraints can be understood as a convenient choice of gauge-fixing condition. Secondly, when a Goldstone can be removed via inverse Higgs constraints, it is often the case that if we did include the Goldstone in the effective action, it would have an energy gap. But we are often only interested in gapless excitations, so we may integrate out these fields. From this perspective, the inverse Higgs constraints correspond to integrating out gapped Goldstones. For the purposes of this paper, with the exception of §5.1, we will take a purely pragmatic approach and always impose inverse Higgs constraints whenever possible, remaining agnostic about the precise reasons for doing so.

### 2.2 Zero-temperature superfluids: a simple example

Thus far, our discussion of the coset construction has been rather abstract. This section will focus on a simple concrete example: the coset construction of the zero-temperature superfluid EFT. First, since our theory is relativistic, it ought to be Poincar-invariant. In our ‘mostly plus’
convention, the Poincaré algebra is

\[ i[J_{\mu\nu}, J_{\rho\sigma}] = \eta_{\nu\rho} J_{\mu\sigma} - \eta_{\mu\rho} J_{\nu\sigma} - \eta_{\sigma\mu} J_{\rho\nu} + \eta_{\sigma\nu} J_{\rho\mu}, \]

\[ i[P_{\mu}, J_{\rho\sigma}] = \eta_{\mu\rho} P_{\sigma} - \eta_{\mu\sigma} P_{\rho}, \]

\[ i[P_{\mu}, P_{\nu}] = 0, \]  

where \( P_{\mu} \) are the translation generators and \( J_{\mu\nu} \) are the Lorentz generators. From the EFT perspective, a superfluid is defined as a system that has a conserved \( U(1) \) charge \( Q \) such that both \( Q \) and \( P_0 \) (i.e., time translations) are spontaneously broken but a diagonal subgroup, \( \bar{P}_0 \equiv P_0 + \mu Q \) is preserved [33-34]. Physically, \( Q \) is the charge associated with particle-number conservation and \( \mu \) is the chemical potential. Additionally, since every condensed matter system (including superfluids) has a zero-momentum frame, boosts are necessarily broken. As a result, the broken generators are the \( U(1) \) charge \( Q \) and Lorentz boots \( K_i \equiv J_0 i \). The unbroken translations are \( \bar{P}_0 = P_0 + \mu Q \) and \( \bar{P}_i = P_i \) for \( i = 1, 2, 3 \) and the remaining unbroken generators are the spatial rotation generators \( \bar{J}_i \equiv \frac{1}{2} \epsilon^{ijk} J_{jk} \). With this symmetry-breaking pattern, the coset is then

\[ g = e^{ix^\mu \bar{P}_\mu} e^{i\pi(x)Q} e^{i\eta^i(x)K_i}. \] 

By explicit computation, the Maurer-Cartan form is

\[ g^{-1} \partial_\mu g = iE^\nu_\mu \left( \bar{P}_\nu + \nabla_\nu \pi Q + \nabla_\nu \eta^i K_i + \Omega^i_\nu J_i \right), \]

where

\[ E^\nu_\mu = \Lambda^\nu_\mu, \]

\[ \nabla_\mu \pi = (E^{-1})^\nu_\mu \partial_\nu \psi - \mu \delta^\nu_\mu, \]

\[ \nabla_\mu \eta^i = (E^{-1})^\nu_\mu \left[ \Lambda^{-1} \partial_\nu \Lambda \right]^{0i}, \]

\[ \Omega^i_\mu = \frac{1}{2} (E^{-1})^\nu_\mu \epsilon^{ijk} \left[ \Lambda^{-1} \partial_\nu \Lambda \right]^{jk}, \]

where \( \Lambda^\mu_\nu \equiv [e^{i\eta^i K_i}]^\mu_\nu \) and \( \psi \equiv \mu t + \pi \). Here, \( \frac{1}{2} \epsilon^{ijk} \Omega^k_\mu \) can be thought of as the spin-connection (or at least the spatial components of it) and transforms as a gauge field under rotations.

Now, notice that the commutator between unbroken spatial translations and broken boosts yields \( [\bar{P}_i, J_j] \supset i \delta_{ij} \mu Q \), meaning that we may impose inverse Higgs constraints to remove the boost Goldstones. In particular, we may set to zero the covariant derivative of \( \pi \) along the \( i = 1, 2, 3 \) directions, yielding

\[ 0 = \nabla_i \pi = \Lambda^\mu_\nu \partial_\mu \psi. \] 

These constraints can be solved to give a relation between the boost Goldstones and derivatives of the \( U(1) \) Goldstones

\[ \eta^i \tanh \eta = -\partial_i \psi \partial_0 \psi. \] 

Using these relations, we can remove the boost Goldstones as dynamical degrees of freedom. Thus, at leading order in the derivative expansion, the only covariant building-block is \( \nabla_0 \pi \). By plugging (11) into the expression for \( \nabla_0 \pi \), we find that

\[ \nabla_0 \pi = \sqrt{-\partial_\mu \psi \partial_\mu \psi} - \mu. \]

Since \( \mu \) is just a constant, we find that at leading order in derivatives, the zero-temperature EFT must be built out of an arbitrary function of

\[ y = \sqrt{-\partial_\mu \psi \partial_\mu \psi}. \]
Since $\det E = 1$, we have that the invariant integration measure is just $d^4x$, so the leading-order action is

$$S = \int d^4x \, P(y),$$  \hspace{1cm} (14)$$

where $P$ is some function that is determined by the equation of state. Terms that are higher order in the derivative expansion can be constructed using $\nabla_\mu \eta^\nu$ as well as $\Omega^\mu_\nu$, which plays the role of a connection and can be used to create covariant derivatives of the form (5). But to keep things as streamlined as possible, in this paper we will only construct leading-order actions.

3 Non-equilibrium effective actions: a review

At zero temperature, the equilibrium state is described by a pure state, namely the vacuum. At finite temperature, however, no such pure equilibrium state exists. Instead, the equilibrium state must be described by a mixed-state thermal density matrix of the form

$$\rho = e^{-\beta_0 \bar{P}_0} / Z, \quad Z = \text{tr} e^{-\beta_0 \bar{P}_0},$$  \hspace{1cm} (15)$$

where $\beta_0$ is the inverse equilibrium temperature and $\bar{P}_0$ is the unbroken time-translation generator.

In order to describe correlation functions in time, we must use the so-called in-in or Schwinger-Keldysh formalism [36]. In this formalism, the sources are doubled. Letting $U(t, t', J)$ be the time-evolution operator from time $t'$ to $t$ in the presence of source $J$ for some field $\Psi$, the generating functional is

$$e^{W[J_1, J_2]} \equiv \text{tr} \left[ U(+\infty, -\infty; J_1) \rho U^\dagger (+\infty, -\infty; J_2) \right]$$  \hspace{1cm} (16)$$

where in the path integral representation, we require that in the distant future, $\Psi_1(\infty) = \Psi_2(\infty)$, and the subscript $\rho$ indicates that field configurations are weighted by the thermal density matrix functional in the infinite past. Because there are two time-evolution operators such that one evolves forward in time and the other backward in time, we can conceive of the SK path integral as existing on a closed contour in time that starts at $t = -\infty$ goes to $t = +\infty$ and then returns again to $t = -\infty$. This contour is often referred to as a closed time path (CTP).

It is possible to use this formalism to construct an effective action of the IR degrees of freedom on the CTP, known as the non-equilibrium effective action. Since the generating functional depends on two copies of the fields, the non-equilibrium effective action will have doubled field content.

Consider the path-integral representation of the generating functional (16). We are interested in the meaning of the low-frequency, long-wavelength dynamics of the system. In typical Wilsonian fashion, we integrate out the fast modes to obtain an effective action for the slow modes. Suppose the fields can be divided up into IR and UV fields by $\Psi = \{ \psi^{ir}, \psi^{uv} \}$, where $\psi^{ir}$ represent the IR degrees of freedom and $\psi^{uv}$ represent the UV degrees of freedom. Define the effective action for the IR fields by

$$e^{i I_{\text{EFT}}[\psi^{ir}_1, \psi^{ir}_2; J_1, J_2]} = \int_{\rho} D\psi^{uv}_1 D\psi^{uv}_2 e^{i S[\psi^{uv}_1, \psi^{ir}_1; J_1] - i S[\psi^{uv}_2, \psi^{ir}_2; J_2]},$$  \hspace{1cm} (17)

\footnote{Here as well as in the remainder of the paper, we use $S$ to denote an ordinary action and $I$ to denote an action defined on the SK contour.}
then \( e^{W[J_1, J_2]} = \int \mathcal{D}[\psi^{ir}_1, \psi^{ir}_2] e^{iI_{\text{EFT}}[\psi^{ir}_1, \psi^{ir}_2; J_1, J_2]} \). Notice that the information contained in the density matrix \( \rho \) is absorbed into the coefficients of \( I_{\text{EFT}} \) so we do not need to include a density matrix for the IR fields \( \psi^{ir}_{1,2} \). Finally, we impose an \( ie \)-type prescription such that the Green functions of \( I_{\text{EFT}} \) are path-ordered on the SK contour; the path-ordered Green functions are given in [1].

### 3.1 Rules for constructing non-equilibrium EFTs

Following the usual EFT philosophy, it is our hope that all the complicated UV dynamics and information about \( \rho \) can be absorbed in the low-frequency limit by a finite number of parameters in \( I_{\text{EFT}} \) at any given order in the derivative and field expansions. It has been demonstrated that this is in fact the case [1], but there are several important constraints that must be imposed upon \( I_{\text{EFT}} \). We outline some important features of this effective action below without proof [1].

- The UV action describing the system of interest is factorized by \( S[\Psi_1; J_1] - S[\Psi_2; J_2] \). The effective action, however, does not admit a factorized form. In general, there will exist terms that couple 1-and 2-fields in \( I_{\text{EFT}} \).

- Notice that, while the coefficients of \( S[\Psi_1; J_1] - S[\Psi_2; J_2] \) are purely real, the coefficients of \( I_{\text{EFT}}[\psi^{ir}_1, J_1; \psi^{ir}_2, J_2] \) may be complex. There are three important constraints that come from unitarity, namely

\[
I_{\text{EFT}}[\psi^{ir}_1, \psi^{ir}_2; J_1, J_2] = -I_{\text{EFT}}[\psi^{ir}_2, \psi^{ir}_1; J_2, J_1]
\]

\[
\text{Im}I_{\text{EFT}}[\psi^{ir}_1, \psi^{ir}_2; J_1, J_2] \geq 0, \quad \text{for any } \psi^{ir}_{1,2}, J_{1,2}
\]

\[
I_{\text{EFT}}[\psi^{ir}_1 = \psi^{ir}_2; J_1 = J_2] = 0.
\]

- Any symmetry of the UV action \( S \) is a symmetry of \( I_{\text{EFT}} \), except for time-reversing symmetries. The fact that these time-reversing transformations are not symmetries of the effective action allows the production of entropy. Because the field values on the 1-and 2-contours must be equal in the distant future, \( \psi^{ir}_1 \) and \( \psi^{ir}_2 \) must transform simultaneously under any global symmetry transformation. Thus, there is just one copy of the global symmetry group.

- If the equilibrium density matrix \( \rho \) takes the form of a thermal matrix, \( \rho \propto e^{-\beta_0 \mathcal{P}_0} \), then the partition function \( W[J_1, J_2] \) obeys what are known as the KMS conditions. These KMS conditions for the partition function can be used to derive the so-called dynamical KMS symmetries of the effective action. The way these symmetries act is as follows. Suppose that the UV theory possesses some kind of time-reversing symmetry \( \Theta \); at a minimum, the UV theory will be invariant under a simultaneous charge, parity, and time inversion. Then, setting the sources to zero, the dynamical KMS symmetries act on the fields by

\[
\psi^{ir}_1(x) \rightarrow \Theta \psi^{ir}_1(t - i\theta, \vec{x})
\]

\[
\psi^{ir}_2(x) \rightarrow \Theta \psi^{ir}_2(t + i(\beta_0 - \theta), \vec{x}),
\]

for any \( \theta \in [0, \beta_0] \). It can be checked that these transformations are their own inverse, meaning that the dynamical KMS symmetries are discrete \( \mathbb{Z}_2 \) symmetries. These symmetries involve temporal translations along the imaginary-time directions because the thermal density matrix can be interpreted as a time-translation operator by imaginary time \( -i\beta_0 \). As a result, they are non-local transformations. This non-locality may seem rather odd, but at any given order in the derivative expansion, these symmetries become local; one need only perform a Taylor
series in $\theta$ and $\beta_0 - \theta$. Further, in the classical limit they become exactly local. To take the classical limit, it is convenient to perform a change of field basis by

$$\psi^{ir}_r \equiv \frac{1}{2}(\psi^{ir}_1 + \psi^{ir}_2), \quad \psi^{ir}_a \equiv \psi^{ir}_1 - \psi^{ir}_2. \quad (20)$$

Then the classical dynamical KMS symmetry transformations are

$$\psi^{ir}_r(x) \rightarrow \Theta \psi^{ir}_r(x)$$

$$\psi^{ir}_a(x) \rightarrow \Theta \psi^{ir}_a(x) + i\Theta \left[\beta_0 \partial_t \psi^{ir}_r(x)\right]. \quad (21)$$

Notice that the change in $\psi^{ir}_a$ is proportional to the derivative of $\psi^{ir}_r$. Thus, when writing down terms of the effective action in the derivative expansion, it is natural to consider $\psi^{ir}_a$ and $\partial \psi^{ir}_r$ as contributing to the same order.

### 3.2 The fluid worldvolume

At finite temperature the effective action is often not defined on the physical spacetime. Instead, we must introduce the notion of the so-called fluid worldvolume. To see why this is so, we will reproduce the derivation of the fluid action presented in [1]. Consider a fluid with no conserved currents other than the stress-energy tensor. The sources for the stress-energy tensor are the metric tensors $g_{s\mu\nu}$, where $s = 1, 2$ indicates on which leg of the SK contour the metrics live. Then, the SK generating functional takes the form

$$e^{W[g_{1\mu\nu}, g_{2\mu\nu}]} = \text{tr}\left[U(+\infty, -\infty; g_{1\mu\nu}) \rho U^\dagger(+\infty, -\infty; g_{2\mu\nu})\right], \quad (22)$$

where $U(+\infty, -\infty; g_{s\mu\nu})$ is the time-evolution operator in the presence of source $g_{s\mu\nu}$. Since the stress-energy tensor is conserved, the generating functional $W[g_{1\mu\nu}, g_{2\mu\nu}]$ must be invariant under two independent diffeomorphism transformations. Let $\zeta_s^i(x)$ for $s = 1, 2$ represent two different diffeomorphisms. Then we have

$$W[g_{1\mu\nu}, g_{2\mu\nu}] = W[g_{1_{MN}}, g_{2_{MN}}], \quad (23)$$

where $g_{s_{MN}}$ for $M, N = 0, 1, 2, 3$ denote diffeomorphism transformations of $g_{s\mu\nu}$. More explicitly, we have $g_{s_{MN}}(\phi) \equiv \frac{\partial \phi}{\partial \phi^M} g_{s\mu\nu}(\zeta_s(\phi)) \frac{\partial \phi}{\partial \phi^N}$. Now, we can use the Stueckelberg trick and promote the gauge transformations to dynamical fields. In particular, we ‘integrate in’ the fields $X_s^\mu(\phi)$ such that the generating functional becomes

$$e^{W[g_{1\mu\nu}, g_{2\mu\nu}]} = \int \mathcal{D}X_1 \mathcal{D}X_2 \ e^{i\text{EFT}[G_{1MN}, G_{2MN}]}, \quad (24)$$

where

$$G_{s_{MN}} \equiv \frac{\partial X_s^\mu}{\partial \phi^M} g_{s\mu\nu}(X_s(\phi)) \frac{\partial X_s^\nu}{\partial \phi^N}. \quad (25)$$

are pull-back metrics. Notice that when performing the Stueckelberg trick, we had to introduce the coordinates $\phi^M$ for $M = 0, 1, 2, 3$. We will refer to $\phi^M$ as ‘fluid coordinates’ and the corresponding manifold on which they live as the ‘fluid worldvolume.’ Then the fields $X_s^\mu(\phi)$ are the dynamical fields and describe the embedding of the fluid worldvolume into the physical spacetime. In a certain sense, it is always possible to ‘integrate in’ these Stueckelberg fields as long as $W[g_{1\mu\nu}, g_{2\mu\nu}]$ is diffeomorphism invariant. However, there is no guarantee that the resulting EFT will be non-trivial; for example, if the equilibrium density matrix is a pure, zero-temperature ground state.
without any SSB then the fields $X_I^\mu$ are pure gauge and hence have no dynamics. It turns out that to ensure the system exists in fluid phase, we must require that the fluid coordinates enjoy a partial diffeomorphism symmetry

$$\phi^M \rightarrow \phi^M + \xi^M(\phi^I),$$

where $\xi^M(\phi^I)$ is an arbitrary function of the spatial fluid coordinates $\phi^I$ for $I = 1, 2, 3$. The reasons for imposing this partial diffeomorphism symmetry are essentially pragmatic; it is not fully understood how they arise, only that they are necessary to describe systems in fluid phase.

4 The non-equilibrium coset construction

Before we are able to state the procedure for constructing non-equilibrium effective actions with the method of cosets, we must first understand the IR field content of condensed matter systems at finite temperature. It turns out that Goldstone and Goldstone-like excitations at finite temperature are a bit different than at zero temperature. After the field content is established, we will outline the procedure for using cosets to construct non-equilibrium effective actions, which we term the non-equilibrium coset construction.

4.1 Goldstones at finite temperature

At finite temperature, SSB occurs when a symmetry generator fails to commute with the equilibrium density matrix. Goldstone’s theorem tells us that for every spontaneously broken symmetry, there is a corresponding Goldstone mode (unless inverse Higgs constraints are imposed). However, at finite temperature, there are other excitations that survive over long distances and extended time scales, which resemble Goldstones. Our claim is that there are in fact Goldstone-like fields for every symmetry regardless of whether it is broken or unbroken (unless inverse Higgs-type constraints are imposed). This claim is best understood from a semi-classical perspective. Semi-classically, the density matrix is a purely pragmatic tool that is used to account for our classical ignorance of the true micro-state of the system. Essentially every (classical) micro-state in a thermal statistical ensemble corresponds to a highly chaotic classical field configuration, which will in general spontaneously break every symmetry. As a result, we expect that the non-equilibrium effective action should consist of Goldstones if every symmetry of the theory were spontaneously broken. We will refer to the Goldstones corresponding to spontaneously broken generators as broken Goldstones and those corresponding to unbroken generators as unbroken Goldstones.

It turns out that there is an important distinction between broken and unbroken Goldstones. In particular, in every known case, unbroken Goldstones possess infinitely many gauge symmetries. For specific examples, consult [1-3,9,35]. While it is not fully understood from first principles where these gauge symmetries come from, Appendix A gives a pragmatic explanation for why they should exist. We will take as a well-motivated assumption that these gauge symmetries act as follows. Let $T_A$ be the unbroken generators and let $\epsilon^A_s(\phi)$ be the unbroken Goldstones. Here, $s = 1, 2$ indicates on which leg of the CPT the fields live. Then we have the gauge redundancies

$$e^{i\epsilon^A_s(\phi)T_A} \rightarrow e^{i\epsilon^A_s(\phi)T_A} e^{i\lambda^A(\phi^I)T_A},$$

for arbitrary spatial functions $\lambda^A(\phi^I)$. We use the convention that $M, N = 0, 1, 2, 3$ and $I, J = 1, 2, 3$. Additionally, the effective action will be invariant under a certain subgroup of diffeomorphisms that act on the fluid worldvolume coordinates $\phi^M$ by [1]

$$\phi^M \rightarrow \phi^M + \xi^M(\phi^I),$$
which we interpret as additional gauge symmetries. Since it is unknown how exactly these symmetries arise, it is conceivable that they may not hold in all situations. However, they do hold for all situations known to this author, so we will proceed with the assumption that (27) and (28) are in fact the correct symmetries.

4.2 The method of cosets

As discussed in the previous subsection, at finite temperature there is a Goldstone mode corresponding to each symmetry of the theory (unless inverse Higgs-type constraints are imposed). As a result, in the coset construction we must parameterize the full symmetry group of the theory with Goldstone modes.\(^4\) Since unbroken Goldstones enjoy a gauge symmetry whereas broken Goldstones do not, we must distinguish between the two types of Goldstones. Additionally, we assume that there exist some sorts of unbroken translation generators\(^5\). The global symmetry generators of the theory are as follows\(^5\)

\[
\bar{P}_\mu = \text{unbroken translations} \\
T_A = \text{other unbroken generators} \\
\tau_\alpha = \text{broken generators}
\]

Finally, let \(G\) be the full symmetry group of the theory (including spacetime symmetries), let \(H \subset G\) be the unbroken subgroup, and let \(H_0 \subset H\) be the subgroup generated by \(T_A\).

We will construct our theory on the fluid worldvolume with coordinates \(\phi^M\) for \(M = 0, 1, 2, 3\). Parameterize an arbitrary group element by

\[
g_s(\phi) = e^{iX_s^\mu(\phi)\bar{P}_\mu e^{i\pi_s^\alpha(\phi)\tau_\alpha e^{i\epsilon_A^s(\phi)T_A}}},
\]

where \(s = 1, 2\) indicates on which leg of the SK contour the fields live. Each \(g_s\) for \(s = 1, 2\) transform under the same global symmetry action. Notice that the spacetime coordinates \(x^\mu\) that appear in the ordinary coset construction (2) have been promoted to dynamical fields \(X_s^\mu(\phi)\) in the non-equilibrium coset construction. These fields serve to embed the fluid worldvolume into the physical spacetime.

We are interested in building-blocks for the non-equilibrium effective action that can be constructed from the Maurer-Cartan one-form and that transform covariantly under the global symmetry group \(G\) as well as under the gauge transformations

\[
g_s(\phi) \rightarrow g_s(\phi^M + \xi^M(\phi^I)), \\
g_s(\phi) \rightarrow g_s(\phi)e^{i\lambda^A(\phi^I)T_A},
\]

for arbitrary spatial functions \(\xi^M(\phi^I)\) and \(\lambda(\phi^I)\).\(^6\) To this end, we will treat the coefficients of unbroken generators of \(H_0\) in the Maurer-Cartan form as gauge-fields that have the partial gauge-invariance defined by the second line of (31). The Maurer-Cartan one-form is

\[
g_s^{-1}\partial_M g_s = iE_s^\mu_{sM}(\bar{P}_\mu + \nabla_\mu\pi_s^\alpha\tau_\alpha) + iB^A_{sM}T_A,
\]

\(^4\)Since we are parameterizing the full symmetry group as opposed to merely the non-linearly realized coset, it is not technically correct to call our construction a coset construction. Nevertheless we will use the term ‘coset construction’ for the sake of linguistic continuity.

\(^5\)When using the coset construction for theories with gauge symmetries, there are two main approaches. In [12,37], gauge transformations are treated as if they are physical symmetries and generators for each gauge transformation appear in the coset. In [31], gauge symmetries are treated as redundancies and only global symmetry generators appear in the coset. Both methods yield correct results, but we will use the second approach as it is far simpler.

\(^6\)Once again, we use \(M,N = 0, 1, 2, 3\) and \(I,J = 1, 2, 3\).
where $E^\mu_{sM}$ are the vierbeins, $\nabla_\mu \pi^\alpha_s$ are the covariant derivatives of the broken Goldstones, and certain components of $B^A_{s0}$ behave like gauge connections.\footnote{Notice that terms like $g_1^{-1} \cdot g_2$ transform covariantly under both the global symmetry group $G$ as well as the gauge transformations, yet they are not used as building-blocks of the effective action. Our claim is that only building-blocks that arise from the Maurer-Cartan one-form are permissible, the proof of which is provided in Appendix B.} These objects transform under (31) as follows. Under the $T_A$-gauge transformations, the vierbeins, the covariant derivatives, and $B^A_{s0}$ transform linearly, whereas $B^A_{sI}$ transform as

$$B^A_{sI} \rightarrow B^A_{sI} h_0^{-1} \cdot T_A \cdot h_0 - i h_0^{-1} \cdot \partial_I h_0,$$

(33)

where $h_0(\phi^I) \equiv e^{iA(\phi^I)T_A}$; that is, $B^A_{sI}$ transform as connections. Under the fluid diffeomorphism transformations, $E^\mu_{s0}$, $\nabla_\mu \pi^\alpha_s$, and $B^A_{s0}$ all transform as scalars, whereas the spatial component of the vierbeins and the connections transform as

$$E^\mu_{sI} \rightarrow \frac{\partial \phi^M}{\partial \phi^I} E^\mu_{sM},$$

$$B^A_{sI} \rightarrow \frac{\partial \phi^M}{\partial \phi^I} B^A_{sM},$$

(34)

where $\phi^M(\phi^I) \equiv \phi^M + \xi^M(\phi^I)$. The building-blocks that transform covariantly under both the global symmetries and the gauge symmetries (31) are as follows: First, there are the building-blocks from the usual coset construction, namely $\nabla_\mu \pi^\alpha_s$, which transform covariantly under (31), and to take higher-order covariant derivatives we can use

$$\frac{\partial}{\partial \phi^I},$$

$$\nabla^H_I = \partial_I + i B^A_{rI} T_A,$$

(35)

where $B^A_{rI} = \frac{1}{2}(B^A_{1I} + B^A_{2I})$ and $I = 1, 2, 3$. To contract coordinate indices, we use the metrics

$$G_{sMN} = E^\mu_{sM} \eta_{\mu\nu} E^\nu_{sN}.$$

(36)

Second, there are new building-blocks that involve the unbroken Goldstone degrees of freedom, namely $E^\mu_{s0}$ and $B^A_{s0}$, which transform covariantly. Finally, we have terms that involve combinations of 1-and 2-fields. Notice that $E^\mu_{1M}(E^{-1}_2)^\nu_M$ and $B^A_{aM} \equiv B^A_{1M} - B^A_{2M}$ transform covariantly and we can contract coordinate indices with $E^\mu_{1M} \eta_{\mu\nu} E^\nu_{2N}$.

After computing these building-blocks, inverse Higgs-type constraints can be imposed to remove extraneous Goldstone modes. The basic idea behind inverse Higgs constraints is that we may set to zero any objects that transform covariantly under the symmetries and gauge symmetries as long as the resulting equations can be algebraically solved for one set of Goldstones in favor of derivatives of another set of Goldstones. We will see in subsequent examples that there are three kinds of inverse Higgs-type constraints.

There are the usual inverse Higgs constraints that exist for zero-temperature systems. Suppose that the commutators between an unbroken translation generator $P$ and a broken generator $\tau'$ contains another unbroken generator $\tau$, that is $[P, \tau'] \supset \tau$. Further, suppose that $\tau$ and $\tau'$ do not belong to the same irreducible multiplet under $H_0$. Then, it is consistent with symmetry transformations to set the covariant derivative of the $\tau$-Goldstone in the direction of $P$ to zero. This gives a constraint that relates the $\tau'$-Goldstone to derivatives of the $\tau$-Goldstone, allowing the removal of the $\tau'$-Goldstone.

Notice that the ordinary inverse Higgs constraints only allow for the removal of certain broken Goldstones by relating them to derivatives of other broken Goldstones. One might wonder if there
are other possibilities. Perhaps we could remove broken Goldstones by relating them to derivatives of unbroken Goldstones; or perhaps we could specify some constraints that allow us to remove unbroken Goldstones. It turns out that both of these are possible; the rules are as follows:\(^8\)

- **Thermal inverse Higgs:** Suppose that at finite temperature, the commutator between a broken generator \(\tau\) and the unbroken time-translation generator \(\bar{P}_0\) contains an unbroken spacetime translation generator \(\bar{P}\), that is \([\tau, \bar{P}_0] \supset \bar{P}\). Then we may set to zero the component of \(E^\mu_0\) in the direction of \(\bar{P}\). This gives an equation that can be algebraically solved to yield an expression for the \(\tau\)-Goldstone in terms of derivatives of the \(\bar{P}\)-Goldstone. This allows the removal of the \(\tau\)-Goldstone.

- **Unbroken inverse Higgs:** Suppose that at finite temperature, the commutator between an unbroken generator \(T\) and an unbroken spacetime translation generator \(\bar{P}'\) contains another unbroken spacetime translation generator \(\bar{P}\), that is \([T, \bar{P}'] \supset \bar{P}\). Consider the matrix \(A_{\mu\nu} \equiv (E_1)^M \mu (E_2)^M \nu\), where \(M = 0, 1, 2, 3\) are coordinate indices and \(\mu, \nu = 0, 1, 2, 3\) are Lorentz indices. Then we may set to zero the components of \(A_{\mu\nu}\) in the directions of \(\bar{P}\) and \(\bar{P}'\). Suppose that under the dynamical KMS symmetry transformation, \(A_{\mu\nu} \rightarrow \tilde{A}_{\mu\nu}\). Then, we may also set to zero the components of \(\tilde{A}_{\mu\nu}\) in the directions of \(\bar{P}\) and \(\bar{P}'\). These conditions give constraints that relate the \(T\)-Goldstone to derivatives of the \(\bar{P}\)-Goldstone, allowing the removal of the \(T\)-Goldstone.\(^9\)

Once inverse Higgs constraints have been imposed and an effective action has been constructed, it is then necessary to impose the dynamical KMS symmetry. Often, at leading order in the derivative expansion (which is the only order to which we will be working in the subsequent examples) the only effect of the dynamical KMS symmetry will be to mandate that the effective action factorize as

\[
I_{\text{EFT}}[\chi_r, \chi_a] = S_{\text{EFT}}[\chi_1] - S_{\text{EFT}}[\chi_2] + O(\chi_3^3),
\]

where \(\chi_r \equiv \frac{1}{2}(\chi_1 + \chi_2)\), \(\chi_a \equiv \chi_1 - \chi_2\), and \(O(\chi_3^3)\) counts as higher order in the derivative expansion. The only exceptions to this rule that appear in this paper are the EFTs for nematic and smectic C phases of liquid crystals. When this rule holds, it allows us to work with just one copy of the fields. Thus, at leading order, the building-blocks \(\nabla_\mu \pi^\alpha\) describe the broken Goldstones and \(E^\mu_0\) and \(B^A_0\) describe the unbroken Goldstones. For the sake of simplicity, in the subsequent sections, we will construct EFTs for various states of matter at leading order in the derivative expansion. As a result, we will construct ordinary actions with just one copy of the fields whenever possible.

## 5 Fluids and superfluids at finite temperature

To demonstrate that our non-equilibrium coset construction presented in the previous section gives correct results, we will reproduce the known effective actions for fluids and superfluids at finite temperature. Along the way, we will find that finite-temperature framids—systems for which only boosts are spontaneously broken \(^10\)—can be thought of as fluids. In particular, at finite temperature, the boost Goldstones automatically become gapped and can therefore be integrated out, resulting in the ordinary fluid EFT.

---

\(^8\)To get a better understanding of why these new inverse Higgs constraints can be imposed, see Appendix C. In this appendix, to keep things as concrete as possible, we perform an in-depth analysis of inverse Higgs-type constraints for fluids without conserved charge.

\(^9\)It turns out that the unbroken inverse Higgs constraints do not necessarily remove the unbroken Goldstones from the covariant building-blocks. However they do remove the unbroken Goldstones entirely from the invariant building-blocks and hence from the effective action; see Appendices C.2-C.3.
5.1 Fluids

Consider a fluid without a conserved charge; the symmetry group is just the Poincaré group, whose algebra is given by (6). The unbroken generators are \( P_\mu \) for translations and \( J_i \equiv \frac{1}{2} \epsilon^{ijk} J_{jk} \) for spatial rotations; the broken generators are \( K_i \equiv J_0 i \) for boosts. Therefore, the most general group element is

\[
g(\phi) = e^{iX^\mu(\phi) P_\mu} e^{i\eta^i K_i} e^{i\theta^i(\phi) J_i},
\]

The resulting Maurer-Cartan one-form is

\[
g^{-1} \partial_M g = iE^\mu_M \left( P_\mu + \nabla_\mu \eta^i K_i \right) + i\Omega^i_M J_i,
\]

where the vierbein, covariant derivative, and spin-connection are given by

\[
E^\mu_M = \partial_M X^\nu [\Lambda R]^{\nu\mu},
\]

\[
\nabla_\mu \eta^i = (E^{-1})^M_\mu [\Lambda^{-1} \partial_M \Lambda]^{0j} R^{ji},
\]

\[
\Omega^i_M = \frac{1}{2} \epsilon^{ijk} [R^{-1} \Lambda^{-1} \partial_M (\Lambda R)]^{jk},
\]

such that \( R^{ij} = [e^{i\theta^i(\phi) J_i}]^{ij} \) and \( \Lambda^{\mu \nu} = [e^{i\eta^i K_i}]^{\mu \nu} \). Because spatial rotations are unbroken, the action must be invariant under the transformations

\[
g(\phi) \rightarrow g(\phi^M + \xi^M (\phi^I)),
\]

\[
g(\phi) \rightarrow g(\phi) \cdot e^{i\lambda^i (\phi^I) J_i},
\]

for arbitrary spatial functions \( \xi^M (\phi^I) \) and \( \lambda^i (\phi^I) \). Notice that \([P_i, K_j] = i\delta_{ij} P_0\), meaning that we may impose the thermal inverse Higgs constraints, allowing the removal of \( \eta^i \). In particular \( E^i_0 \) transforms covariantly under both the global symmetry group \( G \) as well as the gauge and diffeomorphism symmetries (31). Therefore we may fix

\[
0 = E^i_0 = \partial X^\mu / \partial \phi^i \Lambda_\mu^j R^{jj}.
\]

Since \( R^{ij} \) is invertible, this is equivalent to \( \partial_0 X^\mu \Lambda_\mu^i = 0 \), from which we find that

\[
\eta^i \tanh \eta = -\partial_0 X^i
\]

where \( \eta \equiv \sqrt{\eta^i \eta^i} \). For a more detailed calculation, see Appendix C.1.

Now we can impose unbroken inverse Higgs constraints to remove the rotation Goldstones.\(^{10}\) In order to do this, we must recall that the field-content is doubled. Notice that \([P_i, J_j] = i\epsilon_{ijk} P_k\), so we may set

\[
(E_1)_{iM} (E_2^{-1})^M_j - (E_1)_{jM} (E_2^{-1})^M_i = 0,
\]

which gives

\[
R_1 \cdot R_2^{-1} = \sqrt{M^T \cdot M \cdot M^{-1}}, \quad M^{ij} \equiv (\Lambda_2^{-1})^{ij} \partial X^\mu / \partial X^\mu_2 (\Lambda_1)^\mu_\mu.
\]

\(^{10}\)At this level in the derivative expansion, it is not actually necessary to solve the unbroken inverse Higgs constraints, but we will do so just to demonstrate that it can be done. When imposing the unbroken inverse Higgs constraints in later sections, such calculations will be omitted.
See Appendix C.2 for more detailed calculations. To get an intuitive sense of what is happening, let us expand the above equation to linear order in the fields. Transforming from the 1,2-basis to the $r, a$-basis (20), we have

$$\vec{\theta}_a = \vec{\nabla} \times \vec{X}_a,$$

(46)

where $\vec{\nabla} \times$ represents the ordinary curl and not a covariant derivative. Then, performing the (classical) dynamical KMS transformation on both sides gives

$$\frac{\partial \vec{\theta}_r}{\partial \phi^0} = -\vec{\nabla} \times \frac{\partial \vec{X}_r}{\partial \phi^0}.$$  

(47)

But notice that the linearized version of (41) implies that our action must be invariant under $\vec{\theta}_r(\phi) \to \vec{\theta}_r(\phi) + \vec{X}(\phi^I)$, meaning that at linear order, $\vec{\theta}_r$ can only appear in the effective action in the form $\partial \vec{\theta}_r/\partial \phi^0$. As a result, (47) is sufficient to remove $\vec{\theta}_r$ as an independent degree of freedom. Thus, $\vec{\theta}_r$ and $\vec{\theta}_a$ have been successfully removed from the effective action, so no rotational Goldstones remain. To see how $\vec{\theta}_r$ can be removed at the non-linearized level, see Appendix C.3.

Thus the only covariant building-block at leading order in the derivative expansion is $E_0^\mu = \sqrt{-E_0^\mu \eta_{\mu \nu} E_0^\nu}$. Defining the metric by

$$G_{MN} = E_M^\mu \eta_{\mu \nu} E_N^\nu = \frac{\partial X^\mu}{\partial \phi^M} \eta_{\mu \nu} \frac{\partial X^\nu}{\partial \phi^N},$$

(48)

we find that the leading-order action is a generic function of $G_{00} = -(E_0^t)^2$ and is given by

$$S_{\text{EFT}} = \int d^4 \phi \sqrt{-G} P(G_{00}).$$

(49)

Notice that the above system has the same symmetry-breaking pattern as a framid except for the fact that it exists at finite temperature [10]. Thus, we can interpret a finite-temperature framid as a fluid. With this interpretation, the meaning of the thermal inverse Higgs constraint is as follows. At finite temperature, the notion of an energy gap is ill-defined. Really, what we mean is that the propagator of $\eta^i$ has one raised Lorentz index and one lowered coordinate index. Whenever we feel that there may be an ambiguity, we will use $\mu = t$ instead of $\mu = 0$ to indicate time-like components of Lorentz vectors and tensors.

13At finite temperature, the notion of an energy gap is ill-defined. Really, what we mean is that the propagator will die off in space and time exponentially fast. But since the leading-order hydrodynamic action takes the form of an ordinary action with an energy gap, we use the term ‘energy gap.’

14Notice that both $P_0$ and $Q$ are unbroken, so defining $P_0 = P_0 + \mu Q$ reflects a choice since any linear combination of $P_0$ and $Q$ is unbroken. But it is the most natural choice given that this definition of $P_0$ allows us to express the equilibrium density matrix in the usual form $\rho = e^{-\beta_0 P_0}/\text{tr} e^{-\beta_0 P_0}$. 

---

---

---
The resulting Maurer-Cartan one-form is
\[ g^{-1} \partial_M g = i E^\mu_M \left( \bar{P}_\mu + \nabla_\mu \eta^i K_i \right) + i \mathcal{B}_M Q + i \Omega^i_M J_i, \]  
\[ (51) \]
where the vierbein, covariant derivative, and spin-connection are given by (40) and the $U(1)$ gauge field is given by
\[ \mathcal{B}_M = \partial_M \psi - \mu E^\mu_M, \]  
\[ (52) \]
where $\psi(\phi) \equiv \mu X^i(\phi) + \pi(\phi)$. We are interested in constructing an action that is invariant under (41) as well as the chemical shift gauge symmetry
\[ g(\phi) \rightarrow g(\phi) \cdot e^{\lambda_Q(\phi^I) Q}, \]  
\[ (53) \]
for arbitrary spatial function $\lambda_Q(\phi^I)$. As before, we may remove $\eta^i$ by imposing thermal inverse Higgs constraints (42), and we may remove $\theta^i$ by imposing unbroken inverse Higgs constraints (44).

Notice that the $U(1)$ gauge field $B_0$ transforms as a scalar. Since $E^\mu_0$ also transforms as a scalar, it is convenient to define the invariant building-block $B_0 \equiv B_0 + \mu E^\mu_0 = \partial_0 \psi$. The effective action at lowest order in derivatives is therefore
\[ S_{\text{EFT}} = \int d^4 \phi \sqrt{-G} \ P(B_0, G_{00}). \]  
\[ (54) \]
Notice that (49) and (54) are precisely the leading-order actions presented in [1-3]. They appear to differ from the actions presented in [9], but it can be shown that they are equivalent; see Appendix D.

5.2 Superfluids

Consider a superfluid at finite temperature. In addition to possessing Poincar symmetry (6), such a system must also have a conserved $U(1)$ charge $Q$ such that $\bar{P}_0 = P_0 + \mu Q$, $\bar{P}_i = P_i$, and $J_i = \frac{1}{2} e^{ijk} J_{jk}$ are the unbroken generators and $Q$ and $K_i = J_{0i}$ are the broken generators [10,13]. The most general group element is
\[ g(\phi) = e^{i X^\mu(\phi) \bar{P}_\mu} e^{i \pi(\phi) Q} e^{i \eta^i(\phi) K_i} e^{i \theta^i(\phi) J_i}. \]  
\[ (55) \]
And the resulting Maurer-Cartan one-form is
\[ g^{-1} \partial_M g = i E^\mu_M \left( \bar{P}_\mu + \nabla_\mu \pi Q + \nabla_\mu \eta^i K_i \right) + i \Omega^i_M J_i, \]  
\[ (56) \]
where
\[ E^\mu_M = \partial_M X^\nu [\Lambda R]_{\nu}^\mu, \]
\[ \nabla_\mu \pi = (E^{-1})^\mu_M \partial_M \psi - \mu \delta^0_\mu, \]
\[ \nabla_\mu \eta^i = (E^{-1})^\mu_M [\Lambda^{-1} \partial_M \Lambda]^{0j} R^{ji}, \]
\[ \Omega^i_M = \frac{1}{2} e^{ijk} [\Lambda^{-1} \partial_M (\Lambda R)]^{jk}, \]  
\[ (57) \]
such that $\psi(\phi) \equiv \mu X^0(\phi) + \pi(\phi)$, the Lorentz boost matrix is $\Lambda^\mu_\nu(\phi) = [e^{i \eta^i(\phi) K_i}]_\nu^\mu$, and the rotation matrix is $R^{ij}(\phi) = [e^{i \theta^k(\phi) J_k}]^{ij}$. To remove the boost Goldstones, impose inverse Higgs
constraints $0 = \nabla_i \pi = \Lambda^\rho_i (e^{-1})^M_\rho \partial_M \psi$, where $e^\mu_M \equiv \partial_M X^\mu$. These constraints give a relation between the boost Goldstones and the $U(1)$ Goldstones

$$\eta^i \tanh \eta = \frac{(e^{-1})^M_\nu \partial_M \psi}{(e^{-1})^0_\nu \partial_M \psi}.$$  \hfill (58)

Using this relation, we have that $\nabla_t \pi = \sqrt{-G} P_{\mu \nu} \partial_\mu \psi \partial_\nu \psi - \mu$, giving our first symmetry-invariant building-block

$$Y \equiv \sqrt{-G} P_{\mu \nu} \partial_\mu \psi \partial_\nu \psi.$$  \hfill (59)

Equation (58) tells us that $[\Lambda R]^\mu_\nu = \frac{1}{\tau} (e^{-1})^M_\nu \partial_M \psi$, from which we find that $E_0^\mu \nabla_\mu \pi = [1 - \frac{\mu}{\tau}] \partial_0 \psi$, yielding our second symmetry-invariant building-block

$$B_0 \equiv \frac{\partial \psi}{\partial \phi^0}.$$  \hfill (60)

And just as in the fluid case, we have

$$G_{00} = E_0^\mu q_{\mu \nu} E_0^\nu$$  \hfill (61)

as our third symmetry-invariant building-block. Finally, following the same calculation as in the previous section, we can impose unbroken inverse Higgs constraints to remove the rotation Goldstones. Thus, the effective action describing a superfluid at finite temperature is, to lowest order in derivatives,

$$S_{\text{EFT}} = \int d^4 \phi \sqrt{-G} \ P(Y, B_0, G_{00}).$$  \hfill (62)

This effective action looks somewhat different from the one presented in [13], but can be shown to be equivalent; see Appendix D. Further, in the zero-temperature limit, the effective action loses its dependence on $X^\mu(\phi)$, meaning that it only depends on the physical-spacetime version of $Y$, namely (13), reproducing the standard superfluid EFT (14).

6 Solids and supersolids at finite temperature

Now that we have established that the non-equilibrium coset construction can reproduce known results, we turn our attention to the construction of novel EFTs. The simplest physical systems for which the non-equilibrium effective actions are as of yet unknown are solids and supersolids. In this section, we will construct the leading-order non-equilibrium EFTs for these states of matter.

6.1 Solids

Consider a chargeless crystalline solid at finite temperature. In addition to possessing Poincaré symmetry (6), such a system must also have internal translation symmetry generators $Q_i$ for $i = 1, 2, 3$ that commute with each other. We then take $\bar{P}_0 = P_0$ and $\bar{P}_i = P_i + Q_i$ to be the unbroken generators such that $Q_i, K_i = J_{0i}$, and $J_i = \epsilon_{ijk} J_{jk}$ are the broken generators [10]. The most general group element is

$$g(\phi) = e^{ix^\pi(\phi) \bar{P}_\mu} e^{ix^\eta(\phi) Q_i} e^{ix^\theta(\phi) K_i} e^{ix^\phi(\phi) J_i}.$$  \hfill (63)

And the resulting Maurer-Cartan one-form is

$$g^{-1} \partial_M g = iE_0^\mu(\bar{P}_\mu + \nabla_\mu \pi^i Q_i + \nabla_\mu \eta^i K_i + \nabla_\mu \theta^i J_i),$$  \hfill (64)
The corresponding Maurer-Cartan one-form is just (64) with the addition of a term involving the B charge to fluids, we now have the additional building-block in derivatives, describing a crystalline solid with conserved \( u \) conservation. Let \( \vec{\pi} = \nabla \times \psi \). Thus the effective action describing a crystalline solid at finite temperature is, to lowest order in \( g \) and \( \nu \),

\[
S_{\text{EFT}} = \int d^4\phi \sqrt{-G} \ P(Y^{ij}, Z^i, G_{00}).
\]

As when we added a conserved inverse Higgs constraint, we find that

\[
\eta^j \tan \eta = -(e^{-1})^i_t \partial_M \psi^j (a^{-1})^{ij}
\]

such that \( a^{ij} = (e^{-1})^i_t \partial_M \psi^j \). Imposing the second inverse Higgs constraint tells us that \( \nabla^{(1)} = (Y^{1/2})^{ij} - \delta^{ij} \), where

\[
Y^{ij} \equiv G^{MN} \partial_M \psi^i \partial_N \psi^j
\]

such that \( G^{MN} \) is the inverse of the metric (48). We therefore have our first set of invariant building-blocks. Notice that because there is no notion of unbroken rotational symmetry, \( Y^{ij} \) is truly symmetry-invariant and not merely covariant. We have the additional invariant objects \( E_0^\mu \nabla \pi^i = (\delta^{ij} - (Y^{-1})^{ij}) \partial_0 \psi^j \), from which we extract our next set of invariant building-blocks

\[
Z^i \equiv \partial_0 \psi^i.
\]

Lastly, we have the usual time-like piece of the fluid metric (48), \( G_{00} \), as our final building-block. Thus the effective action describing a crystalline solid at finite temperature is, to lowest order in derivatives,

\[
S_{\text{EFT}} = \int d^4\phi \sqrt{-G} \ P(Y^{ij}, Z^i, G_{00}).
\]

Often, solids possess an additional unbroken \( U(1) \) symmetry corresponding to particle-number conservation. Let \( Q \) be the corresponding generator. Then, the unbroken translations are \( P_0 = P_0 + \mu \psi \) and \( P_i = P_i + Q_i \). The most general group element is

\[
g(\phi) = e^{iX^\mu(\phi)P_\mu} e^{i\pi^i(\phi)Q_i} e^{i\eta^j(\phi)K_j} e^{i\theta^i(\phi)J_i} e^{i\xi(\phi)Q}.
\]

The corresponding Maurer-Cartan one-form is just (64) with the addition of a term involving the \( U(1) \) gauge-field \( B_M = \partial_M \psi - \mu E^\mu_M \) for \( \psi(\phi) = X^0(\phi) + \pi(\phi) \). As when we added a conserved charge to fluids, we now have the additional building-block \( B_0 \equiv \partial_0 \psi \). Thus the effective action describing a crystalline solid with conserved \( U(1) \) charge at finite temperature is, to lowest order in derivatives,

\[
S_{\text{EFT}} = \int d^4\phi \sqrt{-G} \ P(Y^{ij}, Z^i, B_0, G_{00}).
\]

\[
\text{Here, } \nabla \times \pi \text{ should be thought of as the spatial components of the covariant derivative } \nabla_\mu. \text{ Thus } \nabla \times \pi \text{ is not the curl of } \vec{\pi}. \]
As a consistency check, let us take the zero-temperature limit. This amounts to removing all dependence on $\partial X^\mu(\phi)/\partial \phi^0$. We see therefore that the zero-temperature EFT only depends on the physical-spacetime version of $Y^{ij}$, namely

$$y^{ij} \equiv \partial_\mu \psi^i \partial^\mu \psi^j, \quad (72)$$

which agrees with the results of [12].

### 6.2 Supersolids

Consider an anisotropic supersolid at finite temperature. In addition to possessing Poincaré symmetry (6), such a system must also have internal translation symmetry generators $Q_\mu$ for $\mu = 0, 1, 2, 3$ that commute with each other such that $\bar{P}_\mu = P_\mu + Q_\mu$ are the unbroken generators and $Q_\mu$ and $J_{\mu\nu}$ are the broken generators [10]. The most general group element is

$$g(\phi) = e^{iX^\mu(\phi)P_\mu} e^{i\pi^\mu(\phi)Q_\mu} e^{i\theta_{\mu\nu}(\phi)J_{\mu\nu}}. \quad (73)$$

And the resulting Maurer-Cartan one-form is

$$g^{-1} \partial_M g = iE^\mu_M \left( \bar{P}_\mu + \nabla_\mu \pi^\nu Q_\nu + \frac{1}{2} \nabla_\mu \theta^\lambda_{\nu\lambda} J_{\nu\lambda} \right), \quad (74)$$

where

$$E^\mu_M = \partial_M X^\nu \Lambda^\mu_\nu, \quad \nabla_\mu \pi^\nu = (E^{-1})^\mu_M \partial_M \psi^\nu - \delta^\nu_\mu, \quad \nabla_\mu \theta^\lambda_{\nu\lambda} = (E^{-1})^\mu_M [\Lambda^{-1} \partial_M \Lambda]_{\nu\lambda}, \quad (75)$$

such that $\psi^\mu(\phi) = X^\mu(\phi) + \pi^\mu(\phi)$ and the Lorentz transformation matrix is $\Lambda^\mu_\nu(\phi) = [e^{i\eta^\mu(\phi)K_i} \cdot e^{i\theta^\mu(\phi)J_k}]^\mu_\nu$. To remove the Lorentz Goldstones, impose inverse Higgs constraints

$$0 = \nabla_{[\mu} \pi_{\nu]} = \Lambda^\rho_\mu (e^{-1})^\rho_M \partial_M \psi_\nu - (\mu \leftrightarrow \nu). \quad (76)$$

Letting $M_{\mu\nu} \equiv (e^{-1})^M_\mu \partial_M \psi_\nu$, the inverse Higgs constraints merely require that $\Lambda^T \cdot M$ must be a symmetric matrix, where factors of $\eta_{\mu\nu}$ have been suppressed. Using this result, we have that

$$Y^{\mu\nu} = G^{MN} \partial_M \psi^\mu \partial_N \psi^\nu \quad (77)$$

are our first set of symmetry-invariant building-blocks and we use the convention that

$$(Y^{1/2})_{\mu\rho} \eta^{\rho\lambda} (Y^{1/2})_{\lambda\nu} = Y_{\mu\nu}. \quad (78)$$

Additionally, we have $E^\mu_0 \nabla_\nu \pi^\mu = (\delta^\mu_\nu - (Y^{-1})^\mu_0) \partial_\nu \psi^\nu$. Our next set of invariant building-blocks is therefore

$$Z^\mu \equiv \frac{\partial \psi^\mu}{\partial \phi^0}. \quad (79)$$

And finally, we have the usual $G_{00}$ building-block. Thus the effective action describing a crystalline supersolid at finite temperature is, to lowest order in derivatives,

$$S_{\text{EFT}} = \int d^4\phi \sqrt{-G} \ P(Y^{\mu\nu}, Z^\mu, G_{00}). \quad (80)$$

As in the solid EFT case, taking the zero-temperature limit amounts to removing all dependence on $\partial X^\mu(\phi)/\partial \phi^0$. Thus at zero temperature, the effective action can only depend on the physical-spacetime version of $Y^{\mu\nu}$, namely

$$y^{\mu\nu} \equiv \partial_\rho \psi^\mu \partial^\rho \psi^\nu, \quad (81)$$

which agrees with the results of [12].
7 Liquid crystals at finite temperature

We now turn our attention to the construction of EFTs for more exotic states of matter, namely those of liquid crystals. There are myriad distinct phases of liquid crystals, so for the sake of brevity (and the reader’s patience) we will focus on four of the most common liquid crystal phases: nematic liquid crystals and smectic liquid crystals in phases A, B, and C. See Figure 1 for a graphical representation of various phases of liquid crystals. At low temperatures, the system exists in the crystalline solid phases, spontaneously breaking all spatial translational and rotational symmetries; the corresponding EFT is therefore given by (69) or (71). As the temperature rises, symmetries are restored until at high temperatures, the system exists in fluid phase in which no symmetries other than boosts are spontaneously broken; the corresponding EFT is therefore given by (49) or (54). The aim of this section will be to construct EFTs for the intermediate phases that partially break the ISO(3) group of spatial translations and rotations.

Notice that in the figure above, (a) spontaneously breaks all translations and rotations, corresponding to crystalline solid phase. Parenthetically, the profile of smectic liquid crystal in phase B appears almost identical to that of the solid; however in phase B, the horizontal layers of molecules are allowed to slide past each other. Phases (b) and (c) both spontaneously break translations in the vertical direction, but not in the horizontal directions; therefore both exist in smectic liquid crystal phase. The difference between these two states of matter is that (b) spontaneously breaks all spatial rotations whereas (c) does not break rotations about the vertical direction; thus (b) depicts phase C and (c) depicts phase A. Phase (d) does not spontaneously break spatial translations in any direction, but does spontaneously break rotations about the horizontal axes, meaning that it exists in nematic liquid crystal phase. Finally, (e) does not spontaneously break any spatial translations or rotations and is therefore in isotropic fluid phase.

7.1 Nematic liquid crystals

Liquid crystals in nematic phase are composed of oblong molecules that, like the molecules of an ordinary fluid, bounce around chaotically and therefore cannot form a lattice structure; however, on average the long axes of the molecules align, thereby breaking isotropy. Because no lattice structure can form, spacetime translations remain unbroken, but the aligned long axes of the
molecules spontaneously break rotations. Non-relativistically, the order parameter associated with broken rotations is a unit vector \( \vec{n} \), pointing parallel to the long axes of the molecules. As a result the \( SO(3) \) symmetry group of spatial rotations is broken to \( SO(2) \) [39]. However, for any choice of \( \vec{n} \), the long axes of the molecules could be equally well specified by \(-\vec{n}\). Therefore, it is common to use the order parameter \( Q_{ij} \equiv n_in_j - \frac{1}{3}\delta_{ij} \), which is invariant under the \( Z_2 \) symmetry \( \vec{n} \to -\vec{n} \).

To extend this order parameter to the relativistic case, it is natural to define \( Q_{\mu\nu} \equiv Q_{ij}\delta_{\mu}^{ij}\delta_{\nu}^{ij} \). We therefore see that boosts are spontaneously broken as well. Then, relativistically, the SSB pattern of the Poincar group is

\[
\text{ISO}(1,3) \to \mathbb{R}^4 \times SO(2),
\]

where \( \mathbb{R}^4 \) represents spacetime translations. We also have the unbroken discrete \( Z_2 \) symmetry associated with \( \vec{n} \to -\vec{n} \). Without loss of generality choose \( \langle \vec{n} \rangle = \hat{z} \) and let indices \( A, B = 1, 2 \).

Then, \( P_\mu \) and \( J_3 \) are the unbroken generators and \( J_A \) and \( K_i \) are the broken generators. It will turn out that we need to use two copies of the fields to construct the leading-order action for this phase of matter.

Parameterize the most general group elements by

\[
g_s(\phi) = e^{iX_s^\mu(\phi)P_\mu + i\eta_s^i(\phi)K_i}e^{i\theta_s^A(\phi)J_A + i\theta_s^3(\phi)J_3}.
\]

The resulting Maurer-Cartan one-forms are

\[
g_s^{-1}\partial_M g_s = iE^\mu_{sM}(P_\mu + \nabla_\mu \theta_s^A J_A + \nabla_\mu \eta_s^i K_i) + i\Omega^A_{sM}J_A + i\Omega^3_{sM}J_3,
\]

such that

\[
E^\mu_{sM} = \partial_M X^\mu_s[\Lambda_sR_s],
\]

\[
\nabla_\mu \theta_s^A = (E^{-1})_s^\mu \epsilon^{AB3}[R_s^{-1}\Lambda_s^{-1}\partial_M(\Lambda_sR_s)]^{B3},
\]

\[
\nabla_\mu \eta_s^i = (E^{-1})_s^\mu [\Lambda_s^{-1}\partial_M\Lambda_s]^{0j}R_s^{ij},
\]

\[
\Omega^3_{sM} = [R_s^{-1}\Lambda_s^{-1}\partial_M(\Lambda_sR_s)]^{12},
\]

where \( \Lambda_s^{\mu\nu} \equiv [e^{i\eta_s^iK_i}]^{\mu\nu} \) and \( R_s^{ij} \equiv [e^{i\theta_s^A J_A + i\theta_s^3 J_3}]^{ij} \). We can impose the thermal inverse Higgs constraints

\[
0 = E^i_{s0} = \frac{\partial X_s^i}{\partial \phi_0}\Lambda_s^{-1}R_s^{ij},
\]

which reduce to \( \partial_0 X_s^i \Lambda_s^{-i} = 0 \) because \( R_s^{ij} \) are invertible. Then, as in the ordinary fluid case, we have

\[
\frac{\eta_s}{\eta_s} \tanh \eta_s = -\partial_0 X^i_s \partial_0 X^i_s,
\]

where \( \eta_s \equiv \sqrt{\eta_s^i\eta_s^i} \). Once again, \( E^i_{s0} = \sqrt{G_{s00}} \). Additionally, we can impose the unbroken inverse Higgs constraint, which removes the rotation Goldstone \( \theta_s^3 \). Define the vector

\[
A^k_a = \frac{1}{2}\epsilon^{ijk}(E_1)_M(E_2^{-1})_j^M.
\]

The unbroken inverse Higgs constraint is then \( A^3_a = 0 \). At this order in the derivative expansion it is not necessary to solve this inverse Higgs constraint, so in the interest of brevity we will not.

In the case of ordinary fluids, we had the additional unbroken inverse Higgs constraints \( A^A_0 = 0 \). But now \( J_A \) are broken so we may not impose such constraints. We therefore have a covariant

\[\text{[Note: The indices } A, B \text{ are not to be confused with the indices indicating unbroken symmetry generators that we used in previous sections.]\]

\[22\]
building-block that mixes 1 and 2 fields, namely $A^A_a$. Notice that $\eta^i_s$, $\theta^i_s$, and $\partial \theta^A_a$ all count at the same order in the derivative expansion. The reason is that $\eta^i_s$ and $\theta^i_s$ have been removed with inverse Higgs constraints, forcing them to count as higher order, whereas $\theta^A_a$ have nothing forcing them to count as higher. Therefore, at leading order in the derivative expansion,

$$ A^A_a = \frac{1}{2} \varepsilon^{ij} (R_2^{-1} \cdot R_1)^{ij}, $$

where $R^{ij}_a \equiv [e^{i \theta^A_a, J_A}^a]^{ij}$.

The full set of covariant building-blocks at this order in derivatives is

$$ A^A_a, \nabla B \theta^A_s, \nabla 3 \theta^A_s, \nabla \theta^A_s, G_{s00}, $$

where $\nabla \theta^A_s \equiv (E_0)^\mu_0 \nabla \mu \theta^A_s$ and $G_{s00} \equiv E_0^\mu \eta_{\mu \nu} E_0^\nu$. Thus, at leading order in the derivative expansion, the effective action is constructed from $SO(2) \times \mathbb{Z}_2$-invariant combinations of the above terms. The contribution to the non-equilibrium effective action that does not contain mixtures of 1 and 2 fields is, up to higher order terms, $S_1 - S_2$, where

$$ S_s = \int d^4 \phi \sqrt{-G_s} \left( \frac{1}{2} [2 P(G_{s00}) + M_1(G_{s00})(\nabla_A \theta^A_s)^2 + M_2(G_{s00})(\nabla^A \theta^B_s)^2 + M_3(G_{s00})(\nabla_3 \theta^A_s)^2] \right). $$

Notice that we could have included a term involving $(\nabla \theta^A_s)^2$, but we will see that the nematic degrees of freedom are diffusive, so we will consider $\partial \theta^A_s$ to count at the same order as $\partial^2 \theta^A_a$ in the derivative expansion. In the $r, a$-basis, the contribution to the non-equilibrium effective action that contains mixtures of 1 and 2 fields is

$$ I_{\text{mix}} = \int d^4 \phi \sqrt{-G_r} \left[ -M_0(G_{r00}) \nabla \theta^A_r A^A_a + \frac{i}{\beta_0} M_0(G_{r00})(A^A_a)^2 \right], $$

where $\beta_0$ is the equilibrium inverse temperature and the relationship between the coefficients of the two terms is fixed by the (classical) dynamical KMS symmetry, which transforms $A^A_a$ by

$$ A^A_a \rightarrow \Theta A^A_a + i \Theta \beta_0 \nabla \theta^A_a. $$

Then, up to higher-order corrections, the full non-equilibrium effective action is given by

$$ I_{\text{EFT}} = S_1 - S_2 + I_{\text{mix}}. $$

To compare the above action built with the non-equilibrium coset construction to more standard results, we now expand to quadratic order in the fields. Define $\varepsilon^\mu_0$ by $X^\mu_0(\phi) = \phi^\mu + \varepsilon^\mu_0$ and perform a change of coordinates so that the Lagrangian is defined on physical spacetime. The quadratic non-equilibrium Lagrangian is

$$ \mathcal{L}_{\text{EFT}}^{(2)} = C_0 \varepsilon_{r0}^0 \varepsilon_{a0}^0 + C_1 (\varepsilon^i_r \partial_i \varepsilon_a^0 + \varepsilon^i_r \partial_i \varepsilon_a^0 + \varepsilon^i_r \varepsilon_a^0) - M_0 (\theta^A_r \theta^A_a) + \frac{i}{\beta_0} M_0 (\theta^A_a)^2 $$

$$ + \tilde{M}_1 (\partial_A \theta^A_r \partial_B \theta^B_a) + \tilde{M}_2 (\partial^A \theta^B_a \partial^A \theta^B_a) + \tilde{M}_3 (\partial_A \theta^A_r \partial_B \theta^A_a), $$

where the coefficients $\tilde{M}_l \equiv M_l(-1)$, for $l = 0, 1, 2, 3$. The terms of the action describing the ordinary fluid degrees of freedom $\varepsilon^\mu_0$ may look complicated, but they ultimately yield the usual fluid dispersion relations. This effective action passes two coherence checks. First, the fluid degrees of freedom decouple from the anisotropies of the rotational Goldstones. Second, comparing with [38],
we can match $\langle \delta \bar{n} \rangle^i = \epsilon^A \theta^A + \cdots$, in which case we obtain the same two-point function for $\delta \bar{n}$ as [38]. Notice that the dispersion relation for the nematic degrees of freedom is of the form $\omega \propto i k^2$, indicating diffusion.

Finally, we often expect particle number to be conserved, requiring the inclusion of an additional unbroken $U(1)$ charge $Q$. Let $\pi$ be the corresponding unbroken Goldstone. Then just as in §5.1 and §6.1, we have the additional invariant building-block

$$B_0 \equiv \frac{\partial \psi}{\partial \bar{n}^i}, \quad \psi(\phi) \equiv \mu X^0(\phi) + \pi(\phi).$$

As a result, the effective action is identical to (94) except $P$ and $M_l$ for $l = 0, 1, 2, 3$ are now functions of both $G_{00}$ and $B_0$.

### 7.2 Smectic liquid crystals

Smectic liquid crystals are composed of oblong molecules that form layers such that along one spatial direction, the liquid crystal has a periodic structure. Without loss of generality, take $P_3$ to be the spontaneously broken translation generator orthogonal to the layers. To ensure that some notion of unbroken translations along the $\hat{z}$ direction exists, it is necessary to introduce an internal translation symmetry generated by $Q_3$ that is spontaneously broken such that the diagonal subgroup generated by $\bar{P}_3 \equiv P_3 + Q_3$ is unbroken. Throughout this section, we will use $A, B = 1, 2$ to indicate spatial indices perpendicular to the $\hat{z}$ direction.

#### 7.2.1 Phase A

In phase A, the long axes of the molecules are, on the average, aligned with the $\hat{z}$ direction. Thus, $\bar{P}_\mu = P_\mu + \delta^3_\mu Q_3$, and $J_3$ are the unbroken generators and $J_A, K_i,$ and $Q_3$ are the broken generators. The most general group element is

$$g(\phi) = e^{i X^\nu(\phi) \bar{P}_\nu} e^{i \pi^3(\phi) Q_3} e^{i \theta^A(\phi) J_A + i \theta^i(\phi) J_i} e^{i \eta^A(\phi) K_A}.$$  

The resulting Maurer-Cartan one-form is

$$g^{-1} \partial_M g = i E^\mu_M (\bar{P}_\mu + \nabla_\mu \pi^3 Q_3 + \nabla_\mu \theta^A J_A + \nabla_\mu \eta^i K_i) + i \Omega^3_M J_3,$$

such that

$$E^\mu_M = \partial_M X^\nu [L A]_{\nu}^\mu, \quad \nabla_\mu \pi^3 = (E^{-1})^\mu_M \partial_M \pi^3 - \delta^3_\mu, \quad \nabla_\mu \theta^A = (E^{-1})^\mu_M \epsilon^{AB3} [L^{-1} L^{-1} \partial_M (L A)]^B^3, \quad \nabla_\mu \eta^i = (E^{-1})^\mu_M [L^{-1} L^{-1} \partial_M (L A)]^0_i \quad \Omega^3_M = [L^{-1} L^{-1} \partial_M (L A)]^{12},$$

where $\psi^3 \equiv X^3 + \pi^3$ and we have $L^\mu_\nu \equiv [e^{i \eta^3(K_A)}/_\nu]_\nu$ and $L^\mu_\nu \equiv [e^{i \eta^3(K_3 + i \theta^A J_A + i \theta^i J_i)}]/_\nu$. Begin by imposing unbroken inverse Higgs constraints; as in the previous subsection, they serve to remove the rotation Goldstone $\theta^3$. And once again, solving these unbroken inverse Higgs constraints is not necessary at this order in the derivative expansion. Next, impose ordinary inverse Higgs constraints $\nabla_i \pi^3 = \nabla_A \pi^3 = 0$, which remove $\theta^A$ and $\eta^3$ and tell us that

$$\nabla_3 \pi^3 = \sqrt{G^{MN} \partial_M \psi^3 \partial_N \psi^3 - 1},$$

---

17We use a somewhat non-standard parameterization of $g$ so that the inverse Higgs constraints are easier to solve.
yielding the first building-block
\[ Y \equiv G^{MN} \partial_M \psi^3 \partial_N \psi^3, \tag{101} \]
where the metric is given as usual by \( G_{MN} = E_\mu^M \eta_{\mu\nu} E_\nu^N \). Now impose thermal inverse Higgs constrains to remove \( \eta^A \) given by
\[ 0 = E_0^A = \frac{\partial X_\mu^A}{\partial \phi^0} [LA]_\mu^A. \tag{102} \]
Then, we have
\[ \frac{\eta^A}{\eta_\perp} \tanh \eta_\perp = -\frac{\partial_0 X_\mu^A L_\mu^A}{\partial_0 X_\mu^A L_\mu^T}, \tag{103} \]
where \( \eta_\perp \equiv \sqrt{\eta^A \eta^A} \). This allows us to construct our final two building-blocks \( G_{00} = E_0^\mu \eta_\mu, E_0^\nu \) and \( E_0^\mu \nabla_\mu \pi^3 \), the second of which is just
\[ Z \equiv \frac{\partial \psi^3}{\partial \phi^0}. \tag{104} \]
Thus, the leading-order action for smectic liquid crystals in phase-A is
\[ S_{\text{EFT}} = \int d^4 \phi \sqrt{-G} \ P(Y, Z, G_{00}). \tag{105} \]
To compare with known results, let us now expand this EFT to quadratic order in the fields. For simplicity, we will neglect the fluid degrees of freedom. Then, transforming to the physical spacetime, the quadratic Lagrangian describing the behavior of the smectic mode is
\[ \mathcal{L}^{(2)} = -\frac{1}{2} \left[ M_0 (\pi^3)^2 - M_1 (\partial_A \pi^3)^2 - M_3 (\partial_3 \pi^3)^2 \right], \tag{106} \]
for constants \( M_0, M_1, \) and \( M_3 \). The resulting equations of motion agree with the results of [40-41].

Finally, if particle number is conserved, we include the additional building-block (96), meaning that \( P \) in (105) may now depend on \( B_0 \).

### 7.2.2 Phase B

Smectic liquid crystals in phase B, like in phase A, consist of vertically stacked layers that can slide past each other. In phase A, the molecules within a given layer are able to move around freely without forming a lattice structure. In phase B, however, the molecules in a given layer are locked in place. If we take the \( \hat{z} \) direction to be perpendicular to the stacked layers, then phase B is essentially a solid that cannot sustain uniform \( x \)-\( z \) and \( y \)-\( z \) shears [41]. As a result, the effective action is almost identical to (69)—or if it contains an unbroken \( U(1) \) charge it is almost identical to (71). The only difference is that to allow the layers to slide past each other, we must impose the symmetries
\[ \psi^A \to \psi^A + f^A(\psi^3), \tag{107} \]
where \( A = 1, 2 \) and \( f^A \) is an arbitrary function of \( \psi^3 \). Physically, these symmetries indicate that we can translate each layer in the \( x \)-\( y \) plane independently without changing the macroscopic state of the system. At the level of the EFT, these additional symmetries mean that the effective action can only depend on \( Y^{ij} \) in the combinations
\[ b \equiv \det Y^{ij}, \quad b_1 \equiv Y^{11}Y^{33} - (Y^{13})^2, \quad b_2 \equiv Y^{22}Y^{33} - (Y^{23})^2, \quad Y^{33}, \tag{108} \]
and it can only depend on \( Z^i \) in the combinations \( Z \equiv \epsilon^{ijk}Z^iZ^jZ^k \) and \( Z^3 \).
7.2.3 Phase C

Phase C is much like phase A except now the long axes of the molecules do not on average align with the $\hat{z}$ direction, meaning that $J_3$ is now spontaneously broken. Thus the only difference between phases A and C is that phase C has a Goldstone associated with the broken generator $J_3$ denoted by $\theta^3$. Further, this Goldstone cannot be removed with inverse Higgs-type constraints.

Going through a similar procedure to the one in §7.2.1, we find that the effective action has the same building-blocks as (105) with five invariant additions. First, we have $\nabla_\mu \theta^3$, where $\mu = 0, 1, 2, 3$ are now merely labels and do not need to be contracted in any particular way since the entire Lorentz group is spontaneously broken. Additionally, we have $A^3_a$, which is the $\hat{z}$-component of (88). The addition of the building-block $A^3_a$, which mixes 1-and 2-fields, means that the non-equilibrium effective action cannot factorize into the difference of ordinary actions.

The contribution to the non-equilibrium effective action that does not contain mixtures of 1-and 2-fields is, up to higher-order terms, $S_1 - S_2$, where

$$S_s = \int d^4\phi \sqrt{-G_s} \left[ P(Y_s, Z_s, G_{s00}) + \frac{1}{2} M^{ij}(Y_s, Z_s, G_{s00}) \nabla_i \theta^3_s \nabla_j \theta^3_s \right], \quad (109)$$

such that repeated indices $i, j$ are summed over and $M^{ij}$ is symmetric under exchange of $i$ and $j$.\(^{18}\)

Just as in the case of nematic phase, we will see that the rotation Goldstone, $\theta^3$ is diffusive, so we will consider $\partial_0 \theta^3$ and $\partial^2_{ij} \theta^3$ to be the same order in the derivative expansion.

In the $r, a$-basis, the contribution to the non-equilibrium effective action that contains mixtures of 1-and 2-fields is

$$I_{\text{mix}} = \int d^4\phi \sqrt{-G_r} \left[ -M_0(G_{r00}) \nabla \theta^3 A^3_a + \frac{i}{\beta_0} M_0(G_{r00})(A^3_a)^2 \right]. \quad (110)$$

As a result, up to higher-order corrections, the full non-equilibrium effective action is

$$I_{\text{EFT}} = S_1 - S_2 + I_{\text{mix}}. \quad (111)$$

If particle number is conserved, we have the additional building-block (96). Then the non-equilibrium effective action is identical to (111), except the coefficient functions $P$, $M_{ij}$, and $M_0$ may now depend on $B_0$.

8 Conclusion

In this paper, we defined a systematic coset construction of non-equilibrium EFTs and used it to formulate both known and heretofore unknown non-equilibrium EFTs for condensed matter systems. We postulated that IR dynamics of thermal systems out of equilibrium can be characterized by Goldstones almost as if every symmetry of the system were spontaneously broken. However, the Goldstones corresponding to spontaneously broken symmetry generators behave rather differently than those corresponding to unbroken symmetry generators. In particular, the unbroken Goldstones possess infinitely many gauge symmetries, whereas the broken Goldstones, like ordinary Goldstones at zero temperature, have no such gauge symmetries.

The approach of [12] was to treat these infinitely many symmetries as if they were true symmetries of the underlying theory. As a result, each of these symmetries required its own generator

\(^{18}\)The sum over $i$ and $j$ is purely for notational convenience as $i$ and $j$ are merely labels.
and Goldstone to parameterize the coset of broken symmetries. By contrast, our approach was to treat these additional symmetries as gauge redundancies in the style of [31], thereby circumventing the need to introduce infinitely many symmetry generators and Goldstones. Further, the coset construction presented in this paper allows one to formulate non-equilibrium actions in full generality, whereas previous attempts at the coset construction for systems with spontaneously broken spacetime symmetries can only be used to formulate ordinary actions that are incapable of accounting for statistical fluctuations and dissipation.

The non-equilibrium coset construction admits generalizations and applications in many directions. First, in the interest of simplicity, all of the EFTs in this paper were computed to lowest order in the derivative expansion and therefore admit nothing of statistical fluctuations and dissipation. We leave it as future work to ‘turn the crank’ and extend the actions presented here to higher orders in the derivative expansion. Second, the ordinary coset construction presented in [30] can be used to construct pseudo-Goldstone EFTs for spontaneously broken approximate symmetries. It will be of interest to extend the non-equilibrium coset construction to cases for which approximate symmetries exist. By the philosophy of this paper, there ought to be associated pseudo-Goldstones whether or not the approximate symmetries are spontaneously broken. Third, some condensed matter systems have excitations that survive over long distances and extended time scales but that cannot be interpreted as Goldstone modes; for example, such modes exist near critical points. Thus, extending the non-equilibrium coset construction to allow for couplings between Goldstone and non-Goldstone modes is of significant interest. Finally, the hydrodynamic degrees of freedom in the non-equilibrium EFTs of [1] do not necessitate a long-wavelength expansion. However our non-equilibrium coset construction—like the ordinary coset construction—is designed to generate covariant terms for an action in a derivative expansion. Extending our coset construction to allow for non-local terms would allow one to formulate actions with much broader applicability, e.g. actions describing low-temperature systems.

Acknowledgments: I would like to thank Alberto Nicolis for his wonderful mentorship as well as Austin Joyce and Noah Bittermann for many insightful conversations. This work was partially supported by the US Department of Energy grant DE-SC0011941.

A Emergent gauge symmetries

In this section, we offer a somewhat pragmatic explanation for why we expect non-equilibrium effective actions to possess the gauge symmetries (27-28). It is pragmatic in the sense that it should convince the reader that these symmetries are necessary in ordinary situations, but it is by no means a derivation of the symmetries from first principles.

In the ordinary construction of the hydrodynamic equations of motion it is usually supposed that the system exists in ‘local equilibrium.’ This essentially means that, ignoring broken Goldstones, the state of the system can be specified by the local inverse temperature four-vector $\beta^\mu(x)$ as well as the chemical potentials $\mu^A(x)$ corresponding to unbroken symmetries $T_A$. From the EFT perspective, we posit that the fluid manifold is a space on which the fluid four-vector is fixed, namely $\beta^M = (\beta_0, 0, 0, 0)^M$, where $\beta_0$ is the equilibrium inverse temperature. Then, in the physical spacetime, we can define the inverse-temperature four-vectors—one for each leg of the SK contour—

\[\text{Since [12] only constructed actions to leading order in the derivative expansion, it was not actually necessary to introduce all of the infinitely many symmetry generators. However, extending to arbitrarily higher orders using their method would require the addition of infinitely many symmetry generators and Goldstones; see [37] for a general discussion of how gauge symmetries can be treated as genuine symmetries in the coset construction.}\]
via the push-forwards
\[
\beta_\mu^s(x) \equiv \beta^M \frac{\partial X^\mu}{\partial \phi^M} = \beta_0 \frac{\partial X^\mu}{\partial \phi^M}.
\] (112)

Additionally, we can identify the chemical potential with\(^{20}\)
\[
\mu_A^s(x) = \mu_A^0 + \frac{\mathcal{B}^A_{a0}}{\sqrt{-G_{00}}}
\] (113)

where \(\mathcal{B}^A_{a0}\) is given in (32) and \(\mu_A^0\) are the equilibrium chemical potentials of the unbroken symmetries. Working in the \(r, a\)-basis of (20), the \(r\)-type fields correspond to classical field configurations, whereas the \(a\)-type fields describe quantum and statistical fluctuations. As a result, we ought to identify the physical thermodynamic quantities \(\beta^\mu(x)\) and \(\mu^A(x)\) with
\[
\beta_\mu^r(x) = \frac{1}{2} [\beta_1^\mu(x) + \beta_2^\mu(x)],
\]
\[
\mu_A^r(x) = \frac{1}{2} [\mu_A^1(x) + \mu_A^2(x)].
\] (114)

If we wish to reproduce ordinary hydrodynamics, then we must require that the equations of motion only depend on the unbroken Goldstone fields as they appear in (114). To ensure that this is the case, we must require that the effective action be invariant under the symmetries (27-28). Further, since we expect that the (classical) state of the system is specified by \(\beta^\mu_r(x)\) and \(\mu^A_r(x)\), these emergent symmetries cannot change the state of the system and therefore ought to be considered as mere gauge redundancies.

It is worth mentioning that beyond these heuristic arguments, there has been some success in deriving chemical shift symmetries for unbroken \(U(1)\) Goldstones using the AdS/CFT duality from first principles; see [42-43].

\section{Stueckelberg tricks and the Maurer-Cartan form}

We claimed in \S\ 4 that the correct way to construct covariant building-blocks for non-equilibrium effective actions was to construct two distinct Maurer-Cartan one-forms (32)—one for each leg of the SK contour—that transform under under a single copy of the global symmetry group \(G\). In this section, we will use a Stueckelberg trick inspired by [1] to demonstrate that using two copies of the Maurer-Cartan form is the correct approach.

We begin by introducing sources for the Noether currents corresponding to each symmetry generator of \(G\). This amounts to introducing external gauge fields. Let
\[
P_m = \text{unbroken translations}
\]
\[
T_A = \text{other unbroken generators}
\]
\[
\tau_\alpha = \text{broken generators}
\] (115)

be the generators of \(G\), where we now use \(m, n = 0, 1, 2, 3\) to denote Lorentz indices and \(\mu, \nu\) to denote physical spacetime coordinate indices.\(^{21}\) As before, let \(H\) be the set of unbroken symmetries and \(H_0 \subset H\) the subgroup generated by \(T_A\) alone. The external sources are as follows.

\(^{20}\)It is not immediately obvious that this combination of fields should be identified with the chemical potential. For some insight into why this should be so, see the discussion surrounding (52-54), and for further readings, see [2,35].

\(^{21}\)It is now necessary to distinguish between Lorentz indices \(m, n\) and physical spacetime coordinate indices \(\mu, \nu\) because the Stueckelberg trick requires that we gauge all symmetries including Lorentz.
• Let $\varepsilon^m_{\mu}(x)$ be the vierbeins, which can be thought of as the gauge fields corresponding to unbroken translations $P_m$. The metric tensors are then given by $g_{\mu\nu}(x) = \varepsilon^m_{\mu}(x)\eta_{mn}\varepsilon^n_{\nu}(x)$.

• Let $A_{\mu}(x) \equiv A^A_{\mu}(x)T_A$ be the gauge fields (or spin connections if the Lorentz group is involved) corresponding to the unbroken symmetries of $H_0 \subset H$.

• Let $c_{\mu}(x) \equiv c^A_{\mu}(x)\tau_\alpha$ be the gauge fields (or spin connections) corresponding to the broken symmetries.

On each leg of the SK contour, we can combine these fields into a single object,

$$\theta_{\mu}(x) = i\varepsilon^m_{\mu}(x)P_m + ic^A_{\mu}(x)\tau_\alpha + iA^A_{\mu}(x)T_A,$$

where the factors of $i$ are included for later convenience. Now, letting $U(t, t'; \theta_{\mu})$ for $s = 1, 2$ be the time evolution operator from $t'$ to $t$ in the presence of external sources $\theta_{\mu}$, the generating functional for the conserved currents is

$$e^{W[\theta_{\mu}, \theta_{\nu}]} = \text{tr} \left[ U(+\infty, -\infty; \theta_{\mu})\rho U^\dagger(-\infty, -\infty; \theta_{\mu}) \right].$$

(116)

Since $\theta_{\mu}$ couple to conserved currents, $W[\theta_{\mu}, \theta_{\nu}]$ must be invariant under two independent copies of the gauge symmetries [1]; that is, for gauge parameters $\zeta_1(x)$ and $\zeta_2(x)$ we have

$$W[\theta_{\mu}, \theta_{\nu}] = W[\theta_{\mu}^1, \theta_{\nu}^2].$$

(117)

We can therefore ‘integrate in’ both the broken and unbroken Goldstone fields using the Stueckelberg trick. In particular, define

$$\Theta_{sM}(\phi) \equiv \gamma_s^{-1} \cdot \left[ \theta_{\mu}(X_s(\phi))\frac{\partial X^\mu}{\partial \phi^M} + \frac{\partial}{\partial \phi^M} \right] \gamma_s, \quad \gamma_s(\phi) \equiv e^{i\varepsilon^m_s(\phi)\tau_\alpha e^{iA^A_s(\phi)T_A}},$$

(119)

where $\phi^M$ for $M = 0, 1, 2, 3$ are the fluid worldvolume coordinates. Now we can implicitly define the non-equilibrium effective action by

$$e^{W[\theta_{\mu}, \theta_{\nu}]} \equiv \int D\phi^M D\gamma_s^A D\varepsilon^m_s e^{\mathcal{L}_{\text{EFT}}[\Theta_{1M}, \Theta_{2M}]}.$$

(120)

Notice that if we remove the external source fields by fixing $\varepsilon^m_{\mu}(x) = \delta^m_{\mu}$ and $A^A_{\mu}(x) = c^A_{\mu} = 0$, we find that $\Theta_{sM}$ are nothing other than than the Maurer-Cartan one-forms (32) defined on each leg of the SK contour. Since $\varepsilon^m_{\mu}(x) = \delta^m_{\mu}$ we can identify the Lorentz indices $m, n$ with the physical spacetime coordinate indices $\mu, \nu$, allowing us to use $P_\mu$ to refer to the unbroken translation generators as we did in (29). Moreover because these fields live on the SK contour, their values must match up in the infinite future, meaning that even though there were two copies of the gauge fields and gauge symmetries, there is only one copy of the global symmetry group $G$.

C Explicit inverse Higgs computations

Since the thermal and unbroken inverse Higgs constraints are new, it may be helpful to see how they can be solved explicitly. This appendix explains how to algebraically solve the thermal and unbroken inverse Higgs constraints in the case of ordinary fluids, thereby removing the broken boost Goldstones $\eta^A$ and the unbroken rotations Goldstones $\Theta^A$, respectively. But before we solve these new inverse Higgs constraints at full nonlinear order, it is first helpful to understand the motivations for
imposing them. To do this, we will investigate these inverse Higgs constraints expanded to linear order in the fields.

Consider the case of a fluid without conserved charge. Let \( X_\mu^s(\phi) = \phi^\mu + \varepsilon^\mu_s(\phi) \) and let the antisymmetric field \( \theta^{\mu\nu}_s(\phi) \) represent all Lorentz Goldstones such that \( \eta^i_s = \theta^{0i}_s \) and \( \theta^i_s = \varepsilon^{ijk}\theta^k_s \).

Then at linear order in the fields, the vierbeins are given by
\[
E^\mu_{sM} = \delta^\mu_M + \partial_M \varepsilon^\mu_s - \theta^i_M \varepsilon^i_s + \cdots, \tag{121}
\]
where \( s = 1, 2 \) indicates on which leg of the SK contour the fields are defined. We are interested in setting to zero components of \( E^\mu_{sM} \) that transform covariantly and that can give an algebraic relation between \( \theta^i_{sM} \) and derivatives of \( \varepsilon^\mu_s \).

To remove the broken boost Goldstones, notice that \( E^i_{s0} \) for \( i = 1, 2, 3 \) transform covariantly under all symmetries and gauge symmetries and are given by
\[
E^i_{s0} = \partial_0 \varepsilon^i_s - \theta^i_s + \cdots. \tag{122}
\]
Thus setting the above expression to zero gives the linearized constraint
\[
\eta^i_s = -\partial_0 \varepsilon^i_s, \tag{123}
\]
which is just the linearized version of (43). This allows the removal of the \( \eta^i_s \)-Goldstones.

Removal of the rotational Goldstones is a bit trickier. There are no terms in a single vierbein that transform covariantly and, when set to zero, allow the removal of \( \theta^i_s \). However, we have two vierbeins—one for each leg of the SK contour—thus we consider the object \( E_{1M}(E_2^{-1})_M \), which transforms covariantly under all symmetries and gauge symmetries. Setting the antisymmetric part to zero gives the relation
\[
0 = E_{1M}(E_2^{-1})_M - E_{1M}(E_2^{-1})_M = \partial_j \varepsilon_{ai} - \partial_i \varepsilon_{aj} - 2\theta_{aji} + \cdots, \tag{124}
\]
where \( \varepsilon_{ai} \equiv \varepsilon_{1i} - \varepsilon_{2i} \) and \( \theta^{ij}_{ai} = \theta_{ai}^{ij} - \partial_i \varepsilon_{aj} \). Solving the above equation gives the constraint
\[
\tilde{\theta}_a = \tilde{\nabla} \times \varepsilon_a, \tag{125}
\]
which is the linearized version of (45). Then, acting with the (classical) dynamical KMS symmetry on both sides gives
\[
\partial_0 \tilde{\theta}_r = -\tilde{\nabla} \times \partial_0 \varepsilon_r, \tag{126}
\]
where \( \varepsilon^i_r \equiv \frac{1}{2}(\varepsilon^i_1 + \varepsilon^i_2) \) and \( \theta^{ij}_{r} \equiv \frac{1}{2}(\theta^{ij}_{1} + \theta^{ij}_{2}) \). Since \( \tilde{\theta}_r \) enjoys a chemical shift-type gauge symmetry, at linear order, \( \tilde{\theta}_r \) can only appear in the form \( \partial_0 \tilde{\theta}_r \). Thus, the constraints (125-126) are sufficient to remove the \( \tilde{\theta}_s \)-Goldstones entirely from the (linearized) effective action.

C.1 Thermal inverse Higgs

Recall that for ordinary fluids, the thermal inverse Higgs constraints are given by (42). Since \( R \) is invertible, these constraints give
\[
0 = \frac{\partial X^\mu}{\partial \phi^0} \Lambda_{\mu}^i = \frac{\partial X^t}{\partial \phi^0} \Lambda_t^i + \frac{\partial X^j}{\partial \phi^0} \Lambda_j^i. \tag{127}
\]
Let \( \lambda \) be the \( 3 \times 3 \) matrix with components \( \lambda^i_j = \Lambda_j^i \) and let \( \tilde{l} \) be the 3-vector with components \( l^i = \Lambda_t^i \). Then we have
\[
\lambda = (1 - \tilde{\eta} \otimes \tilde{\eta}) + \tilde{\eta} \otimes \tilde{\eta} \cosh \eta, \quad \tilde{l} = \tilde{\eta} \sinh \eta, \tag{128}
\]
where \( \eta \equiv \sqrt{\vec{\eta} \cdot \vec{\eta}} \) and \( \hat{\eta} \equiv \vec{\eta}/\eta \). Now equation (127) becomes
\[
\frac{\partial_0 \vec{X}}{\partial_0 \vec{X}} = -\lambda^{-1} \cdot \vec{l},
\]
which simplifies to
\[
\frac{\partial_0 X^i}{\partial_0 X^t} = -\frac{\eta^i}{\eta} \tanh \eta,
\]
as desired.

C.2 Unbroken inverse Higgs

Recall that for ordinary fluids, the unbroken inverse Higgs constraints are given by (44). Expanding out the vierbeins, we find that
\[
E^\mu_{sM} = a_{sM}^j R_s^{ji}, \quad a_{sM}^\nu \equiv \frac{\partial X^\rho}{\partial \phi^M} \Lambda_{s\rho}^\nu,
\]
where
\[
R^{ij}_s = [e^{i\theta \phi^j} J]^{ij}. \quad \text{Then, we have that}
\]
\[
(E^{s-1})^i_j = (R^{s-1})^i_j (a_{s-1})^M_j,
\]
which gives us
\[
(E_1)^i_k (E_2^{-1})^M_j = (a_1)^M_k (R_1)_{li} (R_2^{-1})^j_k (a_{s-1})^M_j \equiv (R^{s-1})^i_j ME^1_j (R_1)_{li},
\]
where \( M^{k l} \equiv (a_{s-1})^M_k (a_1)_M^l = (\Lambda_{s-1})_{k \nu} \frac{\partial X^\mu}{\partial \phi^M} (\Lambda_1)^l_{\mu} \). Then unbroken inverse Higgs constraints (44) yield the 3 \times 3 matrix equation
\[
R_2^T \cdot M \cdot R_1 = R_1^T \cdot M \cdot R_2,
\]
where we have used the fact that \( R_s^T = R_s^{-1} \). Rearranging this equation we have that \( M^T = (R_1 \cdot R_2^{-1}) \cdot M \cdot (R_1 \cdot R_2^{-1}) \), from which it is immediate that
\[
M^T \cdot M = (R_1 \cdot R_2^{-1}) \cdot M \cdot (R_1 \cdot R_2^{-1})^T = (R_1 \cdot R_2^{-1} \cdot M)^2. \quad \text{(135)}
\]
Finally, we have that \( (R_1 \cdot R_2^{-1}) \cdot M = \sqrt{M^T \cdot M} \), that is,
\[
R_1 \cdot R_2^{-1} = \sqrt{M^T \cdot M} \cdot M^{-1}, \quad \text{(136)}
\]
as desired. Notice that the above expression, when linearized, gives (125), so it can be used to remove \( a \)-type rotational Goldstones. To remove the \( r \)-type rotational Goldstones beyond the linearized level requires a bit more work; we will carry out the computation in the next subsection.

C.3 More on unbroken inverse Higgs

Now we will see that the unbroken inverse Higgs constraints allow the removal of the \( r \)-type rotational Goldstones beyond linear order in the fields. First, define \( M_a \equiv \sqrt{M^T \cdot M}^{-1} \) and suppose that under the (classical) dynamical KMS symmetries, we have
\[
M_a \rightarrow \Theta M_a - i\beta \Theta \partial_0 M_a, \quad \text{(137)}
\]
where $\Theta$ is a time-reversing symmetry of the UV theory. Then, by applying the (classical) dynamical KMS transformations to (136), we have

$$R_1 \cdot \Omega_{r0} \cdot R_T^T = \partial_0 M_r \quad \implies \quad \Omega_{r0} = R_T^T \cdot \partial_0 M_r \cdot R_2,$$

(138)

where $\Omega_{rM} \equiv \frac{1}{2}(\Omega_{1M} + \Omega_{2M})$ is the $r$-type spin connection. The above equation is our second unbroken inverse Higgs constraint and when linearized, gives (126). It can be checked that in every invariant building-block, $R_s$ can appear without $\phi^0$-derivatives only in the form $R_1 \cdot R_T^T$. But then we can use (136) to remove this combination of rotational Goldstones. Further, if $R_s$ appears in an invariant building-block, the only other package it can come in is $\Omega_{r0}$, in which case we can use (138) to remove $\Omega_{r0}$. This expedient comes at the price of introducing more factors of $R_s$. It turns out that there are two possibilities:

- The additional factors of $R_s$ are contracted in such a way that they cancel completely, in which case we have no remaining factors of $R_s$.
- The additional factors of $R_s$ appear in the form $R_1 \cdot R_T^T$ in which case we can use (136) to remove them.

Therefore, no matter what, the rotational Goldstones can be entirely removed from the invariant building-blocks using (136,138). It should be noted that the covariant building-blocks may still have factors of $R_s$ attached to them that cannot be removed with inverse Higgs-type constraints, but this is not an issue as only the invariant building-blocks are relevant for constructing EFTs.

D Fluids and volume-preserving diffeomorphisms

It turns out that despite appearances, the effective actions for fluids with and without charge that we constructed with cosets, (49) and (54) respectively, are equivalent to those given in [9]. Additionally, the action for finite-temperature superfluids (62) that we constructed with cosets turns out to be equivalent to the action presented in [13]. In this section, we will see how these seemingly different actions are equivalent. For definiteness, consider the action (49), which is defined on the fluid worldvolume. Perform a change of coordinates so that it is now defined on the physical spacetime; then the dynamical degrees of freedom are the fields $\phi^M(x)$ and they enjoy the gauge symmetry

$$\phi^M(x) \rightarrow \phi^M(x) + \xi^M(\phi^I(x)),$$

(139)

for arbitrary $\xi^M$. As always, we use $M, N = 0, 1, 2, 3$ and $I, J = 1, 2, 3$. The resulting action defined on the physical spacetime is

$$S_{\text{EFT}} = \int d^4x \; P(T),$$

(140)

where $T \equiv u^\mu \partial_\mu \phi^0$ such that

$$u^\mu \equiv \frac{J^\mu}{b}, \quad b \equiv \sqrt{-J^\mu J_\mu}, \quad J \equiv \ast[\wedge \phi^1 \wedge \phi^2 \wedge \phi^3].$$

(141)

Now integrate out $\phi^0$. The equation of motion for $\phi^0$ is $0 = \partial_\mu [\frac{J^\mu}{b} P'(T)]$. Since $\partial_\mu J^\mu \equiv 0$ identically, this becomes

$$0 = J^\mu \partial_\mu \left[ \frac{1}{b} P'(T) \right].$$

(142)

---

22 Think of (137) as a definition of $M_r$.

23 It turns out that $T^2 = -G_{00}$. 

32
By the definition of $J^\mu$, we have that
\[ \frac{1}{b} P'(T) = f(\phi^I), \tag{143} \]
for some arbitrary function $f(\phi^I)$. Using the diffeomorphism gauge symmetry (139), we can gauge-fix $f(\phi^I) = 1$. With this gauge-fixing condition, (143) can be solved algebraically for $T$ as a function of $b$, that is $T = T(b)$. Plugging this solution back into the expression for the effective action (140) gives
\[ S_{\text{EFT}} = \int d^4x \, F(b), \tag{144} \]
where $F(b) \equiv P(T(b))$. But this is precisely the action given in [9]. Notice that now the action only depends on the three fields $\phi^I$, which enjoy a volume-preserving diffeomorphism gauge symmetry
\[ \phi^I \rightarrow g^I(\phi^J), \quad \det \frac{\partial g^I}{\partial \phi^J} = 1. \tag{145} \]

By almost identical procedures, it can be shown that (54) is equivalent to the effective action describing charged fluids given in [9] and that (62) is equivalent to the action describing finite-temperature superfluids given in [13].
